An interesting study of the rates of heat absorption in different sections of the firebox and boiler tubes of a small locomotive boiler was made between 1860 and 1864 by the Northern Railway of France,[3] where a boiler divided into five sections was built and the evaporation was determined separately in each section.

Another method of determining the rate of heat absorption in different sections of furnaces and boilers was described by the author in a previous paper[4] before the Society. This method determines heat absorption by measuring the furnace gas temperatures and gas weights at consecutive stages in the travel of the gases, the difference in the heat content of the gases between any two points in the gas travel being the heat absorbed by radiation and convection by any surface between these points.

Results From Heat-Absorption Tests

A diagram of the French locomotive is shown in Fig. 1.[5] The firebox was 3 ft square at the grate, and there were 125 tubes about $1^7/_8$ in. diam and 12 ft 4 in. long. The five divisions of the boiler were arranged for continuous gas flow and separate water levels were maintained. The evaporation from each section was determined by a number of tests at different ratings. Three tests at the highest draft used have been selected for presentation and the essential data are given in Table 1. Tests A-1 and A-2 were made with briquettes and test A-3 with coke. Test A-2 was run with half of the tubes plugged and the total evaporation was about 87 per cent of that obtained in test A-1 or at about 62

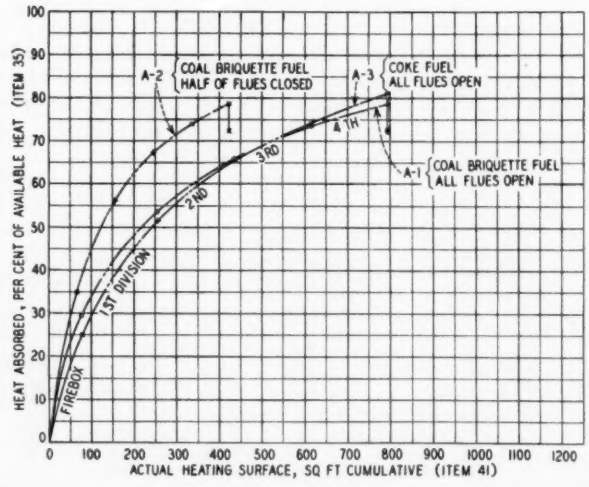

FIG. 2 HEAT ABSORPTION IN FRENCH LOCOMOTIVE BOILER PLOTTED AGAINST ACTUAL HEATING SURFACE
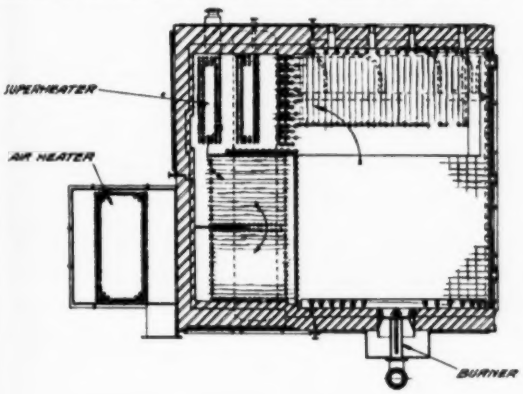
(Boiler of Fig. 1 and Table 1; tests A-1, A-2, and A-3.)

per cent higher rate on a basis of heat available per sq ft of active heating surface. With the same draft the coke gave a lower rate of evaporation. The heat absorbed, expressed as a percentage of the heat available for absorption, item 35, Table 1, is plotted in Fig. 2 against cumulative actual heat-absorbing surfaces, item 41. No useful comparison of these fuels and rates of output can be readily obtained from this plot because there is no way in which the rate of heat available or rate of heat absorption can be graphically indicated.

Tests B-1 and B-2 from Table 2 were obtained from the pulverized-coal-fired boiler of Fig. 3, rated at 100,000 lb of steam per hr. These tests are plotted in Fig. 4, which repeats test A-1, but to a scale suitable for plotting the B series. In this boiler the ash is removed in a dry form by blowing it from the flat water-cooled floor to the hopper at the end away from the burners. A certain amount of dry sponge ash accumulates on the water-cooled furnace walls and roof, which are not normally cleaned; the ash reaches an equilibrium by falling by its own weight from time to time in small amounts. The heat absorptions in the furnace and the different sections of the boiler tube banks, item 32, were obtained by the "gas-temperature-weight" method previously referred to, a brief detailed description of which may be in order. Test data are taken which include items 4 to 27, inclusive, of Table 2, the principal purpose being to determine the total heat input, item 24; the total heat available, item 27; and the total gas weight, item 20.

The total heat available, item 27, is the total heat from the fuel actually burned, plus the heat in the preheated air above 80 F, minus the latent heat in the moisture from the fuel and from the burning of hydrogen. In other words, it is the sensible heat in the gases of combustion which is available for absorption by

radiation and convection by any heating surface over which it may pass.



Another very important determination is item 30, wherein the average true gas temperature is obtained at different points in the path of gases by means of the high-velocity thermocouple.[6] From these temperatures and the gas weights, the total heat absorbed in each section, item 32, is determined.

Item 36, Btu absorption per sq ft per hr for the different sections is also very interesting. The actual furnace heating surface is taken as the projected area or envelope of all water-cooled furnace areas, with no factors for cleanliness or different kinds of cooling surfaces except in the case of spaced tubes with refractory behind or between, where Hottel factors[7] are applied. Boiler, superheater, economizer, and air-heater heating surfaces are taken as the full tube circumference, plus any other exposed surfaces in contact with the actively flowing gases of combustion. No factors for tube arrangement, spacing, or mass flow are used because it is thought best to keep all units on an actual area and Btu available basis and to study the comparative results for the effect actually resulting from different forms of surface, fuel and ash characteristics, values of excess air and mass flow, etc., as determined from test data.

Many other data and calculations are included in the complete test, but only the essential ones pertinent to this paper are included in Table 2.

[6] "The Accurate Measurement of High Gas Temperatures," by H. F. Mullikin, *Power*, vol. 78, 1934, p. 565. This high-velocity thermocouple is inserted into the gas stream at any desired point in the furnace and, by an aspirator, gas is drawn across a shielded thermocouple at a sufficiently high velocity to bring the couple close to the true gas temperature, free from surrounding radiating influences.

[7] "Radiant Heat Transmission Between Surfaces Separated by Nonabsorbing Media," by H. C. Hottel, Trans. A.S.M.E., vol. 53, 1931, FSP-53-19b, pp. 265–271. Discussion, pp. 271–273.

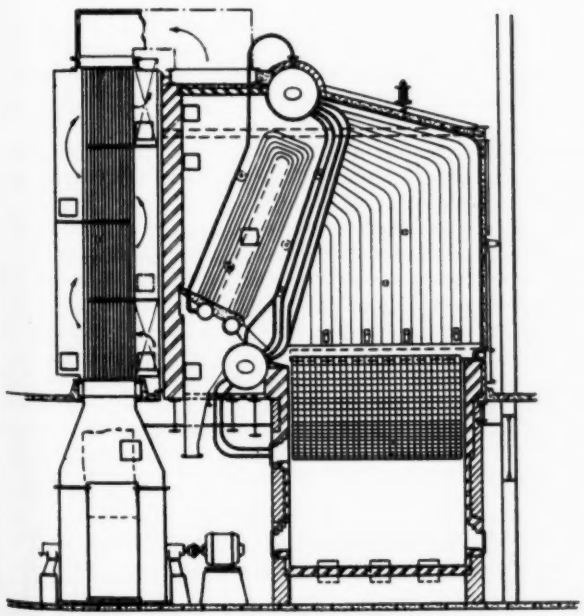


Fig. 3 Pulverized-Coal-Fired Boiler for Stationary Service With Integral Water-Cooled Furnace
(Data given in Table 2.)

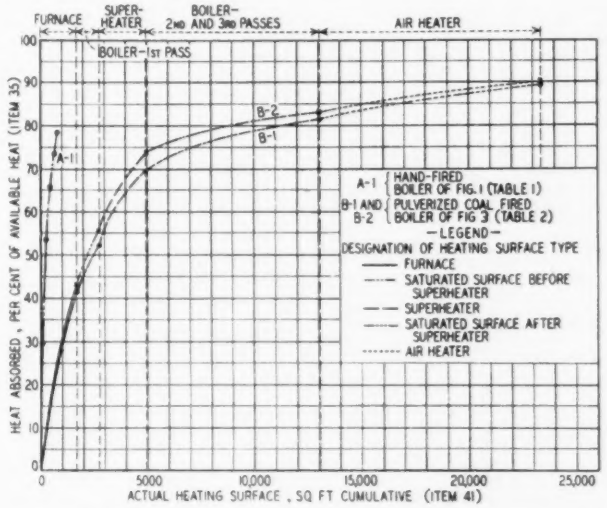

Fig. 4 Heat Absorption in French Locomotive Boiler and in Pulverized-Coal-Fired Boiler Plotted Against Actual Heating Surface
(Boiler of Fig. 3 and Table 2; tests B-1 and B-2, also comparative plot of curve A-1 from Fig. 2.)

During test B-1, the boiler produced 105,900 lb of steam per hr and, during test B-2, 83,300 lb per hr. The higher rating test shows a lower percentage of heat absorbed, but there is no indication from the plots themselves, as given in Fig. 4, as to the relative rates of output or the relative performance. Test A-1 plotted on the same scale of actual surface is still further from being on any useful basis of comparison with the other two curves in Fig. 4, and yet all three curves are plotted on basic units of great significance; viz., actual heating surface and per cent of available heat absorbed. Neither does one obtain any really satisfactory comparison of the relative results from these boilers at the different rates of output by examining all test data relating to them in Tables 1 and 2.

Comparison on Equivalent-Surface-Area Basis

In Fig. 5 the heat-absorption percentages of tests B-1 and B-2 are plotted to "equivalent surface area" instead of actual area. This simple expedient brings into the diagram a rate-of-input factor. The corresponding points of the lower-input test are plotted at higher scale values of equivalent surface areas in order to maintain relationship with tests of greater heat input such that all curve intersections with a given ordinate line shall have the same actual Btu available per sq ft value.

This equivalent surface area is given as item 42 in all tables. It is obtained by using the factor resulting from dividing 500,000,000 by the total Btu available for absorption, item 27, on any test regardless of the size of boiler unit or its rating, and then multiplying this factor by the actual area in sq ft of all cumulative

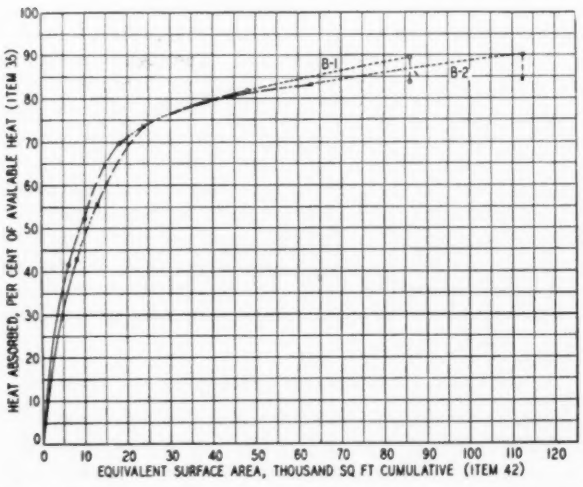

FIG. 5 HEAT ABSORPTION PLOTTED AGAINST EQUIVALENT SURFACE AREA

(Boiler of Fig. 3 and Table 2; tests B-1 and B-2. For legend see Fig. 10.)

surface, item 41, under consideration, including the water-cooled portion of the furnace, and each successive additional portion of heating surface to include boiler tube bank, superheater, economizer, and air heater if present. Each cumulative actual area, item 41, should be multiplied by this factor and plotted as equivalent surface area, item 42, against the total percentage of heat absorbed, item 35, by the corresponding actual surface area.

The arbitrary value of 500,000,000 Btu available per hr was taken after much consideration. It is a nominal value corresponding to many central-station boiler units. Some are much larger and many are smaller. It really makes no essential difference so long as the same unit is used as a standard for all boilers to be compared. It is hoped that others applying this basis of comparison will use this same standard for the sake of uniformity. A unit actually operating at 500,000,000 Btu available input per hr will be plotted with the actual surfaces equal to the equivalent surfaces because the factor is unity.

When comparing tests at different ratings on the same boiler, or any tests on any boiler, it is apparent that all cases at a given value of equivalent surface have identical Btu available per sq ft of the total surface up to that point. If the percentage of heat absorbed is not the same, it may be due to the cleanliness or effectiveness of the surfaces passed over, the temperature, luminosity, or mass flow of the gases or other factors, some of which may not be known or predictable without further study or tests. One may easily determine the Btu available and the Btu absorbed per sq ft per hr for any point on any curve, viz., $\frac{500{,}000{,}000}{\text{Equiv surface}}$ = Btu available per sq ft per hr. This result multiplied by the per cent absorbed gives the average Btu absorbed per sq ft per hr for all surface cumulatively from the fuel bed or burner up to the point selected on the curve. For illustration test B-1, Fig. 5, the entrance to the superheater lies on approximately 10,000 equivalent surface, and therefore corresponds to 50,000 Btu available per sq ft per hr. The percentage absorbed is plotted at 52.3, hence the average rate of heat absorption up to this point is

26,150 Btu per sq ft per hr. The slope of the curve at any individual section is a graphic index of the rate of heat absorption in that section.

In Fig. 5, test B-1 shows 89.5 per cent of the available heat absorbed up to the outlet of the air heater which has an equivalent surface area of 86,200 sq ft. Test B-2 shows only 86.8 per cent heat absorbed at the same equivalent area; this corresponds to a point including all surface of the unit up to the entrance of the air heater plus about 46 per cent of the area of the air heater. However, as the gases pass completely through the air heater, the heat absorbed increases to 90.3 per cent, but the equivalent surface area is 112,600 sq ft, although the actual heating surface is the same as on the other test. At the same actual stages in the boiler unit, test B-2 shows higher percentages of heat absorption than the higher rating test B-1. This difference increases from 1.4 per cent leaving the furnace to 3.3 per cent entering the superheater and 4 per cent leaving the superheater, and then diminishes to 1.5 per cent entering the air heater and 0.8 per cent leaving the air heater. These are all taken from item 35 by subtracting the corresponding percentages from the two tests. This indicates that the first boiler tube bank and the superheater are more responsive to increased heat absorption due to increased heat input because of the temperature and mass-flow factors. The adiabatic or theoretical maximum combustion temperature of test B-2 is higher than on test B-1, hence this will account for some of the difference in heat absorbed in the furnace.

The total heat absorbed by the B-1 and B-2 tests is about 90 per cent and may seem unduly high, but it must be remembered that this is on a Btu available basis, which is more nearly like the net or low heating value often used abroad. The over-all efficiency of the unit by the A.S.M.E. method is shown as item 47 and plotted on the curves as a drop point under the last point on the available basis.

Comparison of Results and Boilers

The French locomotive tests are plotted on the equivalent-surface-area basis in Fig. 6. One cannot help but grasp immediately a realization of the difference between tests A-1 and A-2 due to the higher mass flow and better heat absorption resulting from plugging half of the tubes. There may also have been a lower excess air and higher adiabatic temperature in the firebox of test A-1, as it indicates a higher percentage of heat absorbed in the furnace, contrary to the relationship at the corresponding points of Fig. 5.

In comparing tests A-1 and A-3, it is noted that, even though the rate of heat available is lower on coke-burning test A-3, the percentage of heat absorbed is less, while normally it would be greater. This again may be due to a lower adiabatic temperature, resulting from either higher excess air or perhaps unburned CO, which might have been very likely when burning coke. Another factor is luminosity, as the coke would have been different from the briquettes. Many desirable data are lacking from these tests.

Tests A-1 and B-1 are shown in Fig. 10 on the equivalent-surface-area basis. It is noted how much more useful is such comparison in contrast to that in Fig. 4, where they are both on the actual area basis.

A boiler similar to that of Fig. 3, but fired with oil, was tested by the gas-temperature-weight method and the essential data are given in Table 2 and plotted in Fig. 7. Characteristics similar to the pulverized-coal-fired tests B-1 and B-2 are noted, i.e., the heat absorbed at the lower rate of input tests C-2 are higher than on C-1 for corresponding locations, but lower on the same equivalent-surface-area basis.

The greater heat absorption in the oil-fired furnace, due largely to cleaner furnace walls, is brought out in Fig. 10, where curves B-1, coal-fired, and C-1, oil-fired, are plotted to the same equivalent-surface-area basis. The greatest difference is shown in the furnace, first boiler tube bank, and superheater. Beyond the superheater, the curves are substantially parallel, indicating about the same rates of heat transfer. The coal-fired boiler is operating at a 14 per cent lower Btu available per sq ft of total surface, and is 0.8 per cent lower in the percentage of available heat absorbed but is 0.3 per cent higher in over-all efficiency.

The French locomotive test A-1 follows the pulverized-coal-fired test B-1 very closely, until the superheater is reached on B-1 where it has a steeper slope and higher percentage rate of heat absorption between the 10,000 and 20,000 equivalent surface area. However, it loses out between the 20,000 and 32,000 equivalent surface area, where evidently the mass flow in the boiler tube bank is not as good as in the last two sections of the French locomotive. It is also noted that the saturation temperature of steam in the French boiler is 324 F, while in B-1 tests the saturation temperature is 498 F, causing an appreciable difference in the rate of heat absorption at these corresponding parts of the units.

The discussion so far has related to two kinds of boilers of three different sizes and with three methods of firing, hand, pulverized coal, and oil. Data from two methods of determining rates of heat absorption in different sections of the heating surface have been compared by a method which seems to have much value.

Table 3 includes data from eleven additional tests, the data being limited to the conventional standard test method. Certain data from these tests are plotted in Fig. 10 to show the percentage of available heat absorbed by the boiler and also by the economizer and air heater separately, where installed, and plotted against equivalent surface areas for comparison with the more

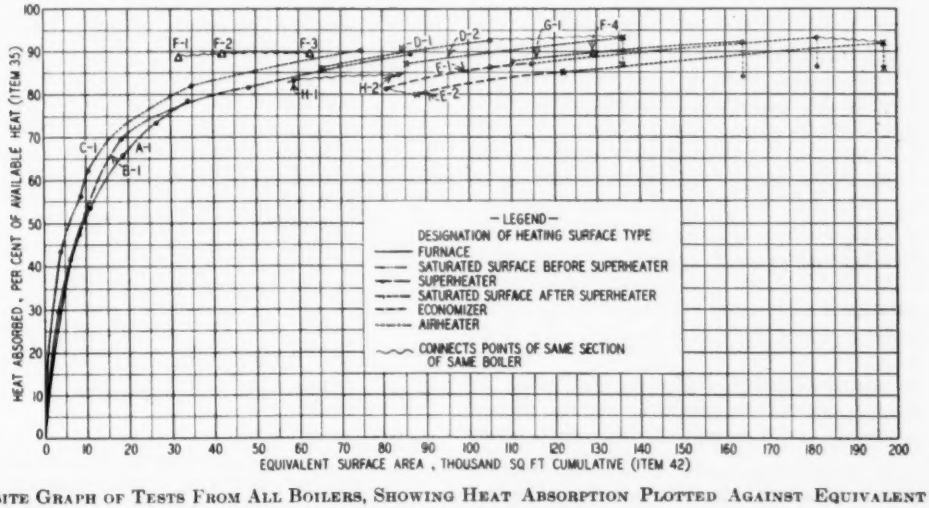

FIG. 10 COMPOSITE GRAPH OF TESTS FROM ALL BOILERS, SHOWING HEAT ABSORPTION PLOTTED AGAINST EQUIVALENT SURFACE AREA
(Data given in Tables 1, 2, and 3.)

complete tests of the A, B, and C series and with each other. This is done because it is believed to be the best known method for obtaining a comprehensive picture of the relative ratings and efficiencies of some representative units in the marine and stationary fields.

Marine Boilers

A typical marine boiler with spreader stoker for coal firing is shown in Fig. 8. It has a rated capacity of 13,000 lb of steam per hr at 400 lb pressure and 750 F. Two tests are given in Table 3 as E-1 and E-2 and are plotted in Fig. 10. While the boiler itself shows relatively low efficiency at lower rates of heat available than others plotted, it is designed with an economizer and air heater to give very good final efficiency.

Tests D-1 and D-2 are from an oil-fired marine boiler similar to Fig. 8, but of 22,000-lb capacity at 600-lb pressure and 850 F steam temperature. It is designed for high efficiency from the boiler itself and has an air heater also. It has less equivalent surface, smaller cubical content, and operates at higher draft loss than the stoker-fired marine boiler, and was operated at lower excess air.

Another marine boiler for Navy use is shown in Fig. 9. Some of the data published by Brierly[8] are reproduced as tests F-1 to F-4 in Table 3. This boiler is rated at 67,000 lb of steam per hr at 600-lb pressure and 700 F, but the tests reported are at 300-lb pressure to be more nearly comparable with present locomotive practice. As no sectional heat absorptions were obtained, only the over-all absorption by the boiler and superheater combined are plotted as triangles in Fig. 10. Even this serves well to show that this high-duty boiler has very good efficiency. It shows about 10 per cent better absorption of available heat than does the French locomotive boiler at the same high relative rating of about 15,000 Btu available per sq ft of total surface per hr. This is undoubtedly due largely to the better arrangement of heating surface and gas-mass flow as indicated by the higher draft loss. It is significant to note the uniformly high efficiency at the wide range of outputs. Tests on the boiler at 600-lb steam pressure show about $1^1/_2$ per cent lower efficiency than those given for 300 lb pressure, due to the difference in the saturation temperature of the heat-receiving surface.

Tests G and H are presented as representative of small stoker-fired stationary boilers of different types, design not shown. Test G-1 has an air heater which shows a comparable rate of heat absorption with other air heaters within the same available heat-rate range.

Comparison of Size, Rating, and Draft Loss

Several items which may be of interest in comparison with locomotive boilers or others are given in the tables but are not specifically discussed in this paper. Coal burned per sq ft of grate is given and, in order to enable a comparison with oil and pulverized fuel to be drawn, the equivalent cross-sectional areas of the respective furnaces are given and also the lb fuel per hr divided by this area.

Btu per cu ft of furnace volume is also given, but it should be remembered that this is a very misleading factor when comparing furnaces of widely different size, even when burning the same kind of fuel. The total cubical contents of the boiler, including the outside dimensions of the casing, economizer, and air heater, may be of interest to some.

Higher draft loss results from higher gas velocities, which are necessary if saving in space and the increasing of rates of heat absorption by convection are to be attained. All arrangements of heating surface are not equally effective, and no conclusions are now attempted from the small amount of data given.

[8] "The Babcock & Wilcox High-Pressure Sectional Express Boiler," by Lieut-Com. R. C. Brierly, U.S.N.R., *Journal of the American Society of Naval Engineers*, vol. 43, no. 4, Nov., 1931, pp. 511–561.

Summary

1 It is very desirable to know the actual rates of heat absorption in different elements of a boiler unit for the purpose of comparing effects of different rates of operation, different values of excess air, kinds of fuel, ash and slag behavior, and kinds of heat-absorbing surface.

2 The direct method of measuring heat absorption by evaporation calls for segregation of heat-absorbing surface which is either very difficult or entirely impossible, due to boiler construction and interference with circulation. The engineers of the Northern Railway of France deserve great credit for having done a very good piece of test work which checks very well with later work by other methods. The heat absorbed in some parts of a boiler unit may readily be determined by the direct method, such as in the case of superheaters, some economizers, and air heaters.

3 A second method is possible, wherein the heat absorbed in a section of the boiler unit, such as the furnace or a tube bank, results from calculation using average gas temperatures and gas weights entering and leaving the section, the difference, allowing for any combustion of fuel taking place within the zone being measured, being the heat absorbed.

4 Data obtained by either method is useful to engineers experienced in calculating boiler performance, but others often find it difficult to grasp an accurate and complete realization of the relative importance and comparisons of different parts of a boiler unit or one with another. A simple method of comparison is presented which consists of plotting a curve showing the relation between the heat absorbed, expressed in per cent of heat available, and the equivalent surface area wherein the heat was absorbed.

5 The data presented have been restricted to relatively small stationary boilers which would be comparable with representative marine boilers, two of which are given, and modern locomotive boilers, data from which are available from another paper.[9] These limited data are not sufficient to draw many conclusions regarding the factors of heat transfer by radiation and convection; however, some well-known facts are clearly demonstrated as being of outstanding significance when presented in this graphic form:

(*a*) Radiant heat produces high rates of heat transfer, as shown by the steep slope of the curve.

(*b*) Excess air and adiabatic temperature affect radiant heat greatly. This point is not fully brought out in this paper, because for the purpose of simplicity, furnace tests were selected with reasonably uniform adiabatic temperatures.

(*c*) High mass flow and high mean temperature difference increase rates of heat transfer. Draft loss, and fan power or its equivalent, are necessary to produce high rates of heat absorption by convection, and high efficiencies with limited surface areas.

(*d*) Surface is the principal requisite for heat absorption. It should be clean for high rates of heat absorption, but sometimes a covering of ash, slag, or other means is a desirable aid toward complete combustion and for protection against too high a rate of heat absorption and to pass higher temperatures on to other surfaces such as superheaters, which will bring the total absorption to a more economical result.

(*e*) Terms like Btu per cu ft per hr of furnace volume, Btu per front ft of furnace width, etc., should be used with caution, because they are not as fundamental in their importance as are some other factors. Pounds of oil per sq ft of

boiler is a basically sound standard, much used in marine engineering, but it becomes less useful with the further use of furnace cooling, economizers, and air heaters. Btu available per sq ft per hr seems to be fundamentally sound, but it needs definition as to its application to furnace alone or to the entire unit. Item 29, Table 2, gives this factor for each cumulative section of the boiler unit. It seems now that this value, including all surface up to the entrance of the superheater, is likely to become more used. It also is useful when applied to the furnace alone.

6 Temperature of gases as measured at different points in the gas path is of great importance regardless of whether these temperatures are used in conjunction with gas weights to obtain heat absorption. A knowledge of temperatures at various points of the entire unit is essential in design and is useful in operation in connection with the behavior of ash and slag. The gas temperature might well be plotted to the equivalent surface area for comparison, but the excess air and air leakage at different points interfere with the same usefulness as is obtained from the heat-absorbed basis herein presented, hence in the interest of brevity for this paper such plots are omitted. Gas temperatures are given in the tables as item 30, and the adiabatic temperature as item 23. The adiabatic or theoretical temperature is useful as an index of the combined effect of excess air, moisture in fuel, and completeness of combustion.

7 Heat absorbed and equivalent surface are undoubtedly the most important basic factors for comparison in studying boiler performance.

Acknowledgment is made for valuable data and assistance from stoker manufacturers and from the author's associates.

Discussion

J. C. Hobbs.[9] Mr. Bailey's use of the French tests illustrates clearly the relations between cause and effect. Each part of the steam-generating equipment being set up independently, there can be no question about the heat transfer and the work done.

The curves show clearly not only the relationships indicated, but the slope of the curves, i.e., the increment heat absorbed by the increment heating surface, shows the punishment, if you please, being carried by the heating surfaces comprising different parts of the equipment.

The writer wishes to emphasize by brevity rather than by voluminous discussion, the great value of a uniform distribution of energy absorption over the entire surfaces in so far as it is possible, so that the apparatus may be more reliable and in the long run the operation more successful.

R. S. Julsrud.[10] It would appear from the writer's personal experience, that designers of steam-generating equipment, in their effort to secure a high efficiency in restricted furnace cavities fired by pulverized coal, are apt to lose sight of the physical and chemical limitations of the coal which makes available this heat.

Most coals have certain limitations; these may include low fusion temperature, generally resulting from high sulphur present in the fuel. Again high volatile content may result in coking and possible burning of the tips of pulverized-coal burners and extremely long flame travel with resultant high temperatures entering the convection surfaces. Also, low-volatile coals present the problem of maintaining ignition at low heat-output rates.

Our knowledge of heat-transfer rates to water-cooled surfaces, both bare and refractory-covered when relatively clean, is now fairly well established. However, when such surfaces have become covered with slag, whether fluid, sticky, or spongy, the heat absorption of the surfaces is considerably reduced, and instead of the predicted heat extraction taking place from the gases in the furnace, they enter the convection surface at considerably higher temperatures which may exceed the fusion point of the ash particles present in the gases. The result is a tendency for these sticky ash particles to build up at the heating surfaces. If this occurs on surfaces with restricted gas passages, the result is plugging of the gas passages and eventual outage of the unit. Again the presence of sulphur in coal, resulting in the formation of ferric sulphides when burned, may in furnaces operated at high heat liberation and temperatures result in a reducing atmosphere. It is also possible, but has not as yet been established, that reducing action of these pyrites results in attacking the surfaces exposed to this action. In any event, under high heat liberations these surfaces tend to wash and eventually fail. This action results in boiler outage and increased maintenance costs.

To attempt to reduce these failures, the surfaces are often built up to a greater thickness with a resultant lower heat-transfer rate and the possibility of high gas temperatures entering the generating tubes, as mentioned. Thus in eliminating difficulty in the furnace, it may be transferred to the convection surfaces.

Until such time as we have a better knowledge of the heat absorption of water-cooled surfaces when coated with ash in its various forms, it would appear that a greater degree of conservatism should be exercised in the design of these units.

A reduction of 1 per cent in the CO_2 at the boiler outlet will result in approximately 200 F drop in the furnace-gas temperatures. This may mean the difference between high furnace maintenance and outage as against continuous performance with somewhat lower efficiency. Moreover, high heat releases per cubic foot of furnace volume, which is a measure of furnace temperatures developed, can well be reduced for the same reason.

Such a design would make available to the consumer a wide variety of coals, attractively priced, now handicapped by their physical and chemical limitations.

E. B. Powell.[11] The author has made available an astonishingly simple, logical, and direct method of graphic comparison for evaluating heating-surface effectiveness. The writer would urge that he eliminate at once the only suggestion of complexity, i.e., the factor 500,000,000. Steam boilers of 500,000,000 Btu per hr input rate will soon be outmoded. The method of heating-surface analysis in this paper will serve for years to come. With such repetitive use certainly ahead, why not immediately eliminate all unnecessary effort, even that of dividing by 2, and adopt a more rational, permanently acceptable multiplier, 10^8 or 10^9. Also, to assure instantaneous interpretation of the chart, Fig. 10, the writer suggests that the term "equivalent surface" be defined merely as the square feet of surface per Btu of total heat liberated or made available to the steam-generating unit per hour, with a factor of 10^8 or 10^9 applied to the quotient to secure a number of convenient size. Furthermore, it is suggested that this formula, abbreviated, should be consistently included in the title of the abscissas.

In the closing paragraph, the author, in mentioning a deficiency of data for certain interpretative purposes, would seem to promise a subsequent paper discussing the influence of such factors as draft loss and arrangement of heating surface upon heat-transfer

[9] Vice-President in Charge of Manufacturing, Diamond Alkali Company, Painesville, Ohio. Mem. A.S.M.E.

[10] Combustion Engineer, Consolidation Coal Company, New York, N. Y.

[11] Consulting Engineer, Stone & Webster Engineering Corporation, Boston, Mass. Mem. A.S.M.E.

effectiveness. The writer trusts he is correct in this inference. The author's clarifying treatment of all factors in steam-generating-unit heat transfer would be a tremendous asset.

In closing, it would be of interest to know whether corrections were applied to observed temperatures in order to allow for possible radiation error of the high-velocity thermocouple.

R. A. SHERMAN.[12] A knowledge of the performace of the various sections of a steam generator is essential to intelligent design for proper distribution of the heating surface to insure that the temperatures in various sections are of the proper order. The rate of heat absorption in the furnace governs the temperature of the gases which, for coal-fired furnaces, fixes the degree of fusion of the ash and, therefore, the type of coal which can be burned in a given furnace or the maximum rate of burning, or minimum excess air that can be maintained with a given furnace.

The Society is indebted to the author for the presentation of the data which he has obtained by gas-temperature measurements, as these permit an analysis of the performance of various sections of a boiler which would otherwise be impossible.

The writer wishes to emphasize the fact brought out by the author that the expression, "Btu per cu ft per hr" is of no significance in comparing the performance of various boilers or of furnace temperatures. Earlier in the year, at Battelle Memorial Institute, we conducted an investigation which indicated that the same expression had no significance in relation to the smoke emission. By a factual survey of 102 power and heating boilers burning up to 1200 lb of coal per hr, and in an experimental investigation of 22 boilers of the same type, no relation was found between the smoke emitted and the rate of heat liberation per cubic foot of furnace volume. Briefly, this may be explained by several facts:

1 It is the time of travel of the gases from the fuel bed to the entrance to the heating surface which determines whether the carbon will be burned before its temperature is lowered below its ignition temperature. Furnaces have volume because they have three dimensions but it is the length of travel which is important. Further, a large part of the volume is frequently not utilized and a large volume is not a definite assurance that the carbon will be burned.

2 Combustion of volatile matter without the liberation of carbon is rapid if the required air is mixed with the volatile and, with good mixing, little time or volume will be required for smokeless combustion. Without good mixing an infinite volume or length of flame travel will not avoid smoke.

3 Still other factors, in addition to the degree of mixing, such as the type of coal, the uniformity of distribution of the coal on the stoker, the excess air, the type of load, and the degree of intelligence and the ability of the operator are of greater importance in the elimination of smoke than the rate of heat liberation.

To return to the author's data, a retabulation of a few of the items given for boilers *A*, *B*, and *C* will emphasize the lack of meaning of the rate of heat liberation per cubic foot of furnace volume. The tabulation is as follows:

Boiler Type	*A* Locomotive	*B* Coal	*C* Oil
Furnace volume, cu ft	33	6030	7494
Furnace heating surface, sq ft	76.8	1695	1633
Ratio, surface/volume	2.33	0.28	0.21
Heat release, Btu per cu ft per hr	354000	22500	27800
Heat release, Btu per sq ft per hr	152200	79900	127200
Heat absorbed, Btu per sq ft per hr	44900	33200	55400

Judged from the relative rates of heat release per cubic foot of furnace volume in the locomotive and in the other two boilers, the temperatures might have been thought excessive in the locomotive boiler but, because of the high ratio of heating surface in the furnace walls to the total volume, the rate of heat absorption was high and the temperatures were probably no higher than in the other boilers. On the basis of the rates of heat liberation per square foot of furnace wall, the differences among the three boilers were much less and the rates of heat absorption per square foot of furnace wall were also of much the same order.

Basing the comparisons of boilers on the ratio of the heating surface to the heat available will bring various boilers more into line but variations will be due, as the author points out, to cleanliness of the surface and to the luminosity and emissivity of the flame. The emissivity of a flame increases as its depth increases owing to greater furnace dimensions, but the emission per square foot of flame surface cannot increase in the same order as the area decreases with respect to the volume.

A spherical furnace would be the least desirable shape of furnace because this gives the lowest ratio of surface to volume. The cubical box-like furnaces which we have in many present-day furnaces are also unfavorable for obtaining a large area of heat-absorbing surface. High, narrow furnaces are more favorable in presentation of surface; this principle can be extended by introduction of division walls of water tubes to obtain greater surface and lower the furnace temperature.

The adoption of the author's method of obtaining data on temperatures and gas weights by many other workers would be desirable. Further studies on the relation of the radiant emission from the flame to the dimensions of the furnace would also be valuable.

The writer agrees with a previous suggestion that the term "equivalent surface area" be replaced by the expression, "ratio of surface area to heat available," multiplied by a simple factor such as 10^6 on the ground that this is a more accurate expression and less likely to introduce confusion. Let us hope that we can mark this day as that on which the interment of the term, "Btu per cu ft of furnace volume," was completed, never to rise again.

JOHN VAN BRUNT.[13] The method suggested by the author for comparing performance of furnaces, boilers, superheaters, economizers, and air heaters, comprising a complete steam-generating unit, is interesting and the selection of a unit of 500,000,000 Btu input for such comparisons serves the purpose perhaps as well as any other arbitrary value.

In the design of large steam-generating units it is necessary to determine the amount of heat absorbed by each portion of the entire unit by using actual fluid quantities and heat-transfer rates, etc. After such a unit is in operation, it is customary to check the calculated performance, and the basic design rates used for its determination.

The amount of heat to be absorbed by each division of the total surface is determined by the performance requirements and the conditions imposed by the purchaser and by the economic factors of each case, plus limitations dictated by the fuel characteristics and factors governing availability of the unit for continuous operation.

Given two units, for example, of 100,000 and 300,000 lb capacity, the smaller for 300 lb per sq in. pressure and 750 F steam temperature with 250 F feedwater, and the larger for 1200 lb pressure, 925 F steam temperature with 380 F feedwater temperature; there can be no purpose in comparing such units on the basis of a 500,000,000-Btu unit, as suggested by the author.

The per cent of heat absorbed in the furnaces in the various tests given in the paper are low, in fact, considerably lower than would be expected in a modern furnace. In tests A-1, A-2, and A-3, the low rate of absorption is probably due to poor combustion conditions and can be compared only with locomotive boilers.

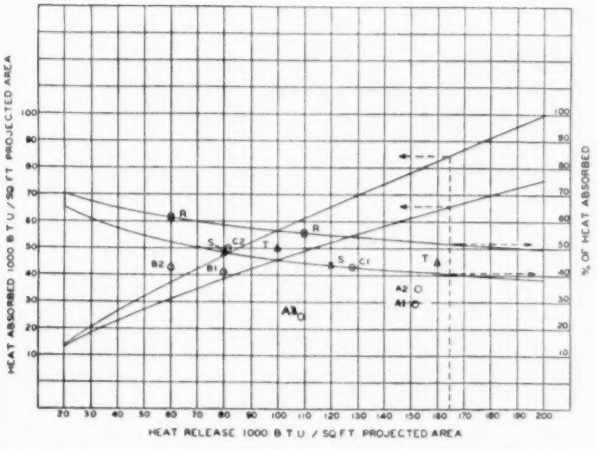

FIG. 11 APPROXIMATE RELATION OF HEAT RELEASED TO HEAT ABSORBED IN A PULVERIZED-COAL WATER-COOLED FURNACE

Fig. 11 of this discussion reproduced from Fig. 9 of the writer's paper,[14] shows the ratio of heat absorbed to heat released, both in Btu and in per cent. The curves sloping upward from the lower left-hand corner are read in Btu per lb per sq ft, to the left, and the curves sloping downward read percentage of heat absorbed or efficiency of furnace absorption, to the right.

The points from the tests in the author's paper are plotted against the percentage of heat absorbed. With the exception of C-1 and C-2, the points are well below the lower of the two efficiency curves. In a modern oil-burning furnace, the points C-1 and C-2 would be expected to fall near the upper efficiency curve. For comparison, the two points *R* are plotted from test results of a tangentially fired pulverized-coal slag-bottom furnace on a unit of 300,000 lb per hr capacity. The points *T* are from a 450,000 lb per hr tangentially fired pulverized-coal slag-bottom furnace and points *S* are from a vertically fired slagging-bottom furnace, pulverized-coal-fired. In all of these units, the furnace walls are composed of bare fin tubes.

The influence of both the amount and character of the ash and of the method of firing on the amount of heat absorbed is marked. It may be seen from the curves and from the points plotted from the tests that the per cent of heat absorbed in any furnace decreases as the rate of release per square foot increases.

Absorption below the lower curves would indicate inefficient use of the furnace wall surface, poor combustion, or walls covered with an excessive amount of ash. Waterwall tubes covered with refractory or refractory coatings will also fall below the lower curves.

AUTHOR'S CLOSURE

The comments of Messrs. Hobbs, Powell, and Sherman are very much appreciated as they fully grasped the importance and significance of this method of comparing the performance of furnaces and heat-absorbing surfaces in steam-boiler units. Mr. Powell has raised a question, in which Mr. Sherman concurs, i.e., whether the equivalent-surface area might be simplified to a factor of square feet of surface per Btu available. Mathematically this would seem to be simpler, but psychologically the author fears it would be more confusing because the logic of the factor is not quite so evident. For instance, assume a unit having 500,000,000 Btu available and, at the point to be plotted 10,000 sq ft of actual surface have been passed over; this factor would be 0.00002. The suggestion of multiplying this by 10^5 would leave it 20. This seems like a very inadequate figure to plot when it actually represents 10,000 sq ft of surface. Even multiplying this by 10^9 or 10^{10} seems in the author's opinion only to add to confusion rather than to simplify the method of comparison used in the paper.

There may well be some question concerning the choice of 500,000,000 Btu when some boilers may go as high as 1,000,000,000 and others may be only $^1/_5$ or $^1/_{10}$ this amount. The value of this entire method comes through standardization and while, as Mr. Powell says, the 500,000,000 may be outmoded, it is greatly to be doubted if the average boiler unit to be considered will vary so much from 500,000,000 Btu available that it cannot still be used as a perfectly logical standard. Certainly 100,000,000 Btu is not a satisfactory standard and 1,000,000,000 is applicable in only a few cases. As a matter of fact, it is felt that the odd number of 500,000,000 has some real value in that it makes one stop to think what it really is, while otherwise it might be an abstract factor and not carry the significance to the mind of the user, which condition now seems to prevail. Another point of significance is that most coordinate papers bring out the values on this basis very nicely, while figures $^1/_5$ or 2 times those used would not be as convenient to plot.

Mr. Julsrud mentions several matters pertaining to furnace design and the characteristics of ash which are really outside the scope of the paper as presented, since the data given were limited purposely to a range of boiler operation permitting a comparison with the sizes prevailing in locomotive practice, and also to bring out the method of comparison rather than to go into the many phases of slag, heat absorption, etc. As indicated by Mr. Powell, there is great opportunity in the future for all these matters to be studied through this method of comparison.

As a matter of fact, Mr. Van Brunt in Fig. 11 of his discussion has already compared some of the data on dry-ash coal-fired and oil-fired furnaces with data on slag-tap furnaces for which he has information.

Before replying to Mr. Van Brunt's discussion, the author checked with him and was assured that his "heat release 1000 Btu per sq ft projected area" is identical with the author's "heat available." It is significant to note that the lower curve of Mr. Van Brunt's Fig. 11 on the percentage basis is substantially identical with Mr. Orrok's curve, which the author reproduced on a similar basis and presented as Fig. 20 in his discussion[15] of Mr. Brandt's paper. We have found that not only do the points C-1 and C-2, which Mr. Van Brunt has plotted in his Fig. 11, fall on this curve of Mr. Orrok's, but they also are in close agreement with many other data obtained on oil-fired boilers having normally clean heat-absorbing surfaces and where the adiabatic temperature is close to 3600 F. Points B-1 and B-2 for the pulverized-coal-fired furnace with dry-ash removal are approximately 20 per cent lower in rate of heat absorption than are those of the Orrok curve on which fall the oil-fired tests. This indicates a certain amount of ash accumulation on the surface of such furnace, which also has been substantiated with many other data. As noted in the author's paper, all of these data, except those concerning the French locomotive, are based upon tests with the high-velocity thermocouple of the single-shield variety, and to answer Mr. Powell's question no correction has been made. It is now known, however, that many of these temperatures are likely to be from 50 to 75 deg low. This would indicate that the actual rates of heat absorption are still lower than those indicated by the *B* and *C* points and, therefore, closer to the French data which Mr. Van Brunt believes to be low. They are in the same region as Goss's locomotive tests of 1912, where heat absorption

[14] "Design of High-Capacity Boiler," by John Van Brunt, Trans. A.S.M.E., vol. 60, 1938, paper FSP-60-17, p. 487.

[15] "The Locomotive Boiler," by C. A. W. Brandt, discussion by E. G. Bailey, published on page 399 of this issue of the Transactions.

in the firebox alone was determined by direct evaporation without depending upon any gas temperatures. These data from Goss's tests are also given in Fig. 20 of the author's discussion[15] of Mr. Brandt's paper.

Mr. Van Brunt has questioned why all of these rates of heat absorption are so low in comparison with his points *R*, *S*, and *T*, taken in furnaces of the slag-tap type where the walls are apparently coated to some extent with slag. However, since Mr. Van Brunt does not give the fluid temperature of the ash or other data, it is beside the point to question them further than to state that any inaccuracies in the measurement of gas temperatures in these portions of boiler units may lead to very erroneous conclusions.

Dr. Mullikin has presented papers[16] before the American Institute of Physics showing comparative results from bare thermocouples of different sizes, single-shield high-velocity thermocouples, and multiple-shield high-velocity thermocouples. A great deal of field data were included. These data emphasize the importance of further studies in gas-temperature measurement.

Further evidence has been obtained showing that the multiple-shielded high-velocity thermocouple is more nearly correct than anything else that has yet been devised. In boiler installations where the heat absorbed in the air heater, economizer, and superheater can be determined separately, the gas temperatures entering the superheater may be determined by calculating back from an accurate measurement of the gas temperature leaving the air heater. Such data check very closely with the multiple-shielded high-velocity thermocouple.

Other confirmation on rates of heat absorption in furnaces has been obtained by a thermal probe wherein the rate of heat absorption has been determined by the rate of flow of a fluid and its rise in temperature through the element when inserted into different parts of furnaces.

Mr. Van Brunt states that there is no advantage gained in comparing a unit of 100,000 lb per hr output at 300 lb per sq in. pressure, 750 F steam temperature, and 250 F feedwater temperature, with a larger unit of 300,000 lb per hr output, 1200 lb per sq in. pressure, 925 F steam temperature, and 380 F feedwater temperature. If the fuel burned and furnace construction are the same, a comparison of heat absorption up to the entrance of the superheater will be well worth-while, for the temperature gradients are not sufficiently different to have any measurable effect upon the rate of heat absorbed up to that point. There will, of course, be a justifiable difference in the shapes of the curves through the superheater, later boiler bank or economizer, and the air heater. However, it is not beyond our experience to learn a great deal from even these comparisons. Of course, the real advantage comes in comparing units in which similar temperature gradients exist, in order to detect the effect of excess air, different kinds of fuel and ash, arrangement of surface, etc. The main purpose of the present paper was to show a simple method of making these comparisons, leaving it to the judgment of those using this method as to the value obtained by the variety of comparisons they might choose to make.

The Locomotive Boiler

By C. A. BRANDT,[1] NEW YORK, N. Y.

For many years increased traffic and the demand for high operating economy of the railroads resulted in the development of locomotives of high tractive effort capable of starting trains close to the limit of length for practical handling through yards and terminals. The ever-present demand for still higher transportation capacity of the railroads and competition have compelled the further development of locomotives to handle these long and heavy trains at high speeds. This has meant proportionately larger and more efficient boilers. The author discusses in this paper some of the problems of boiler designs and proportions that affect the efficiency and capacity of the conventional locomotive.

THE PUBLIC, which is served by the railroads, is continuously demanding higher speeds for both freight and passenger trains and this, in conjunction with a more intensive utilization of their motive power, is one of the many important problems confronting the managements of the American railroads today.

Until recent years the steam locomotive had been the principal power unit, but its supremacy is now being challenged by other forms of motive power, particularly the electric- and Diesel-driven locomotives. To meet this challenge the designers of steam locomotives are constantly studying the problem of building boilers of greater steam-generating capacity within the permissible limits of size and providing engines of lowest possible steam consumption per unit of power.

The fact that higher boiler capacity for minimum weight has been an ever-present problem throughout the years of locomotive development in America can best be illustrated by citing the evolution of the eight-coupled locomotive. The first of this design, or the 2-8-0, utilized 90 per cent of the total locomotive weight for adhesion. The demands for higher speeds, requiring greater steam-making capacity, led to the addition of truck axles to carry the heavier boilers, which resulted in the successive development of the 2-8-2, the 4-8-4, and last the 6-4-4-6 type high-speed locomotive, exhibited at the New York World's Fair this year.

The total weight of an early-design 2-8-0 type locomotive with 270,000 lb on the drivers and a tractive power of 67,500 lb was only 300,000 lb. To supply the steam for the high-speed 6-8-6 type locomotive with the same weight on drivers and the same tractive power requires a boiler of such size as to double the total weight of the locomotive to 600,000 lb, as is illustrated in Fig. 1.

As this and other modern locomotives are examples close to the maximum practical size that can be built, the important question is whether greater boiler efficiency is attainable, particularly at high-capacity operation, and what can be done to accomplish this.

The question of reducing the steam consumption of the engines is outside the scope of this paper, but the possibility of reducing the average steam consumption per ihp from an average of 18 lb to 13 lb is possible by the adoption of compound cylinders as reported from tests on French locomotives, as well as by the use of still higher superheat and valve gear adaptable for its utilization.

The paper will be confined to a discussion of those problems of design believed to be most essential in the advancement of the art. To enhance the value of this contribution, Tables 1 to 6 are included which give the principal dimensions and boiler ratios of representative locomotives of various types built in America in recent years. Locomotive test curves are also presented.

The subject matter will be centered on problems affecting the design of the conventional locomotive fire-tube boiler only, not because of any belief that this type of boiler is the final answer to the locomotive steam generator, but because at present most of the locomotives in the world are equipped with this type of boiler. The best solutions to some of the problems encountered in the design of large boilers have not yet been agreed upon principally because of the lack of reliable test data.

A committee of the Association of American Railroads (A.A.R.) submitted a report this year recommending a conventional type of boiler for a proposed 6400-hp high-speed locomotive, which is an acknowledgment that the fundamental principles of this boiler design have proved practical and are the best available at the present time.

TYPE	WHEEL ARRANGEMENT	TRACTIVE POWER LBS	WEIGHT ON DRIVERS LBS	TOTAL WEIGHT OF LOCO LBS	WEIGHT ON DRIVERS PERCENT OF TOTAL	INCREASE IN WEIGHT OF LOCO TO GAIN ADDITIONAL BOILER POWER ACTUAL	PERCENT
2-8-0	4-0-○○○○	67500	270000	300000	90		
2-8-2	4-0-○○○○-0	67500	270000	360000	75	60000	20

TABLE SHOWING INCREASE IN THE TOTAL WEIGHT OF AN AVERAGE 8 COUPLED LOCOMOTIVE OF THE SAME WEIGHT ON DRIVERS AND SAME TRACTIVE POWER

FIG. 1 INCREASE IN TOTAL WEIGHT OF EIGHT-COUPLED LOCOMOTIVES DUE TO LARGER BOILER CAPACITY

It is unnecessary to recite in detail the advantages of the conventional boiler; this has been done many times before. The virtues of the completely water-cooled radiant-heat-absorbing furnace, high gas velocities over the convection heating surfaces with forced draft, and high superheat, all originally inherent in the locomotive boiler, are now being recognized as essentials to efficient steam generation in other fields and are being rapidly adopted in stationary-power-plant boilers.

Locomotive boilers of designs radically different from conventional construction have been built in the past, but so far none has proved sufficiently practical for general railroad service. There will soon be placed in service in America a different type of steam generator for operation in conjunction with condensing steam turbines, and still other types are under consideration.

There has been a great increase in the size of locomotive boilers built in recent years in America; many of these have proved very efficient. However, much remains to be done to make possible the burning of more fuel per hour at higher combustion efficiency

with lower draft loss, greater heat-absorption efficiency, and higher superheat with less boiler weight per pound of steam produced.

Definition of Boiler Capacity and Existing Formulas

In designing a locomotive, the steam required for a given maximum horsepower capacity can be determined quite accurately from existing knowledge of steam consumption per ihp-hr, when initial and final steam conditions are specified. To this must be added the steam required for auxiliaries, train heating, air conditioning, and other uses. The boiler design must be such as to deliver this maximum steam output at a superheat as high and a back pressure as low as that figured on, or else the steam consumption per ihp will increase and the cylinder power fall below that required. To determine the excellence of a particular boiler design and compare it with others, it is necessary to have a standard measure of comparison.

It would appear logical that the weight of steam produced per pound of total weight of the boiler in service should provide a satisfactory measure when a definite steam pressure, superheat, and draft loss are specified. It is obvious that such a yardstick is of no value, unless a standard method of predetermining the maximum evaporative capacity is found which will satisfy all conditions in a reasonable way.

In reviewing the existing methods of calculating the maximum evaporating capacity of a locomotive boiler and the over-all boiler efficiency, the designer is confronted with the fact that formulas now generally used are inadequate for predetermining the result with accuracy, particularly when large boilers are involved.

In America the theory generally followed is that the steam-generating capacity[2] of a boiler is directly proportional to the amount of evaporating heating surface in square feet.

A set of evaporative values, giving the maximum quantity of steam in pounds per square foot of heating surface per hour, generated by the firebox and flues, was prepared some years ago by F. J. Cole.[3]

These values are generally used by the locomotive builders and railroads today.[2,3,4,5]

Any method of calculation that takes square feet of heating surface only into consideration must be inadequate. It is evident that the arrangement of the heating surfaces, their relationship to the grate area, furnace volume, gas area, firebox heating surface, and hydraulic depth and length of the flues must be considered to give approximately correct results. The reason is that it is these relationships which determine the boiler efficiency, the back pressure required to produce the steam, and the superheat, all of which have a great influence on the efficiency and power output of the cylinders.

Strahl proposed a formula in 1913[6] which takes into consideration the size of the grate area and its ratio to the evaporating heating surface

$$WS = \frac{a}{\frac{S}{R} + 7} \times S$$

where

WS = total steam produced, lb per hr
R = grate area, sq ft
S = evaporating heating surface, sq ft
a = coefficient for superheated locomotive, 778 lb per sq ft

This formula, with the coefficients established by Strahl, comes close to test results on boilers with proportions similar to those which Strahl used in his analysis, but leads to unsatisfactory results on boilers with different ratios. The Strahl formula may be modified to suit different arrangements by changing the coefficients to suit, but this is not an entirely sound procedure.

A method originated by Lawford H. Fry[7] for determining the maximum evaporating capacity of a boiler from the over-all boiler-efficiency curve appears to be a better approach. Fry suggested that, if the over-all boiler efficiency is plotted against pounds of coal or total heat in Btu fired per square foot of grate per hour, the relationship between the efficiency and rate of firing becomes a straight line. The correctness of this theory has been proved on tests examined. The fundamental equation established by Fry is

$$F = m - nG$$

where

F = boiler efficiency in per cent
G = dry coal fired, lb per sq ft of grate per hr
m = coefficient denoting theoretical efficiency at zero firing rate
n = coefficient determining slope of curve

If sufficient test data were available for all kinds of fuel and types of boilers so that the coefficients m and n or the origin and slope of the over-all boiler-efficiency curve could be predetermined with accuracy, together with the superheat and pressure at the outlet of the superheater, then the evaporation for any quantity of coal fired could be determined, as well as the maximum capacity.

It appears to the author that the Fry or other methods proposed do not satisfy the requirement as they stand, because draft loss and back pressure are not part of the picture.

The inadequacies of both the Cole and Strahl methods are apparent when a comparison is made between the data calculated by the different methods, and the actual test results as shown in the following table:

	Evaporation, lb per hr				
Locomotive	Strahl	Cole	Difference, per cent	Actual test	Difference, per cent
P.R.R. K4S No. 5341	48000	52150	+ 8.6	72000	+50
P.R.R. M1A No. 6706	53350[a]	67850[a]	+27.2	99095[a]	+85.7
N.Y.C. J3A	60700[a]	60500[a]	− 0.3	85000[a]	+40

[a] With feedwater heater.

The author called attention to this some twelve years ago.[1] As far as is known, however, no tests have been made of locomotives of greatly varying boiler ratios and types of fuels to establish a satisfactory formula which may be used universally and permit evaluation of the effect that varying proportions have upon the economics of boiler performance and costs.

Boiler Tests

In its 1936 report, the A.A.R. Committee on Locomotive Construction expressed the opinion that the Cole ratios were inadequate and recommended approval of plant tests to obtain neces-

sary data. The director of equipment research at that time, L. W. Wallace, made a report and recommended complete locomotive tests, but this program has never been carried out.

Many tests have been made by the Pennsylvania and New York Central railroads and the respective managements deserve the greatest praise for their valuable contributions to the art. Most of these tests, however, have been made on locomotives with relatively small grate areas and with approximately the same ratios of grate areas, gas areas, firebox volumes, etc. There are few data available on the effects of very large grates and large fireboxes.

The tests recommended by the Research Division of the A.A.R. were complete and necessarily expensive. It is believed by the author that adequate information as to the efficiency and maximum capacity of boilers with large grates and furnaces can be obtained with stationary blowdown tests of some three or four boilers with widely different boiler ratios. Such tests should be conducted with oil fuel and also with several different grades of coal, sufficient to establish fundamental data now lacking. With complete data on the quantities, qualities, etc., of the fuel, water, and air used, and the gases and steam produced, all losses could be segregated and closely determined.

This would permit the determination of coefficients m and n in Fry's formula. It is hoped that such a test program will be made possible as this matter is not one merely of academic importance, but is a vital item of railroad economics. The method of standing blowdown tests developed and used by the New York Central Railroad in recent years has proved very effective. Results of such tests are dependable since the boiler testing is separated from and is independent of the locomotive-engine performance. This facilitates the adjustments for setting the required operating conditions for each capacity test and the continuance of each test run for a sufficiently long period of time at constant rate, without interruption by locomotive- and test-plant running conditions.

The New York Central Railroad's method of blowdown test is conducted so that the steam exhausted from the cylinders through the nozzle is desuperheated to a temperature closely agreeing with that actually observed on road tests for equal capacities. The correctness of this test procedure has been proved by the fact that the front-end design and nozzle size established by such test have proved correct for best maximum performance in road service.

Gas Area in Relation to Boiler Efficiency and Capacity

It is well known that the efficiency of the boiler decreases with an increased firing rate. The rapid drop is mainly due to the high losses occurring in the form of unburned fuel escaping with the flue gases. The problem of greater fuel-burning capacity at higher efficiency of combustion is, therefore, the first item which should be considered and involves the arrangement and relative size of the gas area through the boiler, the grate area, combustion volume of the furnace, and the firebox heating surface, also, stoker construction, arrangement of firebrick arches, amount of air opening through the grates, and the introduction of secondary air above the fire bed.

In considering the matter of locomotive-boiler design, as in the case of any other structure, it is well to establish a base from which to start. This is difficult with a locomotive because the problem of its design involves a cycle of successive approximations to obtain maximum power and efficiency within the weight limitations.

In the past either the heating surface or the grate area has been the basis on which the size of the other component parts of the boiler has been determined. This is not the most logical procedure as the dimensions of these parts do not control the limit of size to which the boiler can be built, since they may be increased with the length of the boiler within considerable limits. The diameter and gas area through the boiler constitute the limiting factors because the height, width, and weight are fixed and cannot be exceeded. It is, therefore, more logical that this factor be made the basis on which the other parts are proportioned.

The capacity of the locomotive boiler is limited by its diameter because this determines the gas area of the flues through which all the gases of combustion must pass; in addition it must provide space for the superheater through which all the steam generated must flow. It determines the flue heating surface that can be installed per unit length of flue, the area of the steam-disengaging

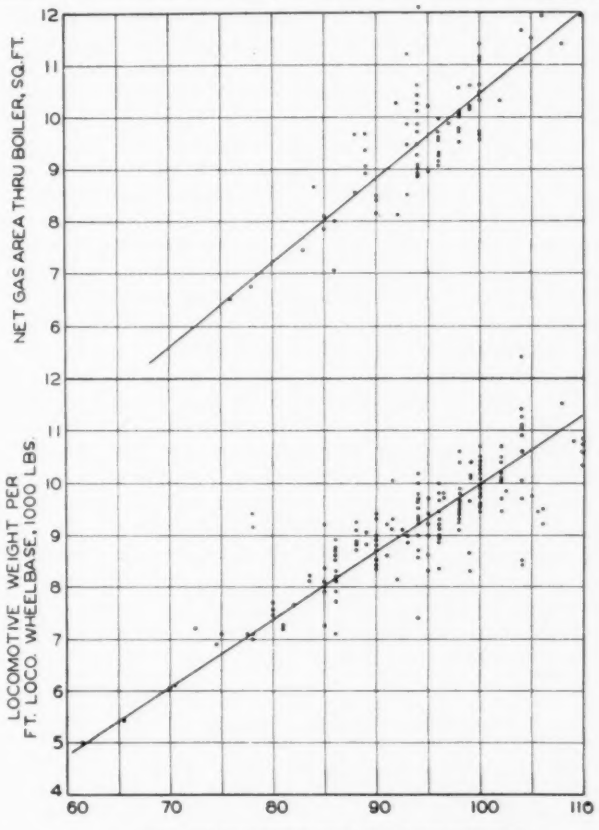

Fig. 2 Relation of Boiler Diameter to Total Weight of Locomotive per Foot of Wheel Base and Also Gas Area

surface, and the steam volume above the water level in the boiler. This last item is of the greatest importance and is, in reality, the limiting factor in high-output operation, as evidenced by the serious difficulties experienced with water carry-over into the superheater and cylinders in many boilers.

Within the clearance, the maximum diameter of the boiler is determined by the weight limits. In order to analyze this problem, the proportions of 165 different designs of modern locomotives have been studied to ascertain the relationship between the diameter of the boiler and the total weight of the locomotive. The curve, Fig. 2, shows this relationship. It is apparent that, while there are many factors which influence the weight, the boiler diameter has been sacrificed for other features of design in many cases. If, as an example, the 104-in. boiler is noted, the total locomotive weight per foot will vary from a minimum of 8400 lb to a maximum of 12,400 lb, or an increase in total locomotive weight of nearly 50 per cent for the same boiler diameter. The chart indicates that there is a uniform increase of 133 lb per ft of total locomotive weight for every 1-in. increase in the boiler diameter. This curve may facilitate studies in efforts to obtain

the greatest possible diameter and gas area for allowable weights.

A relatively large gas area through the boiler in relation to the grate area and heating surface is not generally followed, as noted from a study of the ratios Nos. 30, 31, and 32, Tables 1 to 6.

That the gas area through the boiler is one of the most important items affecting the boiler capacity is not generally appreciated, but may be better understood if actual test figures are analyzed. From the test of the Pennsylvania Railroad, class M1A, locomotive No. 6706, column 10, Table 4, on which sufficient data are available to permit determination of the weight of the gases passing through the boiler, the data shown in Fig. 3 have been compiled. It is interesting to note that, at high firing rates, the gas velocity through the tubes near the back tube sheet reaches the high figure of 204 miles per hour. The great importance of eliminating unnecessary restrictions in the gas passages and the superheater units is apparent.

As the gas area is increased, the velocity and frictional resistance of the gases passing into and through the boiler flues are lowered. This will reduce the draft requirement and in turn the cylinder back pressure, enlarging the power output of the locomotive in direct proportion to the resultant increase in the mep. This is important when high power output is desired at high speed as the reduction of 1 lb of cylinder back pressure gives as much increase in power as a 4-lb gain in pressure on the steam inlet or admission side.

The importance of a large gas area through the boiler was recognized years ago. C. D. Young[9] pointed out in 1915 that from his experience the maximum evaporative capacity of a boiler was in direct ratio to the total gas area through the flues and was apparently limited to an amount of 7000 lb actual or 9100 lb equivalent evaporation per hr per sq ft of gas area for the engines tested up to that time. This has been bettered considerably on modern locomotives with type-E superheaters and more powerful draft arrangements to about 11,000 lb equivalent evaporation per sq ft of gas area. The test results given in the following table confirm this point:

Railroad	Class engine	Engine no.	Max equiv evap per hr, lb	Total net gas area through boiler, sq ft	Max lb of steam per hr equivalent evap per sq ft gas area
P.R.R.	K4S	1737	87,414	9.10	9605
P.R.R.	M1A	6706	123,870	9.71	12755
B.L.W.	3 cyl	60000	84,186	9.37	8985
P.R.R.	I1S	790	89,235	9.9	9015
N.Y.C.	J3A	5408	89,500	8.9	10055

To illustrate the limiting effect that the gas area has upon the evaporative capacity of a locomotive boiler, the test results from several locomotives have been plotted in Fig. 4. The relation between equivalent evaporation and back pressure is illustrated in Fig. 5.

A study of the relationship between the gas area and the boiler diameter of a number of modern boilers has been plotted in Fig. 2; it will be noted that full advantage has not been taken in many cases in providing the largest possible gas area. For some boiler diameters the gas area is as much as 31½ per cent smaller than the maximum possible. This is perhaps due to a difference of opinion as to the most suitable distance between the top of the crown sheet and the inside of the boiler shell at the top; as to the water space between the combustion chamber and boiler shell, or the clearance between tube holes and tube-sheet flanges; and as to tube spacing. The type of combustion chamber, the thickness of the flues, and the superheater design also influence the gas area. Offhand, it may seem that these details are not of great consequence, but really they are very important.

The distance between the top of the crown sheet and the boiler shell determines the steam space and steam disengaging surface. It is obvious that the smaller this distance is made the greater will

[9] Test Bulletin, No. 28, Pennsylvania Railroad, 1915, p. 35.

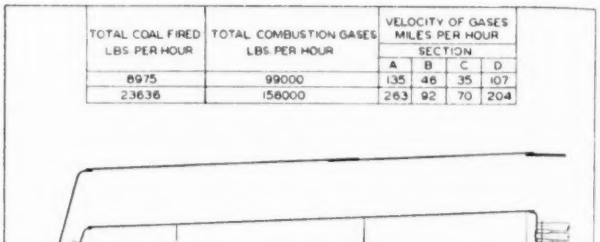

FIG. 3 GAS VELOCITIES THROUGH LOCOMOTIVE FIREBOX AND FLUES

be the tube-sheet area. Information as to the most satisfactory relationship between the height of the crown sheet and other dimensions of the boiler is lacking, but this question deserves most careful consideration.

A slight increase in the water space between the combustion chamber and boiler shell decreases the available gas area considerably. On some boilers, this water space has been made as large as 8 in., while very many large boilers are operating successfully with a water space of only 5 in., giving a large percentage increase in gas area. It appears that the smaller water space imparts a higher velocity to the water circulation at this point, minimizing mud collection which the large water space was supposed to eliminate.

The important influence that the superheater construction has upon the gas area is apparent and will be discussed in more detail under the subject of superheater design.

FIREBOX VOLUME IN RELATION TO COMBUSTION EFFICIENCY

Earlier in this paper, it was pointed out that the firebox volume is not subject to such limitations as the gas area. There are limitations to the width and height of the firebox which are important, but the length of the grate and firebox may be extended considerably beyond present general practice. This is fortunate as the most serious matter confronting locomotive designers today is the problem of improving the efficiency of combustion in the firebox, particularly at high-capacity operation. Incomplete combustion of fuel causes heavy losses in unburned fuel, high maintenance cost due to cinder cutting of firebox sheets, stay-bolt heads, tubes, and superheater. Damage due to fires along the right of way set by sparks, loss in good will to the general public due to smoke near railroad terminals, and loss of passenger traffic for the same cause constitute a serious challenge to designers and operators of steam locomotives.

Improvement in the combustion process of the locomotive furnace is a problem of primary importance and the proportions of the furnace should be such as not only to make possible complete combustion of the fuel with the elimination of smoke and cinders, but also to absorb sufficient radiant heat to cool the furnace gases to a temperature low enough to prevent slagging at the flue sheet and on the superheater units.

One would assume that sufficient data were available today to determine the correct volume of the firebox in relation to the grate area and heating surface. A study of Tables 1 to 6 indicates, however, that there is little agreement on this subject; great variations exist in these basic ratios. To cite an example: The important ratio of firebox volume to grate area ranges from a minimum of 3.70 to a maximum of 8.28 cu ft per sq ft of grate

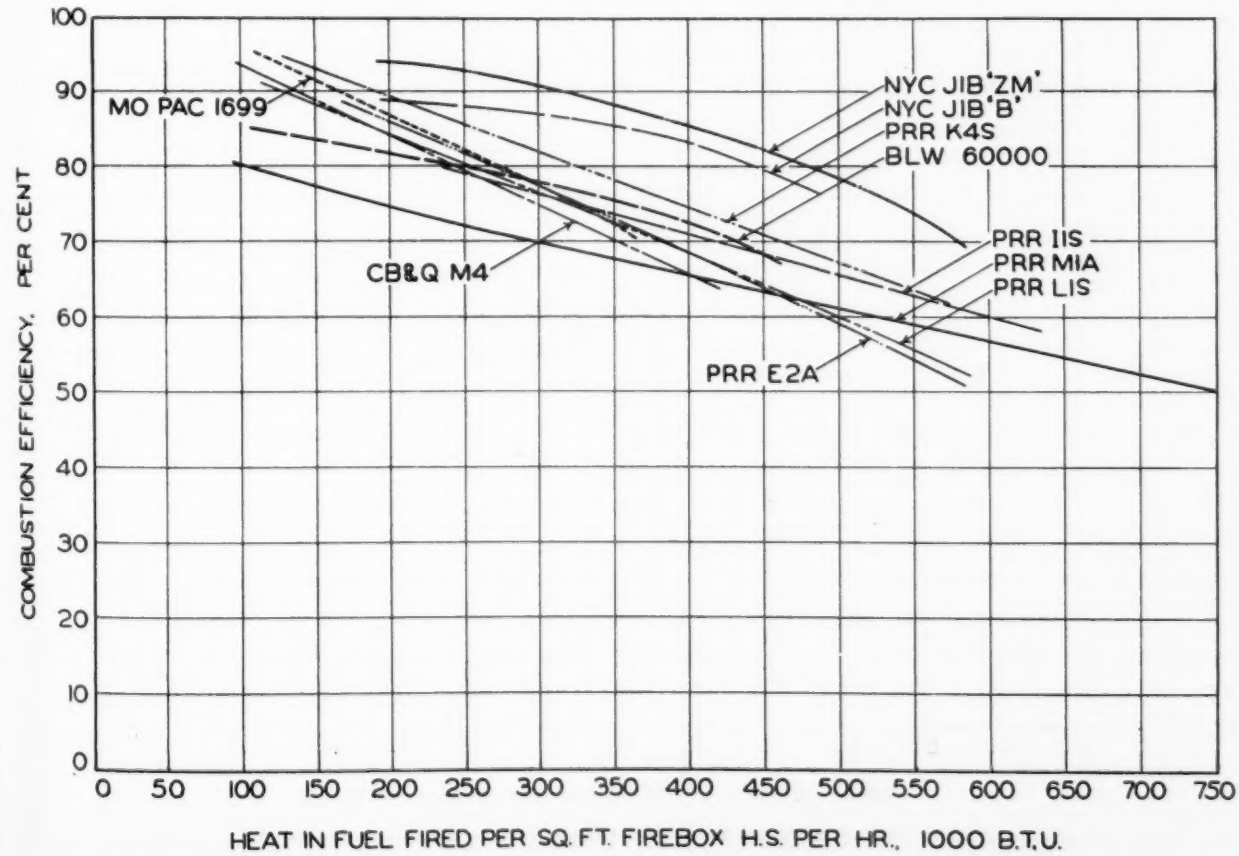

Fig. 9 Combustion Efficiency Versus Heat in Fuel Fired per Square Foot of Firebox Heating Surface per Hour

area. Compared on the basis of tractive power the furnace volume varies from a minimum of 4.04 to a maximum of 11.67 cu ft per 1000 lb of tractive power.

The difference in opinion among locomotive designers as to the correct size of firebox and combustion chamber is due to the absence of pertinent facts and test data to permit a scientific evaluation of the various factors. It is known that the first cost of the heating surfaces in the firebox and combustion chamber is very high as is also the cost of the maintenance and inspection when compared with the tube heating surface. What the relative cost of firebox and tube maintenance amounts to is unknown. Little information is available as to the cost of boiler maintenance, since few American railroads keep accounts to permit such a study. In the report of the Federal Co-Ordinator of Transportation, November, 1935, the estimated average cost of boiler maintenance is given as 30 per cent of the total cost of locomotive repairs. The firebox maintenance is the greatest part of this cost. As a large modern boiler will have from 5000 to 8000 stay bolts in the firebox which must be tested at regular intervals, the size of the firebox is a very important item when the question of intensive utilization of the locomotive is considered.

Against these items of cost should be balanced the great improvements in boiler efficiency and capacity which are generally believed to be obtained by the use of large fireboxes. The heat absorption of the firebox heating surfaces is from six to ten times as great as the average tube heating surface. Another important point not usually considered is that the radiant-heat absorption by the firebox is accomplished without the expenditure of any energy, while the heat absorption by convection in the tubes consumes considerable power to create the high draft required. The energy required to move the gases increases with the fourth power of the weight velocity. Only a few tests have been made which supply data permitting the calculation of combustion efficiency. These tests have been mainly on engines, the boiler ratios of which are very much alike, and thus the effect of greatly different boiler ratios is not clearly discernible from available data.

To illustrate the effect which different boiler ratios have upon combustion efficiency, the data from all tests available have been plotted in Figs. 6 to 9. The combustion efficiency is plotted against various factors as follows:

Fig. 6.... Heat in fuel fired per hr
Fig. 7.... Heat in fuel fired per hr per sq ft of grate area
Fig. 8.... Heat in fuel fired per cu ft firebox volume per hr
Fig. 9.... Heat in fuel fired per sq ft firebox heating surface per hr

It is, however, becoming more generally recognized that the larger the furnace volume of a locomotive, the greater is the opportunity for completing the processes of combustion. This is true only if the larger furnace volume is obtained in conjunction with maximum boiler diameter, furnace width and depth, and not by furnace length alone.

An examination of a typical boiler diagram, Fig. 3, shows the gas velocities at several points in the firebox, an explanation being given why the largest possible cross-sectional area through the firebox is very important. The velocity of the furnace gases in this case between the top of the arch and the crown sheet is as high as 260 miles per hour. It is remarkable that the small particles of coal being blown by the stoker jets into the center of a hurricane of such velocity are able to settle on the grate or have time to burn at all.

A particle of fine coal caught in the gas stream will pass through

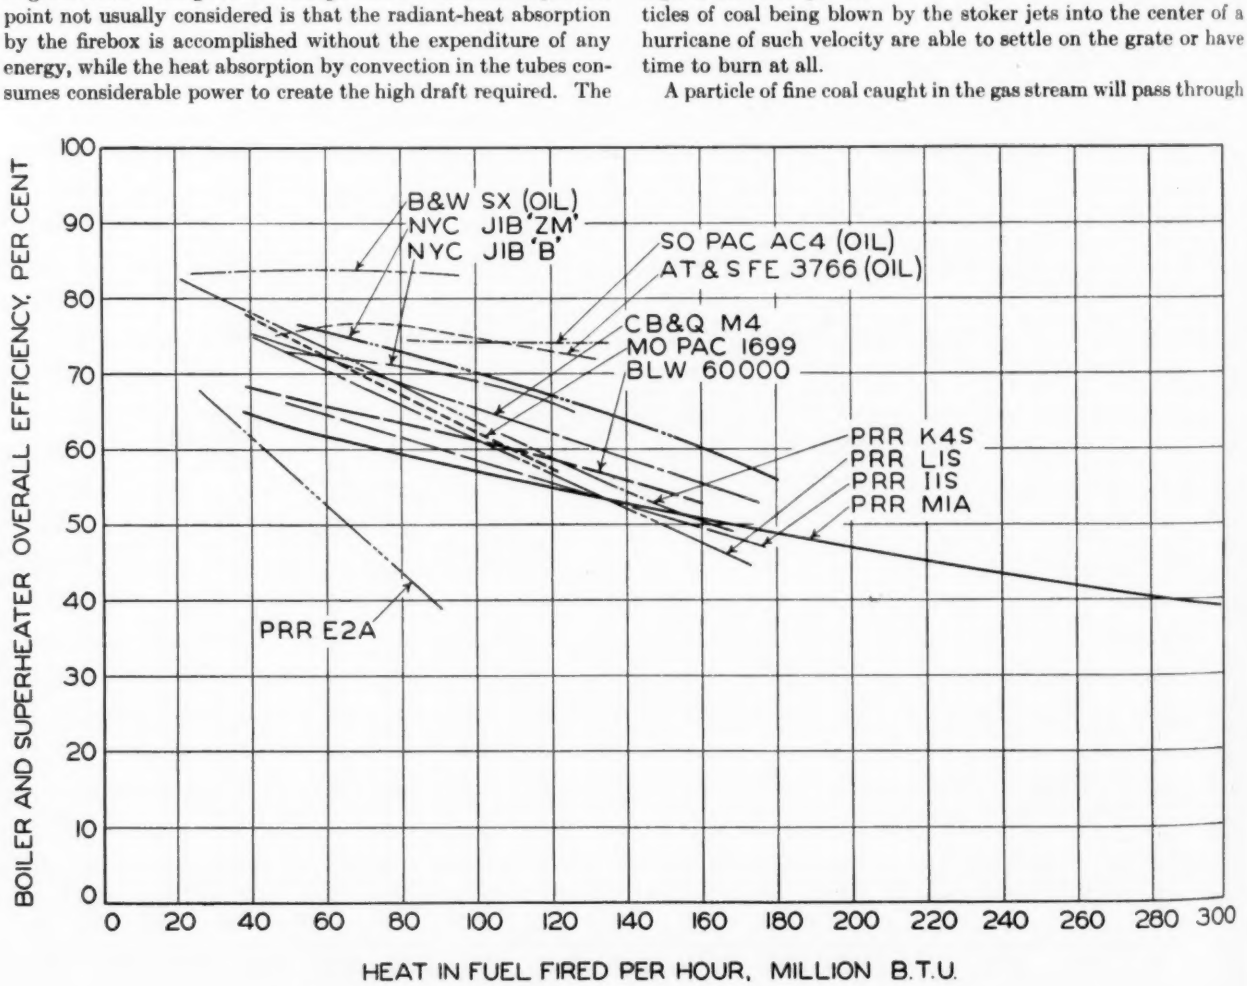

Fig. 10 Over-All Boiler Efficiency Versus Heat in Fuel Fired per Hour

this furnace in 0.1 sec and this is one of the reasons for the great loss of carbon at high-capacity operation. As a comparison, in stationary practice the velocity of the gases just before entering the tube bank is about 10 miles per hour at a maximum. A study of the designs of many recent boilers indicates that the width of the firebox, as well as the depth, could have been increased to give the advantage of a larger combustion volume under the firebrick arch, as well as a larger gas area between the top of the arch and the crown sheet.

A few modern boilers have been built with a firebox ring as low as 53 in. from the rail which with a horizontal grate would give a good depth of the firebox at the rear. On many locomotives with the grate sloping up toward the back end, the distance from the rail to the firebox ring is 72 in., or more, and thus there is a loss of 18 in. in the depth of the firebox. The author has not been able to get a satisfactory reason why sloping grates are still continued, especially since so many boilers have been built with horizontal grates and have given satisfactory service.

While discussing the subject of furnace volume, attention is called to the boiler-efficiency curves plotted in Fig. 10. Three efficiency curves from oil-fired boilers are shown. Two are locomotive boilers and one is a water-tube boiler, tested by the United States Navy.[10]

The following table gives certain pertinent data on maximum-capacity operation:

User	Santa Fe	Southern Pacific	U. S. Navy
Type	4-8-4	AC4	Marine
Engine number	3766	4108	Type 8X
Furnace volume, cu ft	795	970	423.6
Gas area through boiler at furnace, sq ft	10.3	11.98	30.06
Maximum oil burned, lb per hr	7000	6800	5051
Maximum oil burned per cu ft furnace volume, lb per hr	8.8	7.0	11.9
Maximum oil burned per sq ft gas area	680	558	168
Maximum coal equivalent, lb per hr	10800	10500	7850

It is interesting to note that it was possible to burn 35 per cent more oil per cu ft of furnace volume with 8 per cent higher boiler efficiency in the Navy boiler than was attainable in the locomotive boiler. The gas area in the Navy boiler at the gas exit of the furnace, however, was three times greater than on the locomotive boiler, which again confirms the importance of gas area.

Absorption Efficiency of the Heating Surfaces

The absorption efficiency of the surfaces should be expressed as the total heat absorbed in per cent of the total heat available for absorption; that is, of the total heat drop from the furnace temperature to the metal temperature of the flues and superheater units at the smokebox. This is termed the true efficiency and is very high, about 90 per cent in a locomotive boiler, due to high gas velocity and cooling of the gases to within 75 F of the temperature of the water at low rating, and 200 F at high capacity.

On locomotives with type E superheaters the smokebox gases are from 100 to 150 deg lower than the steam temperature. The losses due to the sensible heat escaping in smokebox gases range from 19 to 25 per cent of the heat in the coal fired, at high rating, and the only hope of reducing these is by a radical change in the boiler design whereby the average temperature head could be increased by the use of a counterflow economizer. In this manner the smokebox gases could be lowered some 210 F which would give a 7 per cent increase in the over-all boiler efficiency.

The importance of an effective arrangement of the flue heating surfaces is most apparent at high capacity when 70 per cent of the liberated heat is delivered to the flues. The ratio of the net gas area of a flue to its gas-swept perimeter (sometimes called hydraulic depth) determines the gas-carrying capacity of the flues. The larger this ratio becomes the more gas will flow for equal pressure drop. This has been labeled the "flue capacity factor," or F.C.F.

The longer a flue of a given F.C.F. is made, the greater becomes its true efficiency and also its draft loss. Now if the length of the flue in inches is divided by the F.C.F. a value is obtained which expresses the true efficiency of any diameter and length of flue. This factor has been termed the "flue efficiency factor" or F.E.F. The larger it becomes the more efficient a flue is.

In Fig. 11 has been plotted a curve showing the true efficiency that will be obtained on any size and length of flue with a given flue efficiency factor, or F.E.F.; that is, the ratio of length to hydraulic depth.

In Fig. 11 is also shown the true efficiency of several sizes of flues for different lengths. The F.E.F. for a 2-in. inside-diameter flue 18 ft long is 432 and gives a true efficiency of 88 per cent. If this flue is made 25 ft long the F.E.F. becomes 600 and the true efficiency is increased to 94.5 per cent, but the draft loss is increased in the same ratio as the length. In America many boilers have been built with flues 22 ft to 25 ft long, but usually efforts are made to keep the flue lengths down by lengthening the combustion chamber where this can be done. It is evident from Fig. 11 that a larger-diameter flue of a greater length can be used to give the same true efficiency as a smaller flue of shorter length.

The heat-absorption efficiency of locomotive boilers increases with an increase in the flue efficiency factor of the tubes and flues and ranges usually between 78 and 88 per cent. The absorption efficiency of several boilers has been shown in Fig. 12; it is noted that there is a very small decrease in this efficiency as the rate of firing is increased.

The combined absorption and combustion efficiency gives the over-all efficiency of the boiler and superheater and these data are shown in Fig. 10 for the engines previously cited. The general proportions and boiler ratios of all the engines shown in this and previous curves are given in Tables 1 to 6, as follows:

Heat balances showing the heat absorbed by the boiler and superheater together with the various heat losses for two modern locomotives are shown in Figs. 13 and 14.

Before leaving the subject of heat absorption, a few words may be said as to the heat-absorbing capacity of the firebox. Cole proposed 55 lb of steam per sq ft as the maximum based on Professor Goss's test at Coatesville, the only test made on a locomotive where the firebox evaporation was determined separately. This value of evaporation rate has continued to be used up to now even though the size of the locomotive firebox has increased five to six times since the Coatesville tests. It is reasonable to suppose that the same evaporation rates cannot very well apply to a firebox with 800 sq ft of heating surface having siphons, circulators, etc., as to a firebox with only 150 sq ft.

Since the adoption of waterwalls in stationary boilers, the heat absorption due to radiant heat has received much attention and analysis.

The general behavior of radiant energy as expressed and defined in Stefan-Boltzmann's law, Prevost's law, Kirchhoff's

[10] "The B&W High-Pressure Sectional Express Boiler," by R. C. Brierly, *Journal of the American Society of Naval Engineers*, vol. 43, Nov., 1931, pp. 511–561.

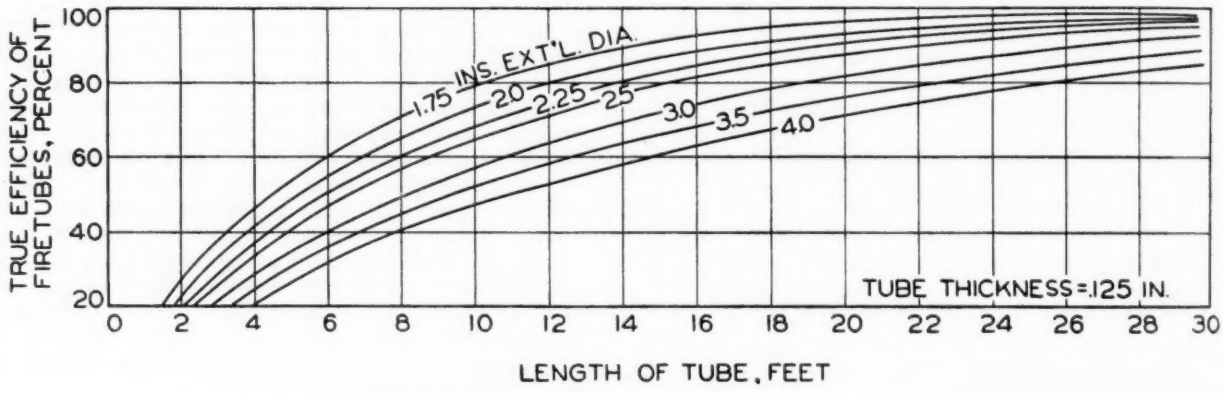

FIG. 11 TRUE ABSORPTION EFFICIENCY OF FLUES

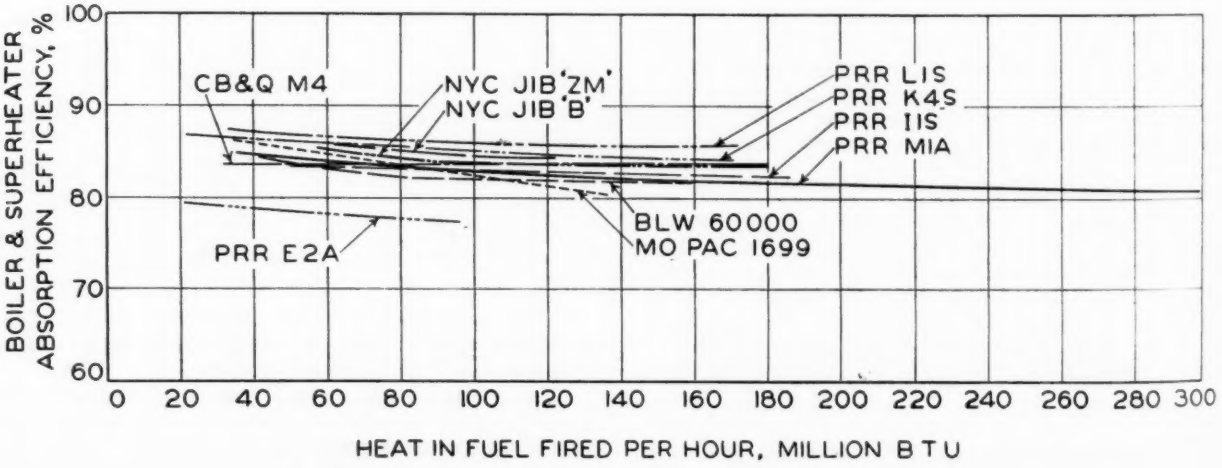

FIG. 12 ABSORPTION EFFICIENCY VERSUS HEAT IN FUEL FIRED PER HOUR

law, Planck's formula, and studies by many other investigators, permits definition and determination of the coefficients of emission, absorption, reflection, and transmission of radiant heat. To apply these laws to locomotive fireboxes, additional test data will be required.

The proportion of the total heat liberated in the furnace, which is absorbed by the firebox heating surfaces has been termed "furnace absorption efficiency," and this determines the temperature of the combustion gases as they leave the firebox. An accurate knowledge of this temperature is important as it determines the design and performance of the superheater.

In tests where complete gas analyses have been made to determine the quantities of air used for combustion, it is possible to calculate the per cent of fuel fired that is actually burned and the total heat liberated in the furnace. A fraction of the liberated heat is absorbed by the firebox and the balance leaves as sensible heat in the combustion gases which, with the total known weight of gases, determines the mean temperature of these gases leaving the furnace. The furnace absorption efficiency can thus be stated in terms of the average temperature of the gases leaving the furnace.

Thus, if

t_1 = temperature of combustion gases leaving firebox, F
C_P = mean specific heat of combustion gases between t and 60 F
H_T = total heat liberated in firebox per lb of combustion gases
H_g = heat in 1 lb of combustion gas leaving furnace
H_F = heat absorbed in firebox in per cent of total liberated

then $$H_g = C_P(t_1 - 60)$$

and the per cent of total heat liberated in the firebox that leaves the furnace in the gas is equal to

$$C_P \frac{(t_1 - 60)}{H_T} \times 100$$

The furnace absorption efficiency, therefore, is

$$H_F = \left[1 - \frac{C_P(t_1 - 60)}{H_T}\right] \times 100$$

The relation between the percentage of heat absorbed by the firebox and the temperature of gases leaving, depends upon the heat liberated per lb of combustion gas, which again depends upon the excess air used for combustion. If, therefore, an accurate measure of the gas temperature leaving the firebox is obtained with a reliable pyrometer the furnace absorption efficiency can be determined.

It has been demonstrated that the radiation from the flames is largely due to incandescent particles of fuel and ash in the flame. The quantity and distribution of this radiating material in the flames, together with the amount of firebox heating surface, determine the coefficient of emission or absorption. This explains why boilers fired with oil give higher superheat; the less luminous flames of the oil fire will give up a smaller percentage of heat to the firebox by radiation, and the gases entering the flues are therefore hotter.

Several formulas have been proposed for the determination of the furnace absorption efficiency. The author has checked a number of the formulas proposed by Hudson, Broido, Wohlenberg, Orrok, Munzinger, Bottomly, and Adloff, but sufficient test data are not available to confirm their methods closely enough for locomotive-firebox conditions. All formulas, however, show that the fraction of the total heat liberated, which is absorbed as radiant heat by the furnace walls, decreases as the total heat liberation is increased. It will range from about 50 to 55 per cent at low rating down to perhaps 25 to 30 per cent at high-capacity operation.

At low rating the heat absorption per square foot of firebox heating surface will be near the figure commonly used, or 55 lb of water evaporated per sq ft but at high capacity the heat absorption will approach a figure of 125 lb of water per sq ft of heating surface. From the studies made of this problem, it is doubtful if the percentage of heat absorption can be increased to much more than 50 to 55 per cent of the heat liberated, by increasing the amount of firebox heating surface, because the amount of radiant energy absorbed is limited by the effective surfaces of the fire bed and the luminosity of the flames.

Grate Area in Relation to Efficiency and Capacity

The size of the grate area should be in proportion to the maximum output expected of the boiler and the quality of the coal to be burned. With the exception of the Dakota and Wyoming lig-

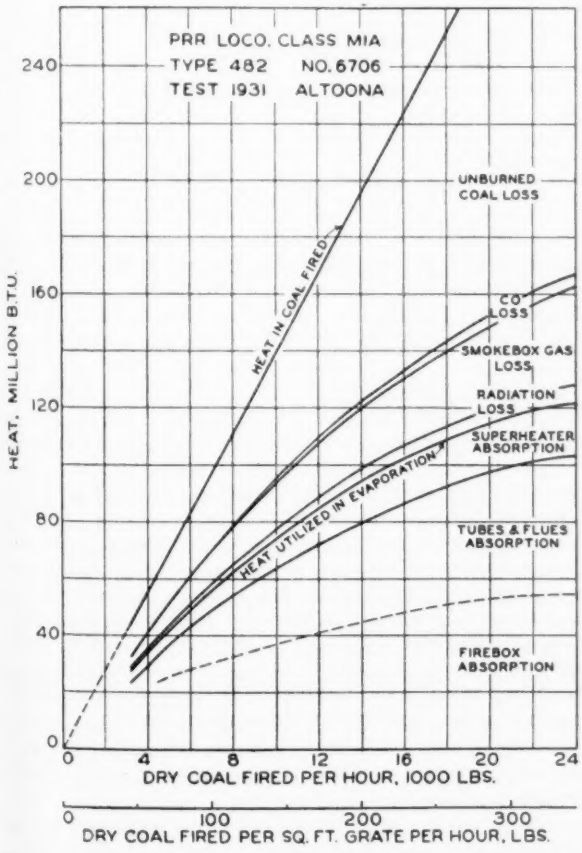

Fig. 13 Heat Balance Versus Dry Coal Fired per Square Foot of Grate per Hour; P.R.R., Class M1A

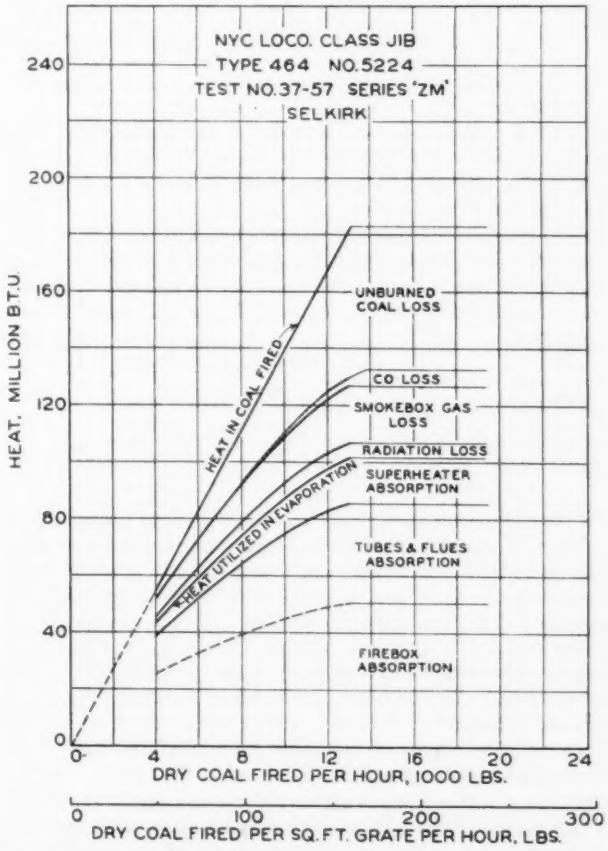

Fig. 14 Heat Balance Versus Dry Coal Fired per Square Foot of Grate per Hour; N.Y.C., Class J1B

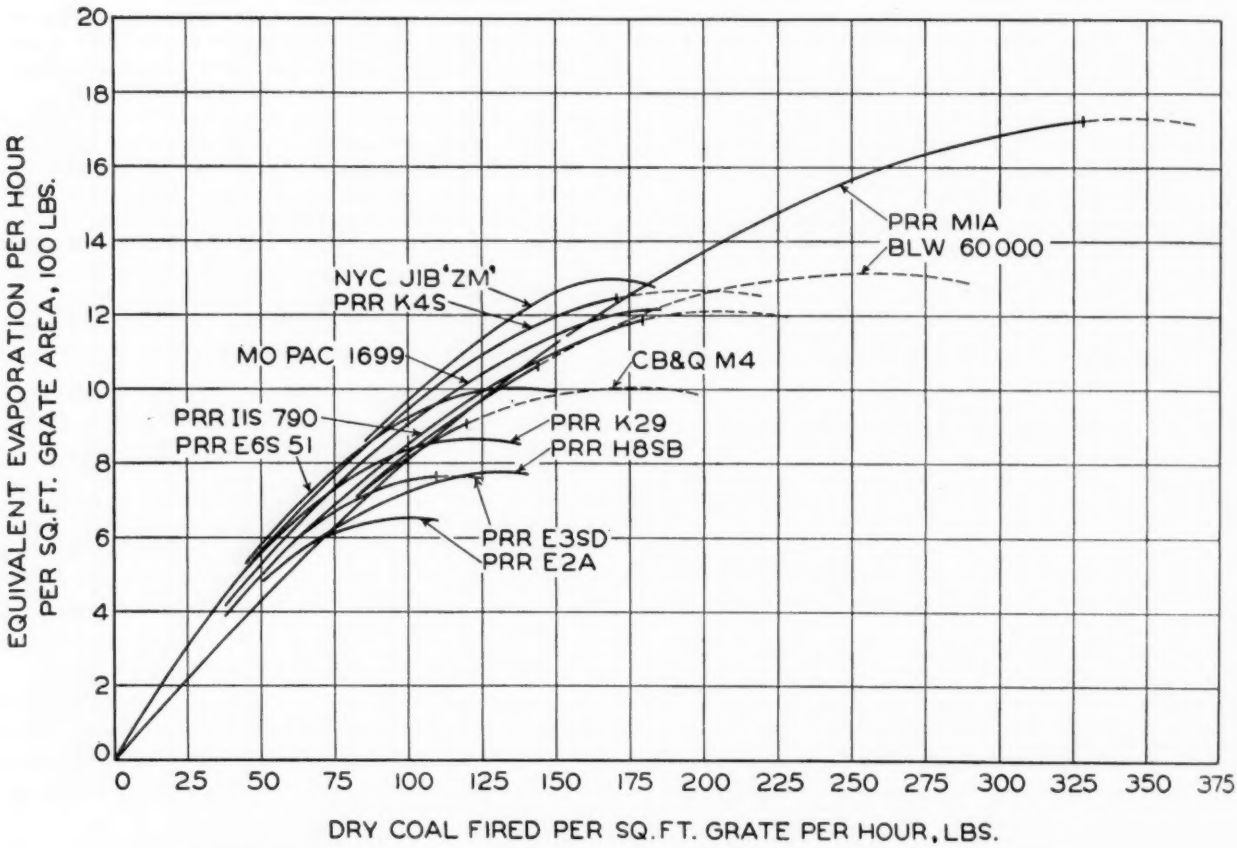

FIG. 15 EQUIVALENT EVAPORATION VERSUS COAL FIRED PER SQUARE FOOT OF GRATE PER HOUR

nites, the average maximum variation in the heating value of the coals mined east of the Mississippi is from 12,000 to 14,000 Btu per lb, and west of the Mississippi from 10,000 to 12,000 Btu per lb, or about 17 per cent for each class of coal.

If the grate-area ratios of modern locomotives, however, are studied it will be noted that they vary to a much greater extent than the heating value of the fuel, as shown in the following table:

	Ratio		Range of difference, per cent
	Minimum	Maximum	
Grate area per 1000 lb tractive effort	0.78	2.32	1:2.97
Grate area per sq ft total heating surface	0.0119	0.0262	1:2.20
Grate area per sq ft firebox heating surface	0.101	0.353	1:3.50
Grate area per sq ft net gas area	7.1	13.8	1:1.94

It would appear that much thought and study must be given to this subject as the proper size of grate area is important in obtaining high furnace efficiency and capacity. If too small a grate is selected, the firing rate will be too high at maximum-capacity operation and, if too large, it is difficult to keep the grate covered at low capacity, which results in bare spots, a high per cent of excess air, reduction of boiler efficiency, and superheat. The service condition and the profile of the road must be carefully analyzed for best results.

The question of the percentage of air openings through the grates has been explored during the last few years. Recent tests on one railroad, where grates with air openings of 10, 24, and 32 per cent were tried, indicated a very small variation in boiler efficiency between the various percentages of air openings, or less than $1^1/_2$ per cent above and below the mean percentage.

The relation between equivalent evaporation per square foot of grate area and coal fired per square foot of grate area per hour has been plotted in Fig. 15.

SECONDARY AIR FOR COMBUSTION

The length of the firebox and the combustion chamber is of importance, but there is a question whether the function of the latter which gives it its name is operative, as there is no air admitted ahead of the arch on most locomotives to permit the carbon to burn completely in its passage through the combustion chamber.

Today, most modern locomotives in America are fired with a stoker which distributes the crushed coal with steam jets through the boiler backhead. The coal is thus thrown into the firebox through and against the gas stream at the point of its highest velocity. The heaviest coal lumps fall on the grate, but many of the fine coal particles are caught in the high-velocity gas stream and partially burned in suspension while traveling at high speed. During the short time the coal particles pass through the furnace, they must be heated to ignition temperature, the moisture driven off, and the volatile gas distilled and burned before the solid carbon is consumed. It is quite possible that most of the carbon now escaping could be completely burned in the large fireboxes if sufficient oxygen were admitted into the firebox and combustion chamber as secondary air. The beneficial effect of admitting secondary air above the fuel bed has been known for many years and recognized by authorities on combustion as very desirable, yet little has been done along this line.

This subject was investigated by Henry Kreisinger[11] as early

[11] "Combustion of Coal and Design of Furnaces," by Henry Kreisinger, C. E. Augustine, and F. K. Ovitz, Bulletin No. 135, United States Bureau of Mines, Washington, D. C., 1917.

as 1917. In these tests it was proved that, with a firing rate up to 185 lb per sq ft of grate and with the thickness of fuel bed varying from 6 to 12 in., all the oxygen in the air which entered through the grate and fuel bed was consumed at the level of approximately 4 in. above the grate.

A sufficient quantity of secondary air admitted above the fuel bed in such a manner as to create a turbulence in the gases would permit of an intimate mixing of the hydrocarbons thrown off by the coal, and provide the necessary oxygen for the complete combustion of volatile gases and carbon. Another very important result from the use of a correct amount of secondary air is that it will help to eliminate smoke which always has been a serious nuisance in locomotive-boiler operation.

Kreisinger states in his report,[11] "the ratio between the weight of air supplied and the weight of fuel gasified remains practically constant at about seven to one so that only about one half of the fifteen pounds of air required to burn the fuel should be supplied through the fuel bed. In order to complete the combustion of all the fuel fed into the furnace, the balance of the air should be admitted above the fuel bed to consume the volatile, as well as fixed carbon present in this zone, or it will escape unburned."

Any scheme to admit secondary air above the fire should be arranged so that the air is controlled in accordance with the demand, in order to keep the excess air at a minimum and not decrease the fuel-burning capacity of the furnace or decrease the over-all boiler efficiency by too much excess air. Several schemes have been prepared to admit secondary air above the fire. The simplest is that of applying air-inlet thimbles in the sides of the firebox and the effectiveness of this should be fully explored. Some studies have been made of the introduction of preheated air by means of blowers. Actual tests have been conducted on one railroad by using blowers without air preheating, but so far no definite advance has been made. It is possible that the cost of such a scheme may be justified from the standpoint of smoke elimination alone.

Front-End Design and Draft

Because of the very high draft required in a locomotive boiler, the proportion of the draft-making equipment in the smokebox has received much attention in recent years and a great many tests have been conducted to discover the most efficient front-end design.

It is well known that most of the large railroads in the United States have conducted many front-end tests in recent years. The best arrangements arrived at differ considerably in design. The important result, however, is that the efficiencies of the draft arrangements have been increased by handling greater quantities of gases with lower back pressure, and that it has been possible to increase the diameter of the stack to a considerable extent without causing the trailing of smoke, which is undesirable from the standpoint of signal observation.

Curves are given in Fig. 5, which show the equivalent evaporation plotted against back pressure. This curve, test *ZM*, shows the improvements gained by the use of an improved front end developed for the New York Central class J1B locomotives as compared with the standard front end.

Superheater

Of all the improvements made on the locomotive, since George Stephenson invented the first one, the superheater holds the first rank. Its great success has been due to the fact that it attacks the heat cycle at a point where the losses are the greatest, i.e., in the cylinders, by the elimination of cylinder condensation during admission and expansion and re-evaporation at exhaust.

Of the many tests made that have proved the beneficial effects of high superheat, those conducted by the Pennsylvania Railroad have been the most complete and conclusive. In his report[12] on the performance of the superheated passenger locomotive E6s, C. D. Young presented a most thorough analysis of the beneficial effects obtained by the use of superheated steam. The following summary is quoted therefrom:

"The application of the superheater to this locomotive increases its economy from a minimum of 23 per cent to a maximum of 46 per cent, the economy increasing with the increased power required of the locomotive.

"It was found that 30 per cent higher capacity was derived from the E6s locomotive when using superheated steam than with the same size and type of locomotive using saturated steam."

This result was obtained with a comparatively low superheat, of 200 to 225 F, as compared with present-day practice. This showed an average increase in economy of 1.15 to 2 per cent for each 10 F increase in superheat. Experience and tests have shown that this rate of increase in economy holds good up to the limits of present acceptable practice of 350 to 400 F superheat. That every effort must be made to maintain highest superheat temperature is apparent.

This problem has become more and more difficult as the available heat for superheating has been reduced because of the high heat absorption in the large fireboxes of modern locomotives. To compensate for this, much larger superheaters have been found necessary and the introduction of the type E superheater was a natural development. This type has been used on most modern locomotives which have been built during the last fifteen years in America.

Because of the great influence that the superheater design has upon the efficiency and capacity of both the cylinders and the boilers, considerably more space could be devoted to the discussion of superheater design than is here available.

A great deal of research work and testing have been done with many different types of superheater units to discover the unit which will give the maximum superheat with the lowest possible draft loss and steam pressure drop, which is at the same time practical and keeps weight, first cost, and maintenance at a minimum.

The improved type E superheater is a very excellent arrangement as it gives a combination of maximum evaporating and superheating surfaces coupled with the greatest possible gas area through the boiler and steam area through the superheater. This assures high sustained superheat at low as well as high rating with minimum draft and pressure loss.

Feedwater Heating

A feature of great value in obtaining sustained capacity of the boiler, which may only be mentioned here, is the beneficial effect of feedwater heating. The increase in economy or power output of a locomotive ranges from 8 to 14 per cent through the recovery of the heat in the exhaust steam that otherwise would be wasted. The feedwater heater is now well recognized as necessary for economical locomotive operation.

Conclusion

In conclusion it may be said that the modern locomotive boiler is a very effective steam generator. Boilers[13] which can produce highly superheated steam at a rate of 1 lb equivalent evaporation per hr per 1.3 to 1.4 lb of total boiler weight, compare very favorably with stationary boilers of about the same capacity which weigh about four times as much, or 6 lb per lb of steam produced not including stack, breeching, brickwork, or draft fans.

[12] Test Bulletin No. 21, Nov. 4, 1912, pp. 82–89, 150–151.

[13] Class M1A, Pennsylvania Railroad; class J3, New York Central Railroad.

The weight of the locomotive boiler cited includes the boiler complete, superheater, smokebox, front end, stack, stoker, grate, and water.

While continued efforts must be made further to improve the boiler, clearly, it is the engine which deserves the most attention, as its thermal efficiency is so low that even a slight improvement is important. This may mean less simple mechanical parts than in the present reciprocating engine, but the mechanical-maintenance forces of the American railroads have proved to their great credit that very difficult mechanical problems, such as those connected with the maintenance of Diesel and electric locomotives, can be handled successfully.

This gives hope that apparatus and equipment proposed for the improvement of the steam locomotive will receive favorable consideration in the future, and that the hazards of added complications will not be considered as formidable as they once seemed.

Acknowledgment

The author wishes to express his appreciation to F. W. Hankins, assistant vice-president, chief of motive power, Pennsylvania Railroad; P. W. Kiefer, chief engineer, motive power and rolling stock, The New York Central System; Frank Russell, mechanical engineer, Southern Pacific Railroad; and E. E. Chapman, mechanical assistant to vice-president, Atchison, Topeka, and Santa Fe Railroad, for their courtesy in supplying the test data used in plotting the curves and for permission to use the data in this paper. Acknowledgment is also made for the assistance rendered by Charles Guarraia in preparation of the curves.

Discussion

R. W. Anderson.[14] In his paper, the author clearly shows the importance of locomotive design ratios and successfully points out the limitations of formulas advocated by various locomotive-boiler authorities. Such limitations are primarily due to the lack of test data. For modern boilers, this in turn necessitates yet further approximations in the present inadequate formulas which must be used as a basis of design. Locomotive boilers are now being subjected to greater demands than ever before and the performance required will certainly not be lessened to ease the situation.

Weight and clearance dimensions immediately fix limitations which cannot be exceeded and which have the definite effect of hindrance in the design from its inception. However, in spite of these limitations and with the admittedly inadequate design formulas, filled as they are with estimated coefficients, boilers have been and are being built which generate more than the calculated quantity of steam, although the ratios between the grate areas, flue areas, firebox volumes, heating surfaces, etc., on successful boilers, vary within wide limits from the steam-generating viewpoint. However, when such boilers require more than the usual amount of attention considered necessary to keep them in proper condition, they can hardly be classified as being satisfactory for continuous operation.

All these conditions certainly point to the necessity of a central testing plant for such jobs. The experiments on the design formulas and ratios would no doubt take several years. Independent investigations and tests are often unsatisfactory due to lack of adherence to standard test codes and methods of collecting information.

The high draft-tube readings which are obtained in front-end experiments on some railroads lead others to try similar arrangements only to find that the new application could not survive transplanting. It would have been much cheaper to borrow the draft tubes, providing a standard measuring device for testing the existing arrangement.

If a series of boilers of various proportions were developed in such fashion, the major problem, namely, availability, is then only started. Modern locomotives have an exceptionally high first cost. Under present demands, boilers require considerably more than the usual amount of attention in roundhouses and shops. The metallurgist is being drawn further into this problem and it is his responsibility to determine the physical and chemical properties of the boiler steels which will be capable of withstanding present-day loads. He may be the one who will be required to tell the manufacturers to set the side sheets at a certain slope in order to prevent warped plates and leaky stay bolts. Continual firebox-repair work should not be a necessary evil attached to 300-lb-pressure boilers; to eliminate this condition a thorough study should be made of various furnace designs and the proper materials to use in their construction.

The engine portion of the locomotive has always received the greatest amount of attention from the designer's viewpoint. Consequently, the boiler is often changed to accommodate certain other parts which no doubt could have been altered to avoid affecting the boiler design. For instance, the trailer-truck design limits the grate and ashpan arrangement but, if the furnace design were given the attention it should have on modern locomotives and every effort made to have the trailer come within the limits specified, there would undoubtedly be a considerable saving realized in firebox, grate, and ashpan maintenance charges.

The performance of high-speed engines on long runs has created many problems in regard to lubrication and materials which must be solved. It will take a lot of coordinating to accomplish this.

E. G. Bailey.[15] The writer will confine his discussion to one phase of this paper, applying the data therein presented to the method of comparison of steam-boiler performance, covered by his paper[16] on that subject.

Throughout his paper the author has very properly mentioned the question of absorption efficiency and combustion efficiency, or total boiler and superheater over-all efficiency, which is in reality the product of the other two. The data given in his Figs. 13 and 14 are sufficiently complete to show wherein the difference lies between combustion efficiency and absorption efficiency, both relating to coal-fired boilers. However, in Fig. 10 he gives data of an oil-fired marine boiler which happens to be the same as boiler F, Table 3, in the writer's paper,[16] and also two oil-fired locomotive boilers, Southern Pacific AC4 and Santa Fe 3766. The difference between the efficiencies of these and

the oil-fired marine boiler is outstanding, and further data as to the breakdown of this efficiency difference would be interesting.

Fig. 16 of this discussion includes a typical pulverized-coal-fired stationary boiler, as represented by test B-1, Table 2 of the paper,[16] and test F-1 for an oil-fired marine boiler from Table 3 of the same source. The latter has been calculated to show the percentage of heat absorbed in the different sections of the unit, although the official efficiency tests cover only the over-all efficiency, as is plotted in Fig. 10.[16] In addition to the data which were plotted from Pennsylvania Railroad class M1A, the author's Fig. 13, and the New York Central class J1B, Fig. 14, the writer has also gone back to the data of Goss's tests at Coatesville in 1912 and selected the one with the most representative maximum rating giving complete results on a coal-fired radial-

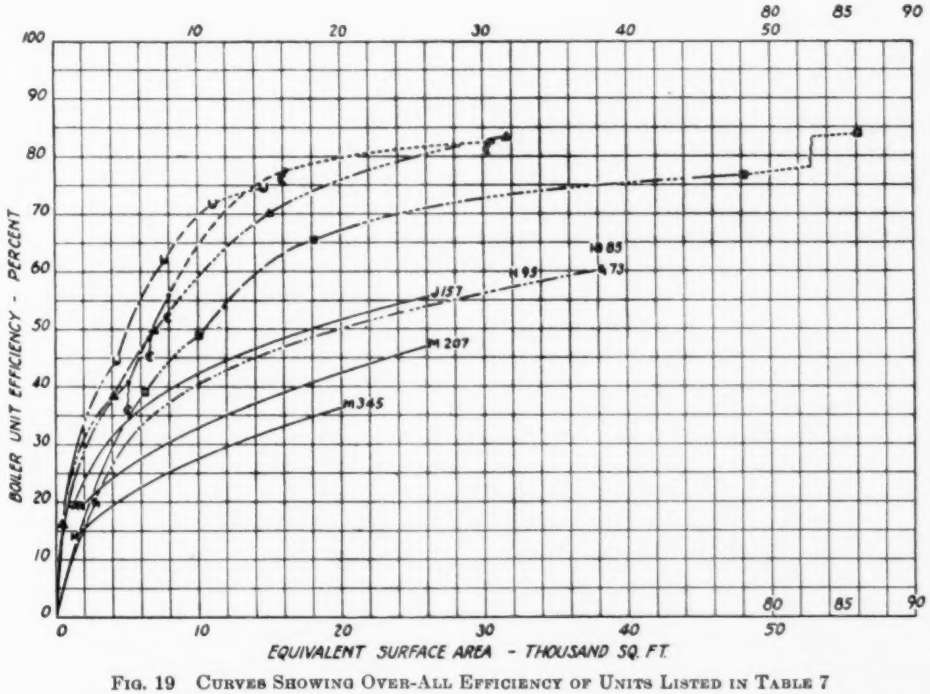

FIG. 19 CURVES SHOWING OVER-ALL EFFICIENCY OF UNITS LISTED IN TABLE 7

stay-bolt firebox, in which Dr. Goss determined the heat absorption in the firebox separately. From Hitchcock,[17] the writer has also selected two road tests on locomotives conducted in 1902, from which sufficient reliable data were obtained to plot the absorption efficiency and the over-all efficiency, but without measured distribution between the firebox and the flues. Both the Goss and Hitchcock tests were without superheaters. Also from the paper,[16] test A-2 of the French locomotive, with one half the tubes plugged, falls directly in line as to rate of output with the Pennsylvania class M1A at 345 lb of coal fired per sq ft of grate per hr. The other point of Pennsylvania class M1A plotted is taken to duplicate exactly the equivalent-surface area of the New

[17] "Road Tests of Consolidation Freight Locomotives," by E. A. Hitchcock, Trans. A.S.M.E., vol. 25, 1904, pp. 550–588.

York Central class J1B at its maximum rate. It is to be noted that they come closely together and are quite consistent, while there is an indication that the tests on the French locomotive with its small firebox showed somewhat less efficiencies.

Superposed on these curves are also data from the oil-fired Steamotive boiler as tested at Schenectady and reported in a paper[18] by E. G. Bailey, A. R. Smith, and P. S. Dickey; from the oil-fired Steamotive boiler on the Union Pacific steam turboelectric locomotive which has been described[19] recently; as well as from tests on pulverized-coal-fired Steamotive boiler, conducted at Erie, Pa., during 1939.

The Steamotive generators are high-pressure high-temperature units, as indicated in Table 7 of this discussion, and the slopes of the curves after the gases enter the superheater and economizer show very high rates of heat absorption due largely to the high mass flow and the suitable arrangement of the tubes with respect to gas velocity and gas temperature. A cross section of the Union Pacific oil-fired Steamotive boiler is shown in Fig. 17 and the pulverized-coal-fired unit in Fig. 18.

Fig. 19 gives data from most of the units listed in Table 7 on the over-all efficiency basis. This includes boiler, superheater, economizer, and air heater.

The pulverized-coal-fired stationary and Steamotive units, as well as the oil-fired marine and Steamotive units show only the normal difference between the absorption efficiency and the total efficiency, but the coal-burning locomotives show a marked diminution in efficiency due largely to cinder loss, which increases in general with the increased rate of firing. However, it is noted that the New York Central at 157 lb of coal fired per sq ft of grate per hr comes within the same range of over-all efficiencies as were obtained from Goss's tests at 73 lb of coal per sq ft, and the Hocking Valley tests at 85 and 95 lb, respectively.

In the author's Figs. 13 and 14, by means of dotted lines, he shows the heat absorbed in the firebox. His treatment of that subject in the text indicates definitely that he has the correct conception of the variation of this figure with rates of heat available, rather than the use of a constant figure of 55 lb of steam per sq ft of firebox per hr, which was evidently based on Goss's tests, as reproduced herewith. Fig. 20 expresses per cent of heat absorbed in the firebox as a function of the Btu available per square foot of actual heating surface. This gives data from Goss and the French locomotive tests as plotted points. It also gives a curve, calculated from the Hudson-Orrok formula[20] for which a basis of 13,900 Btu of coal with 11.8 lb of air per lb of coal, has been selected, which corresponds closely to 19 per cent excess air and 3600 F adiabatic temperature. Broido's average curve also is shown within the range in which it is given in his paper[21] before the Society. It would seem from this that the author's dotted lines of Figs. 13 and 14 may be somewhat high, and the curves of Figs. 16 and 19 of this discussion are plotted on the basis of being taken from the Orrok curve. One could readily plot in Fig. 16 the curves from Brandt's data as shown in Fig. 20. This would indicate a relatively higher rate of heat absorption in the firebox than seems to exist on other types of furnaces and, even at the same rates of Btu available, they are markedly higher than is indicated by Goss and the French locomotive, both of which were based upon actual weights of water evaporated by the firebox surface.

It is doubtful if this question of distribution of heat absorption between the firebox and the flues of a locomotive boiler can be accurately determined by gas-temperature measurement. The difference in the size of the flues, the resistance, gas velocity, and stratification of both quality of gas and temperature make it difficult, even though a device could be used which would get the true gas temperature. The cold surroundings of the tube sheet and flues will influence any thermocouple readings, even with the high-velocity method, to the extent that the data would be questioned. Therefore, it seems that the method used by

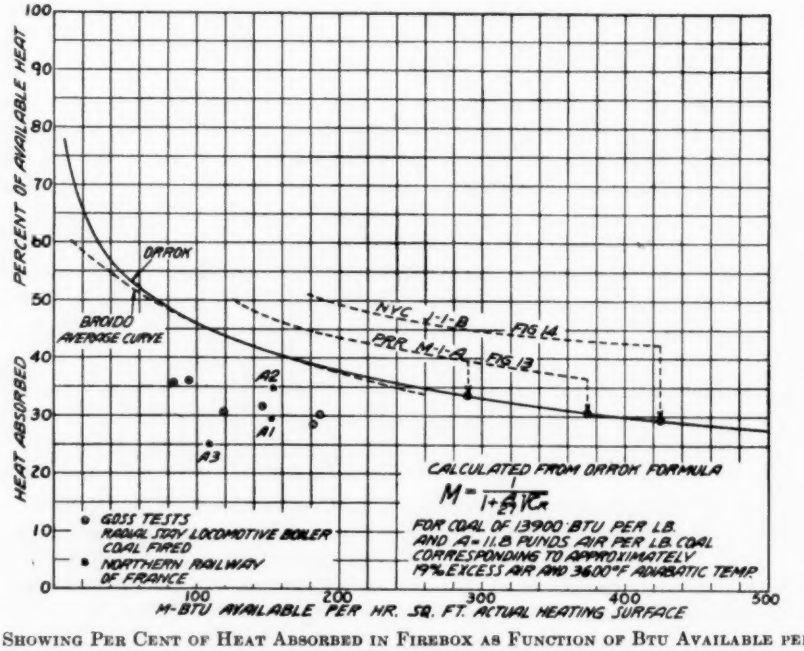

FIG. 20 CURVE SHOWING PER CENT OF HEAT ABSORBED IN FIREBOX AS FUNCTION OF BTU AVAILABLE PER SQUARE FOOT OF ACTUAL HEATING SURFACE

Goss and the French locomotive may be the only one in which such distribution can definitely be determined. Knowledge of this, however, only affects the detailed slope of the curve at the lower portion, when plotted on the equivalent-surface basis. The upper points on both the absorption-efficiency basis and over-all efficiency basis are equally reliable from well-conducted tests and show the important part of the over-all efficiency and the rate of heat input.

The author brings out clearly the limited area for gas flow entering the tubes and flues of the locomotive boiler. On a water-tube arrangement of heating surface, such as used in the Steamotive, this area can be made anything desired within reasonable limits. The designs now operating have more than twice the area on a given capacity basis than is possible on the locomotive units as shown by the author.

A further study of draft loss through the respective units is also of interest. The different tests in the writer's paper[16] give the over-all draft loss including the air heater, if any, burners, or fuel bed, draft loss through boiler settings, superheater, economizer, and air heaters, if any, as the total pressure drop. It would be helpful if in his closure the author could supply the data in a form which might be compared more readily than that as given in Fig. 5, showing back pressure.

J. M. DUNCAN.[22] The author reminds us that, in current locomotive practice, combustion rates and heat releases are far higher than any realized commercially in stationary plants. If industrial and central-station heat-power engineers could approach these rates, they would advance their art by materially reducing capital costs.

Pennsylvania Railroad locomotive class M1A appears to be designed for a heat liberation of 250,000 Btu per cu ft of furnace volume per hr, burning 121 lb of coal per sq ft of grate area per hr. Figs. 8 and 12 of the paper indicate that under these conditions combustion is substantially complete, the dry flue-gas loss being moderate, but the unburned-coal loss is 30 per cent. The furnace heat absorption is 41 per cent of the heat liberated, and the average heat absorption in the furnace is about 87,000 Btu per sq ft of furnace walls per hr. Data on furnace temperatures and excess air are not given. The writer calculates the exit furnace temperature at 1800 F and the excess air at 70 per cent. These figures may be considerably in error as essential data are lacking. Unburned-coal losses for other locomotives are above and below this 30 per cent figure at the same heat-release rate. At this rate, New York Central locomotive J1B has a loss of 12 per cent.

The author's objective is to develop means for increasing locomotive capacity and efficiency. Any increase in efficiency accomplished within existing weight and space limitations will, if present fuel-burning ability is maintained, automatically increase locomotive capacity. Two opportunities for increased efficiency lie in reduction of dry-flue-gas loss and reduction of unburned-coal loss. As pointed out by the author, convection-heat transfer is efficient. Improvements must be sought in furnace conditions.

If the underfeed or traveling-grate stoker can be adapted to locomotive service, will not the unburned-coal loss be automatically almost eliminated? The very fact that such large losses are tolerated indicates that the sprinkler type is accepted as indispensable for the large modern locomotive. But, if these other types can be adapted to this service, important advantages will be realized in addition to reduction of unburned-coal loss. This is principally because with these other types furnace absorption efficiency can be greatly increased.

An increase in furnace-absorption efficiency would reduce dry-gas loss almost proportionally if excess air is unchanged. If the increase is accomplished while reducing excess air, a further gain will be made. The following relations are calculated for a New River coal, assuming complete combustion with no air preheat:

Furnace exit, F	Furnace absorption efficiency, per cent	
	20 per cent excess air	80 per cent excess air
1500	63	46
2000	49	26
2500	34	4

These figures indicate that excess air cannot be materially reduced without incurring slag accumulations in flues with many coals which must be burned on railroads, unless furnace absorption efficiency can be greatly improved. The writer believes that the improvement must be brought about by a radical change in stoker design. This appears to be the author's conclusion when he says:

"From the studies made of this problem it is doubtful if the percentage of heat absorption can be increased to much more than 50 to 55 per cent of the heat liberated, by increasing the amount of firebox heating surface, because the amount of radiant energy absorbed is limited by the effective surface of the fire bed and the luminosity of the flames."

In regard to the effect of smoky flames the author says:

"It has been demonstrated that the radiation from the flames is largely due to incandescent particles of fuel and ash in the flame. The quantity and distribution of this radiating material in the flames, together with the amount of firebox heating surface, determine the coefficient of emission or absorption. This explains why boilers fired with oil give higher superheat; the less luminous flames of the oil fire will give up a smaller percentage of heat to the firebox by radiation, and the gases entering the flues are therefore hotter."

These remarks doubtless apply to a comparison of pulverized-coal and oil flames. But the facts cited tend to divert our attention from the controlling influence of luminous flames in reducing over-all radiant-heat absorption in stoker-fired furnaces wherever the grate is not obscured by an arch. The luminous flame will, it is true, lose more heat than the nonluminous flame (if high turbulence is maintained) but it will at the same time hide the incandescent and much hotter stoker fire from the heat-absorbing walls to a great extent. The author's remarks do apply to the stoker-fired-locomotive furnace shown in Fig. 3, where the luminous flames created by the sprinkler-type stoker are of advantage because that stoker requires an arch to reduce the unburned-coal loss. In such a furnace clear flames would be a disadvantage. Data of Fig. 3 do in fact indicate the presence of highly luminous flames. The velocity at section C is materially lower than at section B although the gas areas are practically equal. If flames were completely transparent, temperatures would be nearly equal throughout this section of the furnace.

The importance of clear furnace atmospheres in underfeed-stoker-fired furnaces was forcefully impressed upon the writer when observing some tests using a high-volatile coal. Operators had been unable to obtain smokeless combustion at moderately high rates. Boiler exit temperatures were higher than they should have been although excess air was less than guaranteed. A test operator then took charge for higher rate tests. While maintaining the same percentage excess air as before, he produced a transparent furnace atmosphere at considerably higher combustion rates and the excess boiler-exit temperatures were reduced. It was obvious that a large increase in the percentage of furnace heat absorption had been obtained. This must have been due to the removal of smoke and luminosity from the flames, thus allowing the fuel bed to "see" the furnace waterwalls and roof.

[22] Petersburg, Va. Mem. A.S.M.E.

During those tests it occurred to the writer that furnace heat absorption and over-all boiler performance could have been increased in spite of smoky furnace atmosphere if the "hydraulic mean radius" of the furnace were reduced by installing tubes spaced, say, on three- or four-foot centers throughout the upper portion of the furnace. (The vertical screen used to divide many modern powdered-coal furnaces, e.g., Fisk Street, appears to be a development of this sort, perhaps made more necessary by the essentially opaque nature of the flames in such furnaces.) The degree to which this could be carried out without prejudice to the furnace function depends upon the effect upon combustion. Has the author data upon the relation between furnace temperature and completeness of combustion—of carbon and hydrocarbons as well as of CO?

The sprinkler-type stoker seems inherently incapable of realizing high radiant-heat absorption. Its fuel bed is probably lower in surface temperature than that of the underfeed or traveling-grate type. Heating of green coal should not be spread over the fuel bed if a hot surface and a smokeless furnace atmosphere are desired. The other types of stokers confine the distillation of green coal to a small section of the fuel bed and so leave a large area of highly incandescent coke to radiate to the furnace walls; they also produce less smoke and consume it more rapidly. Such stokers do not require the arch shown in Fig. 3, which completely obscures the fuel bed from most of the furnace walls even if smoke is not produced.

Furnace-gas turbulence has been recognized as desirable to assist in attaining complete combustion. The writer believes it should be sought also in order to insure maximum radiant heat transfer at all times that an absolutely clear furnace atmosphere is not maintained. Evidently the gas velocities shown in Fig. 3 bring a high degree of turbulence. The temperature drop indicated by velocity drop is several times what could be caused by convection heat transfer. Smoky flames require high turbulence successively to turn new envelopes toward cold furnace walls if high radiant heat transfer is to be realized. The importance of turbulence therefore is great even if combustion (of CO) is complete without it, and especially where small excess-air ratios tend to cause hazy or smoky conditions in the furnace. But the sprinkler type of stoker has some critical rate of furnace-gas turbulence above which unburned-coal losses become prohibitive. Turbulence in furnace gases would not adversely affect the underfeed or traveling-grate stoker in this respect.

Thus the underfeed and traveling-grate stoker appear to be capable of increasing locomotive efficiency, and therefore capacity, by increasing furnace-absorption efficiency and reducing unburned-coal loss. Stationary-plant experience does not yet extend economical coal-burning capacities to the rates evident from an inspection of the author's Tables 1 to 6. However, as the author has noted, furnace-wall area is not the controlling factor in radiant heat transfer. The controlling factor is the area of the hot body, and even more, its temperature. Thus a larger grate area could with advantage be adopted, sacrificing furnace-wall area as necessary to obtain it, provided the furnace wall could see the fuel bed so installed. This larger grate area would also be helpful in reducing such slight tendency as there would be (slight, that is, compared to unburned losses now accepted in locomotive operation) for fuel to blow off the grate. In this connection, it would be interesting to know whether the higher combustion efficiency shown in Fig. 8 for locomotive NYC-J1B is due to the lower rate of coal combustion per square foot of grate area, which is inferred from the data given in Table 1.

It is suggested that a design for high efficiency and capacity should aim at:

1 Feeding coal in such manner as to throw no fines up into the furnace atmosphere

2 Confining distillation of volatile constituents to a small area of the fuel bed.

3 Maintaining a large incandescent coke area within full view of the furnace walls.

4 Operating at high rates with about 20 per cent excess air, with little or no smoke and a nearly nonluminous flame.

5 High turbulence in the furnace, with furnace designed for smallest practicable volume-area ratio to increase furnace heat absorption if smoky flames cannot be avoided.

Such a design should operate with little or no unburned-coal loss and with very low dry-flue-gas loss. If applied to locomotive PRR-M1A a reduction in fuel consumption of over 30 per cent should be realized. Designed capacity would in that event be realized with a fuel-burning rate of about 80 lb per sq ft of grate area per hr. Reduction to this moderate rate would, as shown by the author's data, considerably reduce engine back pressure, still further increasing efficiency and capacity. These possibilities are undoubtedly known to locomotive designers. The writer would appreciate knowing the principal difficulties which have stood in the way of their realization so far.

The author's paper suggests that there is a great opportunity for the application of rational design methods to locomotive-boiler practice. It is evident that a large amount of data awaits systematic analysis, following which the several combinations of furnace, stoker, and boiler indicated by that analysis as worthy, could be tested at moderate cost to achieve a fine commercial design.

R. EKSERGIAN.[22] Not only has the author given a comprehensive contribution on locomotive-boiler characteristics and limitations, but he has pointed out some pertinent factors which have not been clearly recognized before. One outstanding factor is the tremendous influence of increased gas area through the boiler on evaporation capacity and its tendency to sustain fair efficiencies through a wide range of firing rates. The slope of the boiler efficiency against firing rate is particularly significant as to the maximum evaporation capacity. On the basis of a linear variation of boiler efficiency against firing rate, we must necessarily have a parabolic evaporation curve against firing rate. The maximum evaporation occurs, then, at a firing rate at which the boiler efficiency is just one half the efficiency at zero firing rate. This means that, to obtain high firing rates at maximum evaporation, the slope of the efficiency curve against firing rate must be flat. Pennsylvania Railroad locomotive M1A shows this to a predominant degree and, with this characteristic, we note the corresponding large gas area through the boiler as compared with some other types.

One major feature of the advantage of the steam locomotive over all other types of motive-power units is its considerable overload capacity. Locomotives under normal operation do not perform at firing rates corresponding to their maximum evaporative capacity. The normal rating may either be limited to a definite over-all efficiency or to a firing rate corresponding to some percentage of the firing rate at maximum evaporation. In a well-designed boiler, both aspects are compatible. Mr. Fry[7] assumes the boiler efficiency to vary as a straight line against firing rate and arrives at a parabolic curve for the evaporative capacity against firing rate. This assumption is well borne out in this paper, Figs. 4 and 10. On this basis if F is the over-all boiler efficiency and x the firing rate in pounds of fuel per hour

$$F = m - nx$$

and, if H is the heating value per pound of fuel, the total evaporation is

[22] Consulting Engineer, Edward G. Budd Manufacturing Company, Philadelphia, Pa. Fellow A.S.M.E.

$$E = KFHx = KH\,(mx - nx^2)$$

The maximum evaporation occurs at a firing rate x_m such that $\frac{dE}{dx} = 0$; that is, $m - 2nx = 0$

$$\therefore\ x_m = \frac{m}{2n} \quad \text{and} \quad E_{max} = K\,\frac{Hm^2}{4n}$$

If the normal firing rate is taken at some percentage k of the maximum firing rate x_m, then $x = kx_m = \frac{km}{2n}$ and, since the ratio of normal to maximum firing rate is

$$\frac{E}{E_{max}} = \frac{mx - nx^2}{m^2/4n}$$

$$\therefore\ E = (2 - k)kE_{max}$$

With $k = 0.5$ then $E = 0.75\ E_{max}$. If $k = 0.66$, then $E = 0.89\ E_{max}$. This shows that firing rates exceeding 50 per cent of the firing rate, corresponding to maximum evaporation, rapidly approach the maximum capacity of the boiler.

Another limitation of firing rates is dependent upon maintaining a fair over-all boiler efficiency F. In fact, if we limit this over-all efficiency to F_0, then

$$x_0 = \frac{m - F_0}{n}$$

$$\therefore\ k = 2\left(1 - \frac{F_0}{m}\right)$$

which gives the per cent firing rate relative to that at maximum evaporation corresponding to the limited efficiency F_0.

For example referring to the author's Figs. 4 and 10, the K4S locomotive, which is representative of good average performance and, with a boiler efficiency limited to 65 per cent, the corresponding firing rate is roughly 50 per cent of the maximum. Considering this as a normal firing rate, the maximum evaporative capacity is roughly 33 per cent greater. But with this overload the boiler efficiency rapidly falls.

With Pennsylvania Railroad locomotive M1A, the relatively small slope permits a large overload capacity but at the expense of relatively poor efficiencies at the lower firing rates when compared with the K4S, and similar types.

It would seem, therefore, that boiler proportions which permit higher over-all efficiencies than are found in the M1A, but with less slope of the efficiency-firing-rate curve as with the K4S type, are more desirable, thus giving higher efficiencies at normal firing rates with greater overload evaporative capacity.

It is of interest to note that, in normal locomotive operation, the heat in fuel fired per cubic foot of firebox volume is in the order of 250,000 Btu per hr. In the M1A this reaches over 650,000 Btu per hr at a combustion efficiency of 50 per cent. The Velox boiler attains the latter value at a combustion efficiency around 90 per cent, by means of injecting the combustion air under pressure. The pressure in the firebox is in the order of 30 lb per sq in., effected through a compressor driven by an exhaust-gas turbine. It appears that, in the orthodox locomotive boiler, greater combustion efficiency can be obtained through turbulence of the injection air above the grate as suggested by the author.

In the conclusion to the paper, he cites that it is the engine which deserves the most attention as its thermal efficiency is so low that even a slight improvement is important. This is true from two aspects, engines can work on improved cycles, i.e., with higher pressures and corresponding temperatures, provided throttling losses can be reduced by more efficient cylinder design, and by improved cylinder performance at high speeds.

On the other hand, it is important to point out that, based on the availability of steam supplied to the engine at orthodox boiler pressures, engine efficiencies are remarkably high. The following analysis of cylinder performance with orthodox boiler-pressure and temperature limitations is of interest. The data relate to a 4-6-2 type locomotive with cutoff at 25.5 per cent.

The steam conditions are given in the following table:

Pressure, gage, lb per sq in.	Temp, F	Superheat F	Enthalpy	Entropy
212	748	356	$H_1 = 1395$	$\phi = 1.727$
12	361	117	$H_2 = 1220$	$\phi = 1.782$
	$H_1 - H_2 = 175$		$\phi_1 - \phi_2 = 0.055$	

Steam consumption:

$$\frac{2545}{H_1 - H_2} = 14.5 \text{ lb per hr}$$

Isentropic expansion:

$$\left.\begin{matrix} H_1 = 1395 & H_2' = 1175 \\ \phi_1 = 1.727 & \phi_2' = 1.727 \end{matrix}\right\} \quad H_1 - H_2' = 220$$

Thus, the cylinder efficiency based on the available energy supplied is, $E_c = \frac{175}{220} = 80$ per cent; the cylinder losses amount to 20 per cent of the available energy across the engine. However, these losses have a much smaller ratio, when considering the availability of the power plant as a whole, based on the availability of the combustion gases. The largest loss from an availability aspect occurs in the locomotive boiler itself due to the large differences in flame and gas temperatures and steam temperatures in orthodox locomotives. The largest increase of the unavailable energy components is due to heat transfer. Raising the boiler pressure and thereby the steam temperature to pressures exceeding 600 to 700 lb per sq in. reduces this loss, and results in marked improvement in over-all thermal efficiencies.

Thus, cutting down the unavailable heat-transfer losses in the boiler really amounts to increasing the Rankine efficiency of the engine by operating on a higher pressure-temperature cycle. To accomplish this in any marked degree requires a radical change in boiler design and cylinder design as well, such as including compounding and other features, resulting in a greatly modified type of locomotive.

Another opportunity for increasing the over-all availability is in lowering the back pressures at the entrance to the exhaust. The author has pointed out the significance of this feature in connection with the boiler design.

J. R. JACKSON.[24] The performances of the steam boiler as described by the author are predicated on the evaporation of water into steam and involve the factors of fuel and water. In locomotive practice, the control of the grades of fuel supplied is fairly well in hand on most railroads, but the supply of water, as regards the foaming characteristics, is largely as nature supplies it. While it is common practice to treat locomotive-boiler waters chemically to reduce scale and corrosion within the boilers, no practicable method of treatment for the control of foaming within the boiler is known. So-called antifoam compounds aid somewhat in foam control with certain waters, and it is common practice to control foaming by blowing boilers at terminals and on the line. However, in territory west of the Mississippi River, we experience a seasonal foaming condition of the surface boiler-water supply which constitutes a serious operating problem.

[24] Engineer of Tests, Missouri Pacific Railroad Company, St. Louis, Mo. Mem. A.S.M.E.

It was for the purpose of making some studies of the actual conditions of foaming within a locomotive boiler that the Missouri Pacific Railroad in collaboration with the Electro-Chemical Engineering Corporation undertook a series of tests and observations at St. Louis, in August, 1939. For these tests a locomotive boiler was fitted with bull's-eye sight glasses in the dome cover and the interior of the boiler was illuminated with special 1000-w electric lamps to permit making observations and taking motion pictures of the interior of the boiler within and immediately under the dome. A series of standing locomotive tests with different arrangements of steam driers and foam-controlling devices was carried out. The motion-picture record disclosed the following:

(*a*) The relatively rapid movement of the surface water in the boiler in a forward direction, the rate of movement being more or less proportional to the rate of evaporation.

(*b*) The swelling of the surface water with the opening of the main throttle.

(*c*) The development of a spongy or bubbly condition or state of the surface water accompanied progressively by a decrease in the steam space under the roof sheet at the dome entrance; the increase in the velocity of steam movement from the firebox end of the boiler toward the dome; the picking off of the expanded or frothy surface water at the dome restriction; the actual splashing of the water particles and foam carried by the high-velocity steam against the dry-pipe extension and up into the dome against the dome cover; and finally the actual carry-over of water and foam into the dry pipe.

(*d*) The instantaneous subsidence of the expanded and foamy surface water within the boiler with the closure of the main throttle.

(*e*) The control of foaming and prevention of carry-over through the medium of overflow into a foam-collapsing trough, located within the boiler at the surface of the water immediately under the dome and extending along the center line of the boiler toward the rear, and discharge from the trough through an electromatic blowoff connection to the outside of the boiler.

The standing tests were later supplemented by road tests between St. Louis and Kansas City during which additional motion pictures were taken of the interior of the boiler.

L. B. Jones.[25] As a matter of interest, the writer will review the history of the development of the boiler referred to in the paper as the Pennsylvania M1A, which is shown to have exceptionally high evaporation capacity.

The first of these boilers to be built was not successful, so much water being carried over with the steam that no superheat was obtained. After some experiments, it was found that the performance was considerably improved by lowering the water level, the indications being that, if the steam space could be increased sufficiently, the trouble would be overcome. The boiler was accordingly redesigned, with a lower crown sheet and the dome barrel course raised slightly. The steam space was increased from 150 cu ft to 199 cu ft which, expressed in per cent of the total cubical content of the boiler, amounted to an increase from 16.5 to 21 per cent. The total evaporative heating surface was reduced from 4499 sq ft to 4319 sq ft, and the superheating surface was reduced from 2283 sq ft to 2052 sq ft. In spite of these reductions in surface area, the evaporative capacity of the boiler was increased, and a steam temperature of 730 F was maintained at very high rates of evaporation.

The author's comments on the necessity for liberal fire-tube area are deserving of special attention. It is pointed out that the energy required to move the furnace gases through the flues increases with the fourth power of the weight velocity, which involves the expenditure of power in the shape of cylinder back pressure at the exhaust nozzle. It is also pointed out that a reduction of 1 lb back pressure is equivalent to an increase of 4 lb in steam-chest pressure for average rates of working. When we consider the relatively low value of tube heating surface as compared with firebox heating surface, it becomes evident that the locomotive as a whole can be materially benefited by an attack on the space between the front and back flue sheets, in a way which will provide greatly increased flue-gas area, with a possible accompanying increase in superheat area, without doing any damage because of reduced tube evaporating surface, which is not needed.

We are inclined to take issue with the author on one point, namely, that the gas area can be increased at the expense of water space in the water legs of the firebox. While many boilers are operating with water space as low as 5 in., we believe that boiler-maintenance experience, compared with boilers having more liberal water legs, will eloquently support the wider space, with its accompanying longer stay bolts and reduced angularity of flexure. Important as flue-gas area is conceded to be, it should be obtained in other ways than by sacrificing water space along the sides of the firebox.

In Figs. 6 to 10, inclusive, the author has tabulated some interesting data on boiler and combustion efficiencies. Considerable danger is involved in comparing boiler efficiencies from tests made at different times and places, and with different fuels, especially at the high rates of combustion necessary in a locomotive boiler. This is particularly true of the various Pennsylvania locomotives reported. The test data for all these locomotives were obtained at the locomotive test plant, but the tests were made at different times, using different methods of firing, and somewhat different fuels, with the result that the relative boiler efficiencies plotted in the diagrams do not faithfully reflect the true characteristics of the boilers. We have found that, when it is desired to compare conditions involving boiler efficiency, it is necessary to confine the source of fuel to one mine room or entry, and otherwise safeguard the handling of the fuel from the mine to the locomotive firebox. Two fuels of equivalent Btu content may show widely different boiler efficiencies in the same boiler because of texture and friability, as well as other variables.

W. G. Knight.[26] The author's deductions as to the limitation of existing methods for calculating boiler efficiency are certainly correct. The writer feels that Mr. Fry's formula[7] would no doubt be adequate if more data were available for the value of the constants involved.

We have run standing tests on the Bangor and Aroostook Railroad which would bear out the New York Central contention that front-end design and nozzle size can be tested in this manner and properly adjusted for road service.

The curve in Fig. 2 of the paper is interesting and has special value due to its being drawn from data concerning so many engines. Boiler diameter and gas area, of new power especially, could be more clearly considered after a study of data of this kind.

When considering the distance from the top of the crown sheet to the boiler shell, it is advisable to do everything possible to increase heating surface in order to produce maximum boiler capacity and keep within the weight limitations. However, because of the general tendency of engineers to carry high water rather than low, it is the writer's belief that too high a crown sheet will decrease dryness of the steam, lower the superheat, and otherwise affect lubrication and general performance.

We have found on the Bangor and Aroostook that a ratio of

[25] Engineer Tests, Pennsylvania R.R., Altoona, Pa. Mem. A.S.M.E.

[26] Mechanical Superintendent, Bangor and Aroostook Railroad Company, Derby, Me.

from 5 to 6, firebox volume to grate area, is decidedly advantageous as the road characteristics demand high boiler capacities for freight service. It is also possible with large fireboxes to adjust the arch to decrease the high velocity of gases at point *A* in Fig. 3 and bring them down to a value equal to or below the velocity in the tubes near the back tube sheet.

During the last 5 years, we have tried several designs and a number of different percentages of air openings in grates, our latest experiment being made on an application with 60 per cent free air opening. As yet, we have not definitely proved its advantage since we are still changing the draft appliances and ashpan arrangement to achieve better combustion efficiency. We feel that a gain will result from using this large percentage opening.

Much has been said in the last year or so on the subject of secondary air for combustion. Whether it would aid the older locomotives without considerable change in their design is a question. It would seem at present that equal efficiency can be obtained by an increased grate area and proper changes in draft appliances.

The general trend of all roads recently has been toward much more efficient draft appliances. We have tried to keep pace with the ever-increasing demand for more horsepower by improving front-end design and decreasing back pressure. The improvements made along these lines have produced satisfactory results.

A. I. Lipetz.[27] The locomotive boiler as part of the steam locomotive has the value advantage of automatic self-regulation; in other words, to a certain limit it adjusts its evaporation to the demand of steam. This automatic feature is actuated by the back pressure from the engine. For a given back pressure the amount of steam exhausted by the engine through the nozzle and the draft of the boiler is fixed. A certain proportion of the combustion gases is then pushed through the flues and tubes of the boiler from the firebox into the front smokebox. This evaporates a certain amount of steam, which in turn is exhausted by the engine. Thus the cycle is completed and then repeated. If the speed and cutoff of the engine are varied, in accordance with the demand upon the locomotive, the back pressure and the evaporation are varied—this is the automatic self-regulation feature.

By assuming a certain back pressure and the resulting draft, and figuring the amount of fuel burned in the firebox, it would be possible to calculate the amount of heat which is thus generated. Being familiar with the laws of heat transmission, and depending upon the gas velocities through the various sections as explained by the author, it would be equally possible to evaluate the amount of steam evaporation. For another back pressure and another fire rate, a different amount of steam evaporation would follow; thus the curve of steam evaporation, as a function of coal firing and back pressure, could be established.

It is evident that this way of figuring, although logical in itself, would involve a great many calculations on the basis of laws of natural phenomena, which are not always known. It is therefore simpler and more reliable to establish these curves by tests with locomotive boilers and to plot the curves, as has been done by the author in Figs. 4 and 5 of the paper. Likewise from tests, the combustion efficiencies can be plotted, the boiler and superheater over-all efficiencies can be figured, and, for further study, depending upon the length of tubes, mean hydraulic depth, etc., the heat absorption and various other factors can be established.

The value of this paper consists of giving us concisely a complete series of curves from reliable tests as material for study. The author did not attempt to draw any conclusions except to say that the present locomotive boiler is a very efficient steam generator, when compared to stationary boilers, especially taking into consideration its simplicity and weight.

However, the writer would like to call attention to the possibilities obtainable from a proper review of the author's curves. From the foregoing statement of the automatic regulation of the boiler cycle, it is obvious that, in application to a locomotive boiler with the same principal fundamentals of design, the efficiency and production of the boiler should be more or less uniform, depending upon certain ratios. These can be established from tests. In analyzing Figs. 7, 9, and 10, especially the latter, it is evident that the efficiency curves are straight lines, as is well known from the investigations of Professor Goss and Mr. Fry.[7] Fig. 12 is still more interesting because it narrows the system of straight lines for a great variety of locomotive boilers tested in Altoona and in actual service on different roads. It also brings out the fact that the Pennsylvania M1A locomotive seems to be represented by a line about the average of all others.

This, together with Tables 1 to 6 given in the paper, permits making a comparison of the various ratios tabulated therein. Thus it can be seen that item 31, which is the gas area per square foot of grate, varies for these locomotives and for these locomotives only, between narrow limits of 1.14 and 1.41 (columns 3 and 4 in Table 1; columns 1, 6, and 10 in Table 2; column 10 in Table 4; columns 6, 7, and 9 in Table 5). For the class M1A locomotive it is 1.39. Further, the ratios of firebox heating surface to the total evaporating heating surface (item 40), of the total evaporating heating surface in relation to the grate area (item 42), and of the superheater heating surface in relation to the total evaporating heating surface (item 43), vary also between limits which represent the best results of American practice.

That these ratios are important and essential has been known for a long time by a great many investigators of American and European locomotives.[8,28,29] They are usually included in articles describing new locomotives. This paper provides an opportunity to study these figures and to establish such ratios as we might consider to be essential. Tables 1 to 6 will permit establishing rules at least for the following boiler ratios: The ratio of the gas area through the boiler to the grate area; the firebox heating surface to the total evaporating heating surface; the total evaporating heating surface to the grate area; the superheater heating surface to total evaporating heating surface.

Of course, variations in these ratios are always necessary, depending upon the grade of fuel and local conditions. However, the writer does not believe that the difference in local conditions justifies the great variations in locomotive design which prevail. Certainly, a certain degree of standardization can be introduced for locomotives on American railroads.

T. C. McBride.[30] This paper indicates the inconsistencies in the proportions of existing boilers and demonstrates the need for further tests to establish the best proportions. The Cole method[3] for determining the evaporation to be expected from locomotive boilers, having the evaporation values based only on heating surface, is condemned as inadequate. Nevertheless, it is stated that "today these values are generally used by the locomotive builders and railroads." With no comparable substitute method in sight, an effort should be made to adapt the old and almost universally used method to present conditions.

[27] Chief Consulting Engineer, in charge of Research, American Locomotive Company, Schenectady, N. Y. Fellow A.S.M.E.

[28] "Die Eisenbahntechnik der Gegenwart," by E. Brückmann, Berlin, 1920, Appendix.

[29] "Handbuch des Dampflokomotivbaues," by Prof. Dr. Igel, Berlin, 1923, pp. 73–86.

[30] Consulting Engineer, Railway Division, Worthington Pump & Machinery Corporation, Harrison, N. J. Mem. A.S.M.E.

It is necessary to reach an understanding of the various terms used throughout the paper to indicate capacity, evaporation, etc. Referring to the first table of the paper, the Strahl formula need not be considered because it is not used in this country. The "Cole evaporation" of this table might be defined as Cole's conception of the maximum evaporation which boilers of about the year 1910 could be depended upon to develop when in operation on the road. Dr. Lipetz, in his 1932 paper[5] on locomotive ratios, endorsed such a definition but applied it to boilers built 20 years later. It is generally conceded now that this evaporation presumed by Cole was very high for the boilers of about 1910 and was not realized until some years later with boilers of better proportions; but today that is immaterial if proper coefficients are applied. The "actual test evaporation" of this table is the ultimate evaporation possible of attainment under the favorable conditions of a standing test of short duration, after elaborate preparations had been made. Often a number of attempts have been made in an endeavor to obtain the highest possible figure. These could not be depended upon for road operation. The Cole evaporation should therefore be lower than the actual test evaporation; the fact that it is lower does not indicate inadequacy but rather confirms its adequacy for the purpose for which it was intended.

The Cole evaporation of the Pennsylvania Railroad K4S locomotive is stated in this table to be 52,150 lb per hr. The actual test evaporation of 65,400 lb given in Table 5, column 6 for the K4S of 1914 should be compared to the Cole value. This was only 25 per cent greater than the Cole, certainly not too great a margin for dependable operation on the road, as implied in the definition of Cole evaporation. The much higher actual test evaporation stated in the table for the Pennsylvania Railroad K4S; the actual test for the Pennsylvania Railroad M1A, 46 per cent higher than the Cole; and the actual test for the New York Central J3A, 45 per cent higher than the Cole, all follow developments and improvements which place these boilers in a later class than was contemplated by Cole. They require the application to Cole evaporation values of a coefficient, such as the "evaporation coefficient" β, of Dr. Lipetz' paper.[5]

However, the maximum evaporation of the greatest importance is that now demanded from modern boilers in operation on the road. A fairly accurate estimate of this evaporation may be obtained by using the pumps of the Worthington heaters as water meters. The pump speed, noted when the locomotive is operating at the highest power output likely to be demanded of it, indicates demands for water up to 115 per cent of the Cole evaporation, that is, an evaporation coefficient of 1.15 for coal burners, with a still higher demand for oil burners.

Twenty years ago, injectors having a capacity 75 per cent of the Cole evaporation were quite usual, at least in the eastern part of the United States. At that time, one 75 per cent injector supplied enough water for most of the operation. Coal burners in the West were operated at a higher evaporation, and oil burners at a still higher rate, but even then the latter did not attain the Cole evaporation. The increase in the evaporation coefficient from not much over 0.75 to 1.15 and the higher pressure and temperature of superheated steam are measures of the progress made in 20 years in feedwater heaters, stokers, better proportions of boilers, and front ends.

Returning to the first table of the paper and applying an evaporation coefficient of about 1.15 to the Cole evaporation of the modern or modernized boilers, it is noted that the Cole value, as modernized by the coefficient, takes its proper position in relation to the actual test evaporation of the table.

While only the proportions of the boiler, principally the firebox proportion, had to be considered, it was not difficult to follow the increasing evaporation coefficient and to predict the evaporation to be expected and the amount of water the boiler would require. But, with the appearance of much more efficient front ends, an additional coefficient, presumably a draft coefficient, is needed.

The author rightly urges more tests to aid in the determination of the best proportions for the boilers of locomotives. However, it is possible that much useful information could be obtained from data of tests already available, if curves were to be drawn showing the relation between boiler efficiency and percentage of Cole evaporation. The boiler showing the highest efficiency at the Cole evaporation would then represent the best proportions, at least as a first approximation. Corrections for differences in draft and other items might be necessary. Comparison of the height and slope of the efficiency curves would indicate which boiler proportion gave the highest efficiency at the higher capacities and therefore promised the highest practical capacity; that is the information desired.

Existing conditions are forcing rapid developments in the boilers of locomotives, especially in capacity. Prompt collection and analysis of all available data are urgently needed. In the writer's opinion useful conclusions can be reached in the shortest time by the determination of the coefficients and the methods reviewed in this discussion.

C. L. MEISTER.[21] Railroad mechanical officials know that in these days of faster train speeds their locomotives must have ample steam capacity to take care of, not only the long-sustained runs, but all the auxiliary demands requiring steam; and careful design of the boiler is the first essential.

This paper gives many timely suggestions: Ample combustion space; reduction at the vital points of the gas flow and the necessity of large gas areas; the relation of boiler diameter to total weight; grate area; flue efficiency factor; front-end design; and others.

A copy of this paper should be in the files of every railroad mechanical officer, and studied not only by the chief, but by his draftsmen as well. It should be carefully studied by locomotive builders, who so often are prone to copy and perpetuate older designs with slight improvements here and there, based on road-performance experience in lieu of scientifically conducted tests.

Although the author has correctly stated: "The superheater holds first rank of all the improvements made on the locomotive since George Stephenson's time," he has refrained from going into detail on this phase of the subject. The writer would like to have further information on the following matters:

1 What is the practical limit to superheat temperatures on the present type of reciprocating locomotive, and what effect has superheat as high as 350 to 400 F, as used in Europe, on the economy and maintenance of locomotives?

2 What are the important problems affecting the design and materials of boilers and superheaters in connection with high steam temperatures?

3 On the basis of final economy would the greatest advantage be obtained by the use of higher boiler pressures or higher superheat, or is there a combination of pressures and superheats which would give the best ultimate economy?

4 In Table 5, column 5, relating to the Pennsylvania Railroad class S1 locomotive, it is noted that this engine is equipped with a type "A" superheater having a large steam area as compared with other types. Is this a special type which permits such a great increase in the steam area, and what should be the advantage, if any, of using such a design?

5 The author points out the desirability and effectiveness of type "E" superheater design in modern boilers, and a review of

[21] Mechanical Engineer, Atlantic Coast Line Railroad Company, Wilmington, N. C.

the tables indicates that this type of superheater has generally been applied. It would be interesting to have a concise statement of the principal differences in the various superheater designs and the improvements which can be obtained by the use of the type "E" superheater.

6 Other features on which further enlightenment would be advantageous are the problem of unburned coal, due to large gas velocities, and the location of the stoker. Would not locating the stoker at the front, instead of back, of the firebox be an advantage even if it meant reducing the coal sizes so as to be more easily handled? Would the problem of high gas velocities and resultant losses caused by unburned coal be improved by the use of pulverized coal?

7 In the paper and conclusion, the author refers to the competitive condition of Diesel and electric locomotives. Has a real economic analysis been made of the comparative economics of the modern steam locomotive with that of the Diesel or electric operation, both as to availability, first cost, operating cost, and maintenance?

R. M. OSTERMANN.[32] The author's wide experience in designing superheaters for locomotives, and proportioning them properly for best over-all performance, has perhaps suggested to him that it might be superfluous to discuss the limitations of locomotive-superheater design in a more detailed manner; his discussion on superheaters is brief indeed. And yet, it would seem, since the superheater is such an integral part of the locomotive boiler, and its design is so bound up with the design and performance of the boiler itself, that locomotive designers as well as the users thereof would have been interested in a more thorough exposition of the various factors which not only determine boiler capacity and boiler efficiency, but also the capacity and efficiency of the superheater, the steam pressure loss which it creates, and the added draft requirement which is the result of its installation. The practice of locating the superheater heating surfaces within the flues has evolved from several past trials of other arrangements, and now can be considered a virtual standard wherever steam locomotives are used. The practice has become standard because superheating the steam either in the smokebox or in the firebox was found to be impractical for a number of reasons. Thus, one is confronted with one general limitation of the locomotive superheater in that it is heated by gases, the temperature of which is that available within the locomotive-boiler flues. Such temperatures generally range between 600 and 2000 F.

The author discusses at length the factors which affect the heat absorption of the evaporative heating surfaces of the boiler barrel when in contact with gases of such temperature. These same factors, of course, also influence the superheating capacity because the latter depends upon the mass velocity of the gases flowing over the superheater units, and the temperature difference between the gases and the steam to be superheated, from point to point in the steam path.

There is, however, one essential difference between the mechanics of heat transfer, as between the gases and the water, and as between the gases and steam. The speed of water circulation along the flues does not affect the total heat-transfer resistance on the water side of the flue nearly as much as the speed of the steam moving within the superheater-unit pipes affects the heat transfer between it and the gas. Experiments, covering such heat transfer, are on record and reveal that the specific heat-transfer resistance from the superheater tube to the steam varies inversely with the 0.75 power of the steam velocity. Whenever the velocity of the steam flow is reduced in the presence of an undiminished heating effect of the gases, heat is impounded in the metal of the pipe and its temperature is raised until the adverse effect of the lowered steam velocity upon the heat transfer between the pipe and the steam is compensated by a larger temperature difference between the two. On the other hand, the rise of the metal temperature causes a smaller temperature head between the gas and the metal, and a lessened heat transfer per square foot of superheater heating surface takes place unless compensation is made through a greater mass velocity of the gas flow. This eases up the specific heat transfer from the gas to the metal but, incidentally, also increases the draft loss.

Quite naturally it would be desirable to build superheaters in locomotives which cause as little pressure drop of the steam as possible, for obvious reasons. However, if the physical laws of heat transfer are kept clearly in mind it is recognized that the superheater capacity, the evaporative capacity of the boiler barrel, the draft loss through the boiler barrel, the heat-absorption efficiency, and the pressure loss in the superheater are all interlinked with the size of the available tube-sheet area.

Locomotive superheaters may well be designed for special low pressure drops, but superheating capacity or draft loss or evaporative capacity have to be sacrificed, and such sacrifices may affect the maximum power output of the locomotive more than the pressure drop through the superheater, which, after all, is not a thermal loss. This emphasizes the author's statement that reduction of back pressure is relatively far more essential than a reduction of superheater pressure drop, pound for pound. Resort may be had to the so-called single-loop superheater which halves the steam velocity, and the tubes may be made of special alloy steel so as to operate them safely enough with the resulting higher metal temperature. However, this would result in a lowered superheating capacity. The steam velocity and pressure drop may also be reduced by increasing the diameter of the superheater-unit pipes but, in that event, either evaporative heating surface must be sacrificed or the net gas area through the boiler reduced. Such limitations do not exist in other types of boilers in which the superheater may be placed at will into the gas stream where it is of a higher temperature than the one prevailing in the flues of a locomotive boiler, and, therefore, where the length of the steam path can be correspondingly shortened. At such a point in the gas path, it may also be possible to dimension the net gas area more liberally and without creating any undue draft loss. In such boilers, low-pressure-drop superheaters can then be more easily provided for than in locomotive boilers.

The superheater research to which the author refers, actually produced several types of superheater units usable with $5^1/_2$-in. flues, which are fundamentally different from the well-known double-loop unit, and which, by reason of this difference, are capable of producing, with the maximum gas load through the flue, a superheating effect which is about 20 per cent greater than with the double-loop design of unit. Unfortunately, however, this type of unit is sufficiently more complex in its structure and sufficiently heavier than the double-loop unit as to make it relatively impractical for the highest boiler pressures which are now used on steam locomotives. It is, nevertheless, interesting to mention briefly that the substantially increased heat transfer to the superheater heating surface of the unit mentioned was only partially obtained at the expense of the evaporating capacity of the flue. In other words, in spite of an increased heat transfer to the superheater heating surface, the total heat absorption of the flue-unit combination could be improved; the draft loss was no greater than it had been through the flue with the double-loop unit. This rather gratifying result was obtained by utilizing counterflow between the steam and the gases to a greater extent than is possible with the double-loop-unit construction, and also by special means designed to prevent the temperature of the gases in contact with the superheater heating surface from dropping as

[32] Vice-President, The Superheater Company, Chicago, Ill. Mem. A.S.M.E.

much as the temperature of the gases in touch with the water-cooled surface of the flue.

With respect to the draft loss through the barrel of the boiler, it should be remembered that it is only a part of the total draft loss through the furnace and boiler as a whole. Thus it must be decided from case to case how much justification there is to decrease the hydraulic depth of the boiler barrel as a whole without running the risk of overloading the draft-making front-end arrangement, and thereby unduly increasing the back pressure of the locomotive. Due to the interaction of the superheater proportions with those of the front end, of the boiler barrel, and of the furnace arrangement—not to speak of differences in fuel—it is impossible to expect that a given standard of superheater design perform in exactly the same manner in locomotives with a wide variety of boiler proportions and operating conditions. Yet, in the interests of maintenance, it is imperative that certain standards of superheater design be adhered to, and it is this phase of the author's subject which the writer particularly wished to bring out.

N. A. Pownall.[33] There is no doubt but that present formulas are inadequate for determining the probable maximum power of a modern locomotive. This is particularly true since the advent of such capacity- and efficiency-increasing appliances as the superheater, feedwater heater, siphon, etc., as well as the effects of variations in exhaust-tip size, stack diameter, front-end appliances, air openings through grates, and various features of boiler design mentioned in the paper. It will be of considerable value if a formula can be developed which will make it possible with fair accuracy to predict the power of a certain design of boiler. It is to be hoped that, by means of the increasingly used standing-test method, such a formula may ultimately be developed, at the same time establishing the best method of boiler design as regards furnace volume, lower gas velocity, greater steam space, etc., as discussed by the author. Research work of this nature will be necessary, for there are certain changes, which are even now being made, that thus far have produced unpredictable effects. For example, opening up the exhaust tip is desirable from the standpoint of reducing energy wasted in back pressure and yet, if this is carried too far, though the engine may still steam well, temperatures may have been lowered so as to affect adversely the superheat, with a resulting negative economy. Any drop in temperature of the superheated steam is attended by a positive rise in fuel consumption.

The steam space above the water level is certainly important. Treated water is now considered a necessity for locomotive boilers, and any antiscale treatment will necessarily increase the foaming tendency of the water, resulting in a greater volume of water bubbles in the steam space, which, because of space limitation, is relatively small for the tremendous steam-producing rate of a modern locomotive. Careful study of the boiler design, in order to increase steam-liberating surface and, by gaining a little here and a little there, to increase steam space above normal water level, will be of considerable value in reducing water carry-over. It is noted that experiments are now under way with a trough or box directly under the dome which increases the steam space at the main-throttle location and offers promise of some relief.

It is astounding to learn that the velocity of gases through the back of flues exceeds 200 mph, and over the arch 260 mph. Therefore, it is not difficult to realize why losses in unburned fuel and stack losses are so high, why stay-bolt heads are cut by cinders, and why there is excessive slagging of flue sheets when the boiler is worked at high rates. As a result, ample gas area is very important, though here again space limitation interferes. Advantage must be taken of small gains here and there; such as, decreasing the space between the combustion chamber and the boiler shell. If water is kept fully treated, and the boiler systematically blown out in service and given thorough washings, this decrease may be made with no bad results.

The cost of boiler maintenance is stated to be 30 per cent of the total cost of locomotive repairs. This is too high. Years ago, the writer had occasion to keep records of the repair costs, divided between the boiler and items not pertaining to the boiler, and found the percentage of boiler repairs to vary from 9 per cent on the best treated water division to 38 per cent on the worst untreated water division. With proper water treatment (and it is prehistoric for any railroad to be without it), this percentage should be kept below 15.

As the author states, at the high combustion rates it is quite important to have maximum possible firebox heating surface and furnace volume, thus reducing the loss of sensible heat up the stack by reducing front-end temperatures; a 210 deg decrease in front-end temperature causes a 7 per cent fuel saving. However, this must not be carried to the point of causing reduction in the temperature of superheat.

Few people realize the high horsepower obtained from this boiler plant on wheels, many 4-8-2 and 4-8-4 type locomotives being capable of developing from 4000 to 5000 hp. We must also pay a tribute to the feedwater heater which heats the water for this 5000 hp up to 210 or 220 F with apparatus of a size that can hardly be seen on the locomotive. Yet under the restricted conditions, we are still striving by intelligent and seemingly insignificant changes in design to develop this high power at even greater efficiency.

Unfortunately trains have to run light, and the engine and boiler do not perform as well as under a heavier loading. The locomotive must be so designed as to operate reliably under all conditions occurring on the territory to which it is assigned. It is preferable and desirable to have a locomotive of general utility but, in view of the many factors entering into the economical development of maximum power, it may be advisable, where it can be done, to adapt design to specific operating conditions.

Our experience bears out the author's remarks concerning front-end design and draft. In this connection, it may be of interest to describe some changes that were made on 4-8-2 class freight locomotives. These engines have 27 × 32-in. cylinders, 245 lb per sq in. boiler pressure, 70-in. drivers, 69,400 lb tractive power, total heating surface 4620 sq ft, grate area 84.2 sq ft, and are equipped with type "E" superheaters, firebox siphons, and feedwater heaters. According to Cole's ratios, their normal expected horsepower was 3214. When received, they developed 3650 ihp, illustrating the inadequacy of this formula for ordinary modern design.

The grates were a finger-bar type with 43 per cent air opening, master mechanic's front end with $6^1/_2$-in-diam round tip, and 19-in-diam stack, and these were changed to 14.9 per cent air opening tuyère-type grates, a Kiesel front end with six-opening 53-in. star-shaped tip, and a $25^1/_2$-in-diam stack. Combustion was better, excess air was considerably reduced which entails a fuel saving, back pressure was reduced, draft was noticeably improved by reason of less impedance to flow of gas in the front end, and the larger stack evidently contributed considerably to greater power. The locomotive developed consistently over 4900 ihp, which confirms the author's feeling that a new formula is needed to measure the power of modern locomotives and the effect of changes in the important parts of the boiler.

We have built locomotives, making use (possibly inadvertently) of correct principles which have resulted in unexpectedly high power; yet now and then we overlook some unrecognized, important feature and are disappointed in the result.

[33] Assistant to Superintendent of Motive Power, Wabash Railway Company, Decatur, Ill.

Mr. Brandt's paper is very comprehensive, should give designers plenty of food for thought, and the writer feels that in the foregoing he has added little, but has tried to confirm Mr. Brandt's reasoning and conclusions.

F. P. Roesch.[34] The writer prefers to leave questions of locomotive design and construction details to those better qualified, and confine his comments to accessories which are not considered as a part of the boiler proper but, nevertheless, have a material effect upon both boiler and locomotive performance.

The Ashpan. During Federal Administration of railroads, a committee from Section 3, Mechanical, American Railway Association (A.R.A.), among other suggestions tending toward fuel economy, reported[35] as follows:

"Many of the older engines are still equipped with ashpans having insufficient air openings, a defect readily detected with a U-tube draft gage. There should be no indication of vacuum in the ashpan. Correction of this condition recently permitted an increase of $^1/_2$ in. in the nozzle diam of several locomotives and not only effected a substantial saving in fuel, but greatly increased the efficiency of the locomotives."

Prior to that time, tests indicated the desirability of free air openings into the ashpan, having a combined clear opening of not less than 14 per cent of the total grate area. This was based on the total air openings through the grates and its relation to total tube area. But apparently these recommendations, as well as those of the American Railway Association committee have either been forgotten or are disregarded for items of presumably greater importance.

Perhaps it may be well to check into the matter to decide the point. A definite amount of air is always required in the combustion of various kinds of coal, as pointed out by the author. Where the area of the supply ports for such air is restricted below requirements, the velocity of supply must be increased. To obtain this velocity we must increase the intensity of the draft. This is usually done by reducing the area of the exhaust-nozzle opening, thereby increasing the cylinder back pressure, so when the cycle is completed, we find that what should be free air has been obtained at the expense of cylinder horsepower.

At this point the writer wishes to make it clear that we are not speaking of test-plant methods in this discussion, but of conditions and methods obtaining in general road service, where a reported engine failure through any cause is a serious matter and any course is often thought justified which will eliminate such reports. At any rate, an engine failure is something real that everybody hears about, while decreased locomotive efficiency is only revealed by the indicator.

However, decreased locomotive efficiency is not the only evil resulting from a restricted air supply. On the contrary, many others such as decreased combustion efficiency, increased stack loss, cinder cutting, etc., all follow in its wake, as will be shown later.

Locomotive Grates. During Federal control a Fuel Conservation Department was organized. One of its aims was to check and reduce waste. In connection with that job, it was noticed when the fire was laid preparatory to firing up a locomotive, that from 500 to 2000 lb of the smaller-sized coals fell through the openings in the grates into the pit over which the locomotive stood. As such coal was afterward covered with ashes falling through the same grate openings, recovery of the unburned coal presented some difficulty and, therefore, was seldom salvaged. To overcome this waste, it was recommended that the grates be covered with perforated sheets of heavy paper before the coal was introduced. This fuel loss received wide publicity. Therefore, when the railroads were returned to corporate operation, many of them applied the logical remedy, where conditions warranted, namely, better-fitted grates with smaller openings.

But little is known of the physicomechanical reactions or behavior of the fuel bed in a locomotive firebox at relatively high rates of combustion. So little in fact, that many of our theories as to what takes place are based on such an insecure foundation that conclusions reached are questionable. The chemical reactions are known and serve as a guide toward improving the combustion of such coal as is actually burned, but this is not what we are concerned about at present. What we need is more definite information covering stack loss, draft currents, both as to direction and velocity, between the fuel bed and the underside of the arch, etc., conditions which can only be observed through small openings cut through the sides, or larger openings in the backhead, covered with some transparent substance. We recommend the latter, as the range of vision through the sides is too limited, although their addition to backhead windows will be helpful.

It has been the writer's privilege to observe some of the physicomechanical behavior of the fuel bed through side holes during tests on a test plant, and later through a large covered opening through the backhead. In the latter case, however, the locomotive was equipped with forced draft. Nevertheless, the behavior of the fire in both instances was quite similar, at least enough so to enable us to set up certain theories, which later practice proved to be sound.

These observations indicated that, while the gases moved in the direction as generally pictured, viz., from front to rear, their velocity above the surface of the fire bed was relatively low until they reached a zone immediately under the rear end of the arch. Here the movement of the particles of coal entrained in the gas currents indicated a point of excessive turbulence and high upward velocity, Fig. 3 of the paper.

This was quite interesting, but the most interesting phenomenon was the behavior of the small lumps of coal lifted above the fire bed by the action of the air jets passing upward through the fire. It was particularly noticeable that in many instances one lump of coal was projected high and far enough to enter the zone of high turbulence, where it disappeared, while another lump of apparently the same size and rising from the fuel bed within 6 or 8 in. from the first one, was only lifted about 1 ft or so and then fell back and was burned. As both were presumably subject to the same pressure or velocity influence, the question excited much interest. Further observations indicated that the same phenomenon occurred at other points. In fact, the fuel bed had the appearance of a group of miniature volcanoes spouting fire and ashes, some far up and others only high enough to overflow the rim.

After the fires were dumped, the reason for all this became clear, viz., difference in size of air openings through the grates. On this observation was based the theory that the lifting action of air jets passing upward through the fire bed was in proportion to the squares of their areas. This theory has been proved and the foregoing observations are largely responsible for the present general use of what are called restricted grates. In these it is not so much a question of the ratio of air openings to total grate area, as a question of the size of the openings, their spacing, and the fit of the bars against each other and against the side and center carrier bars. We do feel, however, that the total air openings need not be much in excess of the total tube area. Or to put it another way, knowing how much air is required to burn 1 lb of coal, air openings can be proportioned accordingly, thus mechani-

[34] Vice-President, The Standard Stoker Company, Chicago, Ill. Mem. A.S.M.E.

[35] "Ash Pans," Report of Committee on Fuel Economy, Proceedings, Section 3, Mechanical, American Railway Association, 1919, p. 481.

cally restricting the supply needed, instead of leaving the matter to the judgment, or lack of judgment, on the part of the fireman.

Needless to say, the general adoption of restricted grates was hailed by locomotive-stoker manufacturers, as it fully supported their contention that stack loss was not a question of coal size as fired, but rather one of air openings through grates and draft influence. Furthermore, stack loss far antedated mechanical stokers and, according to a University of Illinois bulletin,[36] lump coal breaks down during the process of combustion (naturally) and thus accounts for the excess in cinders collected above the amount of fines in the coal as fired. As a matter of fact, a higher heat release is obtained from small-sized coal as fired, other conditions being right, than from lump coal which must be broken down during its combustion.[36]

Draft Streams. In a preceding paragraph, the statement was made that the velocity of the gas streams, moving from the forward part of the firebox to the rear, was relatively slow. In support of this statement, we offer the fact that while the locomotive is in operation it requires a greater distributor-jet pressure to blow a lump of coal from the front of the firebox and presumably with the draft, than it does to blow an equal lump from the rear to the front, and again presumably against the draft. This fact came to light only recently with the introduction of the so-called front-delivery stoker as developed by the Baltimore & Ohio Railroad. However, an approach to the problem with an open mind and no fixed convictions as to what really happens in a locomotive firebox when coal is being burned at relatively high rates, enables one to arrive at a logical solution, namely, the momentum imparted to any mass, in this instance a lump of coal, is proportionate to the velocity or force of the steam jet impinging against it. This should hold true regardless of whether the mass is projected from the rear to the front or from the front to the rear of the firebox. The velocity of the jet is as the pressure. Therefore, it follows, if higher jet pressures are required to blow the coal rearwardly and presumably with the draft stream, it must be subject to other resistance than that of gravity.

This we find the author has clearly indicated in Fig. 3 and subsequent analysis. Reasoning along these indicated lines, we draw the conclusion that the initial momentum is gradually reduced and, when the mass reaches the zone of greatest turbulence and high velocity, it no longer has sufficient momentum to carry it through that zone unless the initial velocity is increased through higher jet pressures. On the other hand, where the coal is introduced at the rear of the firebox and blown forward, the introduction takes place within the high-velocity zone, therefore the mass even at a lower initial velocity still has sufficient momentum to carry it through this zone and deliver it to the forward part of the fire bed.

This theory if accepted, raises another interesting problem. Tests on the Baltimore & Ohio Railroad have definitely shown the advantage of the front-delivery stoker; for instance, a 50 per cent decrease in stack loss, 15.9 per cent reduction in fuel per 1000 gross-ton-miles, and 15.5 per cent increased evaporation per lb of coal, together with the practical elimination of smoke. There is no question as to the correctness of the published data, as the reason for this improved performance is self-evident. However, as the comparisons were made between the front-delivery stoker, which delivers the coal at a point about 14 in. above the normal grate level, and one effecting delivery at a much higher level, there is the possibility that the same performance differences may not obtain where the coal is introduced with a rear-delivery stoker, firing from a level corresponding to that of the front-delivery stoker, for the following reasons:

The statement has been made that the lifting action of the air jets passing upward through the fire bed was as the square of their areas, the velocity remaining the same. In the following, it must be understood that the figures are not at all accurate since, owing to the resistance and varying thicknesses of the fuel bed, accuracy is out of the question, but the comparisons can nevertheless be accepted as valid.

Assuming the author's data as given in Fig. 3 to be based on a grate having an area of 100 sq ft, we find from established tests that an approximate draft equal to $2^1/_2$ in. of water is required to burn coal at the rate of 90 lb per sq ft of grate per hr,[37] and this, neglecting fuel-bed resistance, results in a velocity efflux of 103.30 ft per sec.[38] In contrast, at the higher rates, viz., 236 lb per sq ft of grate, we must have a draft equal to 4 in.,[37] with a corresponding velocity of approximately 130.43 ft per sec.[38] However, in the first instance, due to the expansion of gases, the velocity is increased to 198 ft, and in the second to 386 ft where the gas stream passes over the arch.[8] Therefore, where the fuel is introduced at the lower levels, a lesser amount is caught up by the higher-velocity streams.

Since the velocity of the gas stream, where it passes over the arch, is proportionate to the volume to be moved and the area of the opening between the top of the arch and the crown sheet, it would appear that any increase in this area would decrease correspondingly the velocity at that point. This brings us to a consideration of the setting of the arch.

The Brick Arch. The value of the brick arch is well known and requires no further discussion. Recommended practice[39] suggests a gas area over the arch equal to from 110 to 120 per cent of the minimum net tube and flue area. This is to increase the length of flame travel and reduce the stack loss. However, according to the author, this results in a gas velocity at that point of 198 ft per sec at low rates, and 386 ft at high rates of combustion, while the corresponding velocity through the tubes and flues is 157 and 300 ft per sec, respectively.

The writer believes in a long arch but, as has been shown, the entrainment of the smaller particles of coal is influenced by the velocity of the gas streams. Theoretically, any reduction in such velocity should in turn affect entrainment and, while theory does not always check with practice, it does appear reasonable to assume that some modification in arch application which would tend to equalize gas velocities might be worth our consideration. As a suggestion based on tests conducted by the writer, we propose, beginning at the rear, longitudinal rectangular openings between the arch and both side sheets about 4 in. wide and 36 in. long, leaving the center of the arch to the recommended length. With such an arrangement much of the fines entrained in the gas streams would come directly in contact with the water-cooled firebox sheets, cooling such particles and preventing their adherence to the tube sheet in the form of honeycomb.

We feel this discussion would not be complete without further reference to the mechanical locomotive stoker, as it is only through mechanical firing that the full rating of modern locomotive boilers can be obtained. This being the case, would it not be well when designing such boilers, to give consideration to stoker requirements as to ready and appropriate application?

[36] "Comparative Tests of Six Sizes of Illinois Coal in a Mikado Locomotive," by E. C. Schmidt, J. M. Snodgrass, and O. S. Beyer, Jr., University of Illinois Engineering Experiment Station, Bulletin No. 101, Sept., 1917.

[38] "Mechanical Draft," by W. B. Snow, B. F. Sturtevant Company, Boston, Mass., 1910.

[39] Report of Committee on Locomotive Construction, Proceedings, American Association of Railroads, 1936, pp. 277–436.

We refer particularly to the type and design as developed by the Baltimore & Ohio Railroad, a type which may tend to revolutionize mechanical firing. This design and its prototype which, however, fires from the rear are the only mechanical stokers satisfying the requirements as to secondary air as discussed by the author under "secondary air for combustion."

No doubt this has escaped general notice, but an examination of either type will reveal this fact. While the method used is more in the nature of a heat exchanger, yet it does supply preheated "top air" and always in direct proportion to combustion requirements. Gas analyses verify this statement. The apparatus simply consists of a vertical grate surrounding that part of the stoker-delivery member extending upward through the locomotive grates.

These vertical grates, termed "protecting grates," extend above the fuel bed and absorb heat from it. This heat is in turn absorbed by the free air contacting the inner surfaces, and is in turn drawn into the firebox and over the fuel bed by the draft through $^1/_2$-in. holes drilled radially and spaced so as to give perfect diffusion. The number of drilled holes is always proportional to the total grate area and to the volume of air supplied through the fuel bed, thereby maintaining a fairly even balance. There can be no question but that this supplementary air so admitted contributes materially to the splendid results obtained on the Baltimore & Ohio as reflected in the boiler and fuel performance.

We have so little factual knowledge of what actually transpires in a locomotive firebox at moderate or high rates of combustion, that, in view of the importance of the subject, it would appear that almost any expenditure for tests would be warranted. Such tests, however, should be made on a plant where road conditions could be simulated. While tests[38] conducted by the University of Illinois indicated no material difference as between constant-flow and pulsating draft, many engineers feel that these are inconclusive, hence the suggestion to simulate road conditions. So unless tests are made, and such tests duplicate as far as possible actual road conditions, we will still find ourselves where we started.

To show to what extent the modern locomotive boiler depends upon the mechanical stoker, we might refer to the large simple "Mallets" built for the Northern Pacific some few years ago. These locomotives burn a subbituminous coal and therefore require a relatively large grate. The proportions as to grate area desired and steam output of the boiler were worked out by the engineering department of the Northern Pacific in collaboration with the locomotive builder. The latter, however, would not agree to conform to the dimensions requested (referring to grate area) until the stoker company agreed to build a stoker with sufficient capacity to meet maximum requirements, and would guarantee to distribute the amount of coal fired evenly over the grate. The maximum requirements were estimated at 45,000 lb of coal per hr. While this rate has never been required, nevertheless there are times when a rate of 30,000 lb of coal per hr is actually reached. The firebox first laid down was 20 ft long and $9^1/_2$ ft wide, or a grate of 190 sq ft. This was later reduced to about 184 sq ft. Needless to say, the requirements were met by the stoker company, otherwise the locomotives would never have been built.

L. A. SHIPMAN.[40] In comparing steam-boiler performance on an efficiency basis, we have two vital factors to consider (1) water and (2) coal.

In the case of locomotive M1A tested by the Pennsylvania Railroad, referred to in the paper, wherein burning rates of 345 lb of coal per sq ft of grate area per hr were obtained, one of the main fuel problems, as indicated by the 50 per cent stack waste, was keeping the fuel on the grate until it was burned. This problem can be solved at least partially by fuel selection and sizing.

In connection with the matter of water circulation and foaming, the importance of the water conditions as they affect the efficiencies of the different tests should receive special attention.

While it has been mentioned that forced circulation of water was used in the Steamotive tests, the fact that practically distilled water was used in both Steamotive tests and in the Navy test, as against the regular water-tank water as used in the New York Central and Pennsylvania Railroad tests, was not mentioned. While this fact certainly affects the efficiencies of the test, it also singles out those who have developed the equipment and its methods of operation so that distilled water is economically possible for special distinction.

Because of the fact that there was a difference in the water, in the water circulation, natural against forced, and in the fact that there was a difference in the percentages of the total fuel consumed because of the high stack loss of the conventional locomotive at high burning rates, the performances are not on an equivalent basis for comparison although the facts presented definitely point out the tremendous improvements possible in fuel economies for which those contributing to the new designs should be highly complimented.

L. K. SILLCOX.[41] The locomotive boiler and its operation can scarcely be discussed without referring to the fact that only a limited number of test data are available. The author is fortunate in having access to new information which heretofore has not been reported. Nevertheless he still is compelled to call attention to the need for vastly more information which can only be derived through further boiler research.

No entirely satisfactory method of defining locomotive capacity has yet been derived which will establish its capacity as limited by the features of furnace, boiler, engines, and rail, acting individually. Boiler calculations are the least exact of all the elements involved, although the investigations of Cole, Fry, Strahl, and others have all contributed in important measure to our total knowledge of the subject.

The author presents a table which shows the failure of Strahl and Cole to estimate the actual evaporative capacity of three locomotive types. In the case of the Pennsylvania Railroad class M1A, Strahl estimates capacity at 54 per cent of test values, Cole at 68 per cent. Perhaps, in justice to Strahl and Cole, it should be pointed out that, when evaporating 99,095 lb of water per hr, the locomotive was fired at the rate of 337 lb of coal per hr per sq ft of grate. No such overload is contemplated in the application of the formulas. At this high coal rate, an efficiency of boiler and furnace of but 37.5 per cent was obtained. Yet the absorption efficiency of the boiler was over 80 per cent. This is illustrative of the mass of operating details which must be explained in every case if test conclusions are to bear all their possible significance.

It has been remarked that, even with the stated excessive and uneconomical firing rate, absorption efficiency did not suffer greatly. This would indicate that high gas velocities may not always be objectionable, in so far as boiler performance is concerned. In fact, whereas a gas velocity of 204 mph in the tubes is quoted as very high, velocities of 445 mph are sought in the Velox steam generator, and blowers are introduced to attain this end. There is a vast difference in function and design, of course, but the Velox generator, one of which is now installed in a loco-

[41] Vice-President, The New York Air Brake Company, Watertown, N. Y. Mem. A.S.M.E.

motive of the Paris, Lyons and Mediterranée Railway in France, occupies much less space and represents much less weight than a conventional locomotive boiler of the same capacity. While we are continuing improvements in the conventional firetube locomotive boiler, which no doubt will remain the standard type for general service for many years to come, we cannot afford to confine our attention to this construction to the extent that we are blind to possibilities originating in other fields. Concentration of more boiler capacity within less space and providing this with considerably reduced weight, offers attractive possibilities for investigation by locomotive builders, with available fuel types ever in mind.

It is the limitations imposed by compliance with familiar and proved proportioning of locomotive parts and strict adherence to conventional practices that renders difficult the fitting of required power into the loading restrictions and clearance limits of American railways and calls for a firing rate such as that proposed by the A.A.R. committee appointed to investigate the requirements in a locomotive capable of hauling 1000-ton trains at 100 mph, namely, 152 lb of coal per sq ft of grate per hr under normal conditions. Combustion efficiency would be higher if the unit firing rate were lower, yet weight limitations govern the permissible size of grate which may be practicably employed; approximately 128 sq ft in this case.

The coal-fired steam-locomotive boiler has advanced rapidly and far. It compares phenomenally with central-station boilers in capacity per unit of weight. Present railway-operating practices have taxed its capacity in all practicable sizes yet the demands are unchecked. Perhaps we must search out new approaches to an old problem, replacing well-thumbed pages of past operating manuals and removing the inherent difficulties which have retarded progress in the use of such promising expedients as pulverized coal and the water-tube boiler.

L. W. Wallace.[42] At the outset of this paper, a statement is made to the effect that the public is continually demanding higher speeds for both freight and passenger trains. It may be that such an apparent demand is being taken too literally. Is it higher speed, in terms of miles per hour, that the public wants or is it a reduction in the total elapsed time required to travel between two points? There is a real and significant difference between speed in miles per hour and total elapsed time. The total elapsed time experienced on many runs may be reduced materially without increasing significantly the sustained speed in miles per hour for any major portion of the run. This may be done by reducing the waiting time at stations and elsewhere through more expeditious servicing and handling of trains. It is the waiting period at terminals and elsewhere which causes the largest amount of restlessness and complaint on the part of the traveling public. It would appear that this phase of train operations has not been given the analytical attention which its importance warrants.

The difference between high speeds in miles per hour and a reduction in total elapsed time between two points, realized through more expeditious train servicing and handling, may make a major difference in locomotive design, its first cost, and the cost of maintenance and operation. What this may mean is reflected by the comparison of the 2-8-0 and 6-8-6 locomotive types. This comparison discloses that the weight of the locomotive had to be doubled in order to obtain sufficient boiler capacity. All of which raises the question, "What price is paid for high speeds in miles per hour as contrasted with the price which may be paid for a reduction in total elapsed time?"

The comparison of the locomotives referred to adds emphasis to this significant statement made by the author, ". . . the important question is whether greater boiler efficiency is attainable, particularly at high-capacity operation, and what can be done to accomplish this."

The following pertinent comment also appears in the paper: "The subject matter will be centered on problems affecting the design of the conventional locomotive fire-tube boiler only, not because of any belief that this type of boiler is the final answer to the locomotive steam generator. . . ."

The writer was delighted that the author disavowed any belief that the typical locomotive boiler is the final answer. In my judgment it is not. It may well be that if a broadly conceived and executed line of creative research were undertaken, the final result would be some form of boiler closely akin to the flash type. It seems evident that something different from the present typical locomotive boiler must come, as it is not sound economics to double the weight of a locomotive in order to obtain adequate steam capacity.

Again to quote: "However, much remains to be done to make possible the burning of more fuel per hour at higher combustion efficiency with lower draft loss, greater heat-absorption efficiency, and higher superheat with less boiler weight per pound of steam produced." This is a farseeing, correct, and timely statement of the problem confronting the railroad industry. It is fairly obvious that one approach to relieving the present situation is to supply the steam required for auxiliaries, train heating, air conditioning, and for other purposes through a steam-generating unit other than the locomotive boiler. However, this alone will not give the final answer.

The author states: "The method of standing blowdown tests developed and used by the New York Central Railroad in recent years has proved very effective." This is undoubtedly true. Moreover, it is the writer's thought that considerable valuable work in certain directions can be accomplished by the use of scale models. This means the application of the law of similitude which has been so successfully used in connection with research programs covering a wide range of difficult technical problems. There is no apparent reason why the method cannot be applied successfully to the solution of many railroad problems. The method has the advantage of affording a more definite control of test conditions than for full-scale operations and, furthermore, a material reduction in cost of experimental work may be realized.

The locomotive boiler presents a difficult problem. A comprehensive approach to its solution has been too long delayed. The solution lies in the direction of broadly conceived lines of research coupled with a daring and courageous attitude.

Author's Closure

It is an honor for the author to have the privilege of replying to the many valuable contributions made to his paper, "The Locomotive Boiler."

The interest that this subject has aroused among those responsible for the design and operation of steam locomotives testifies to the importance of further improvements to the coal-burning steam locomotive.

Since the preparation of this paper the European war has started, reminding us that the development of the steam locomotive must not be neglected, and it is pertinent that this subject be again emphasized.

It is often heard today that the railroads, and particularly the coal-burning steam locomotive, are out of date, and will be replaced by airplanes and oil-driven power units on railroads and highways.

Such opinion, if shared by responsible men in government and business, may have a paralyzing effect upon efforts to improve the steam locomotive. Those who are able to see beyond the

[42] Director, Division of Engineering and Research, Crane Company, Chicago, Ill. Mem. A.S.M.E.

present phase in the development of transportation, and are devoting efforts and thought to the perfection of the coal-burning steam locomotive should be encouraged in their efforts.

The struggle now raging in Europe is being fought on land, air, and water with engines of war driven by gasoline and oil power, and one of the major problems of this war is the control of adequate supply of petroleum.

That the world's supply of oil is definitely limited is believed to be true by many eminent authorities. A late estimate of the available oil supply in continental United States, prepared by the Committee on Petroleum Reserve, of the American Petroleum Institute, gives the total available supply as 17,348,146,000 barrels in 1939. The annual production in 1938 was 1,213,186,000 barrels per year which would indicate that our petroleum supply in the United States may approach exhaustion in fourteen years.

That this definitely limited supply of petroleum, absolutely necessary for operation of naval vessels, airplanes, tanks, and trucks, will have to be conserved for our national defense in the future appears reasonable.

The use of oil for the production of power, in places where coal, abundantly available, can be utilized to good advantage, appears unwise from the viewpoint of future national welfare.

The coal-burning steam locomotive has hauled the bulk of the country's traffic in the past. Its gradual replacement now taking place, at a rapidly accelerating pace, with oil-using Diesel locomotives and gasoline power units on highways and in the air, may find this country only a few years hence in a position of having a transportation machine that has cost billions of dollars, but without suitable, or too costly fuel to drive it.

A review of the many discussions reveals a general agreement with the author's thesis, that there is room for improvement and necessity for coordination and clarification of principles with further research and tests.

The opportunity to present a paper on the same occasion as Mr. Bailey is an honor that is very much appreciated by the author. Mr. Bailey's paper on steam-boiler performance[16] is of great fundamental value, and the discussion that he presented on the subject of locomotive boilers is an expression of his theory on "methods of comparison of boiler performance." His discussion, read in conjunction with his own paper just referred to, is so very complete that there is little that can be added for further clarification.

The author in his paper referred to a new type of locomotive boiler soon to be tried out. The boiler referred to is that illustrated and analyzed by Mr. Bailey in his discussion. The results obtained with this boiler, as to efficiency, capacity, and weight, may point the way to further developments on coal-burning steam locomotives.

The author regrets his inability to supply more detailed information on the oil-fired tests of the Southern Pacific, as requested, as these data are not obtainable.

Mr. Bailey suggests that the author supply additional data on the subject of draft loss through various portions of locomotive boilers under different ratings so that the relationship between output and efficiency versus draft loss could be analyzed. It is regretted that sufficient data are not available at the present time to furnish this information.

Mr. Duncan's discussion reveals his interest and insight into the problems under consideration, and deserves a more detailed answer than space will permit at this time. He suggests that if an underfeed or traveling stoker could be adapted to locomotive service a great improvement would result in furnace efficiency. It may be noted here that several designs of both of these types of stokers have been made.

The Crawford underfeed mechanical stoker was built and tested out quite extensively on the Pennsylvania Railroad in 1913 and 1914, and many engines were so equipped. It is believed that there are no underfeed stokers on locomotives now in service. The author has no knowledge of any traveling-grate stokers actually tested, although at least one design was made.

During some thirty years of experiments with different types of stokers the sprinkler type, due to its simplicity and reliability, is the only one that has survived the test of service.

The reason that underfeed and traveling-grate stokers have not been perfected and adapted for locomotive service is due to the fact that they require more room, and weigh more than the existing locomotive limitations permit.

Mr. Eksergian's discussion has amplified and supported the author in several important observations made and it would be superfluous to add anything further to the points touched upon by him, except to express appreciation for his carefully thought out comments.

Any contribution made by Mr. Jones, engineer of test and chief of the locomotive test plant, Pennsylvania Railroad, where most of the tests quoted by the author were made, is of real interest to all. He is eminently qualified to discuss this subject, and his reference to the M1A locomotive with enlarged steam space, emphasizing the improvement possible even with a small change in design, is valued highly.

While on this subject it should be noted that most of the test-plant tests are run with particular attention to keeping the water level below a full glass, or three gages of water, and also without foaming condition of the water. In road service it is known that many times the water level is carried above the highest gage cock and badly foaming water is encountered.

In some cases, on large and long boilers, it has been found that the distance from the water level to the top of the boiler barrel at the dome is as small as ten inches with the water level at the top gage cock. When ascending a heavy grade, say 2 per cent, with engine working at maximum capacity, the water level is usually carried to a full glass of water. When engine is tipping over the grade the water level near the dome will rise as much as 8 in., thus reducing the steam space to nearly zero.

This condition indicates the importance of the use of steam separators in the dome.

The carefully conducted tests of locomotive performance that are frequently being made by Mr. Knight on his railroad are an example of the alertness with which present-day railroad management explores every avenue to improve railway efficiency. His comments based on actual experiences are, therefore, of much interest.

The information pertaining to fuel tests with different grades of coal, furnished by Mr. Knight and quoted elsewhere in this summary, is very valuable. His reference to tests made with different percentages of air openings through the grates is most interesting, particularly the trial with grates having 60 per cent free air opening. Further information on these tests will be of interest.

Mr. Lipetz' contribution is of particular value because of his thorough knowledge of the fundamentals involved. He calls attention to the possibilities obtainable from the proper study of the curves of the test data presented in conjunction with the boiler ratios given in the table.

The data shown represent the results of all the pertinent and complete tests made. Many road tests have been analyzed by the author, but most of them usually lack sufficient test data to permit an accurate analysis of the performance of the locomotive under different conditions of load and speed.

Some road tests analyzed have accurate data on the cylinder performance, drawbar pull, and horsepower, but lack data on the fuel and water consumption or general boiler performance. Other tests have been made with accurate data on coal and water con-

sumption, but without dynamometer or indicator cards to measure the work performed.

The reason for the many incomplete tests run in the past is due to the desire to get a quick picture of the general performance rather than a critical analysis of design; also, the question of the cost of tests is important, particularly when one railroad must bear such cost alone.

The advantage of coordinated research is appreciated by all concerned, and perhaps some day this may be brought about.

Mr. McBride suggests that a prompt collection and analysis of all available data are urgently needed in connection with the problem of proportioning locomotives. The author agrees with this and it was the primary purpose of his paper to make available all the pertinent and accurate test data available just for such analysis and study.

However, the author disagrees with Mr. McBride as to the accuracy of methods suggested by him as they use arbitrarily determined coefficients which apply to empirical formulas, the fundamental sufficiency of which is in question.

We need not be concerned here with a rule-of-thumb method for determining the approximate maximum evaporation of a boiler for the purpose of setting the size of the stoker, injector, etc., but rather a critical analysis of the effect that definite changes in the proportions of various component parts of the boiler have upon boiler efficiency, capacity, first cost, and cost of maintenance.

When this is determined, accurate formulas for calculating the capacity and efficiency of the boiler will follow.

The several questions raised by Mr. Meister, regarding the influence of superheater design upon locomotive economy, are important, and the author will endeavor to answer them.

The first question pertains to the practical limit of steam temperatures on present type of reciprocating steam locomotive; also, its effect on economy and maintenance.

Modern locomotives in the United States, Canada, and Europe operate with steam temperatures of 750 F, and on many locomotives total steam temperature of 800 F, at maximum rate, is not uncommon. With 250 lb boiler pressure this total temperature is equal to a superheat of 350 to 400 deg.

This steam temperature will give a metal temperature of the superheater units of from 875 to 900 F, and units made of open-hearth, low-carbon steel have proved satisfactory for these temperatures. Heat-resisting low-alloy steels are also available to give additional life if desired.

The foregoing statement is predicated on the basis that the units are kept clean from scale on the inside, as it is well known that even a thin layer of scale will decrease the heat transfer from metal to steam and raise the metal temperature.

As far as other parts of the locomotive in contact with superheated steam are concerned the problem of high steam temperatures has been successfully solved by the use of cast steel for the superheater header, throttle, steam pipes, and cylinders. The single-seated multiple-disk valve throttle has proved successful for this service. The lubrication problem has also been satisfactorily solved by the use of the modern high-temperature lubricating oils and forced-feed lubricators.

The question of economy gained by the use of high superheat is answered on page 391 of the author's paper. A reduction of as much as 46 per cent in steam consumption was gained with superheat up to 225 F as compared with saturated-steam operation.

It has been definitely shown on many tests that for each 10 F increase in superheat there would be a reduction in steam consumption of not less than 1 per cent up to the limit of the present practice of 800 F total temperature. This is due to the raising of the total heat content of the steam at admission, and increasing the total heat drop, or the Rankine-cycle efficiency.

The second question raised is a rather broad one and is perhaps best answered by the replies to the other more detailed questions in Mr. Meister's discussion.

The third question, inquiring as to what combination of pressures and superheat will give the best ultimate economy, can best be answered by stating that from a thermal standpoint the higher the pressure and superheat become, the greater will be the Rankine-cycle efficiency of the prime mover. From a practical standpoint it appears that 300 lb gage is the highest to which the conventional stayed locomotive boiler should be built considering material and practice of today. An increase above this pressure would not be of any advantage from an economy standpoint when used in a single-expansion reciprocating noncondensing engine with dimensions of present-day locomotives equipped with piston valves and Walschaerts or similar type of valve gears. With water-tube boilers of types now on the horizon it appears entirely practical to raise the boiler pressure considerably above 300 lb per sq in. and maintain up to 800 F steam temperature.

With the advent of a practical cylinder design having poppet valves and cam-operated valve gear, like the Franklin gear, referred to by Mr. Jones in his remarks at this meeting, it appears that a reciprocating engine has arrived that is not only well suited for handling high pressure and superheat from a practical point of view, but also capable of utilizing the increased amount of energy supplied with each pound of steam with greater efficiency.

The superheater on the 4-4-4-4 type locomotive, referred to in question 4 of Mr. Meister's discussion, is a large-flue superheater with the same size of superheater flue and arrangement as the type "A." The only difference is that each unit consists of two single loops joined to one set of header connections instead of one double-loop unit as with the type "A."

The heating surface of the flue, and superheater, and gas area in each flue, is the same as the type "A," but the steam area through each unit is twice as large. This results in a reduction of the steam velocity in the unit to one half of that of the double loop for any given rating. The pressure drop through the superheater is reduced thereby, but because the lower steam velocity reduces the rate of heat transfer the superheat will also be less.

In the early days of the development of the locomotive fire-tube superheater in the United States, some thirty years ago, a number of locomotives were equipped with single-loop superheaters having two single loops of $1^1/_2$ in. pipe in $5^1/_2$ in. flue.

In view of the desire to keep pressure drop down to a minimum interest in single-loop superheaters has been renewed.

The problem to be solved with the single-loop superheater is the relatively greater differential expansion of the pipes—this is receiving careful study.

On the basis of an increase of 350 deg in the steam temperature from the inlet side of the superheater unit to the outlet side there would be a difference in the average temperature of the metal in the pipes of each unit loop of 175 F.

As the two ends of each unit loop are fixed the large difference in the expansion of the unit pipes sets up a heavy strain on the unit joints that may cause them to leak and finally break.

The Superheater Company has experimented and tested many different types of single-loop superheater units, most of them based upon the principle of placing the bulk of the superheating surface of the unit so that the steam flows in counterflow with the gases, and only one pipe is used for the return of the steam to the front end in uniflow with the gases.

Example of such units are the "H" type, 5P, 6P, and 7P units. All of these types of units are subjected to the same differential temperature stresses. In the "HA" type unit this has been compensated by the use of a short section of double-loop pipe which acts like an expansion joint thus taking care of the differential expansion.

In the standard double-loop superheaters, both type "A" and type "E," there is sufficient flexibility to distribute and absorb this differential expansion without setting up undue stresses that cause trouble.

In view of the desirability of improving the tractive power of steam locomotives at high speeds the question of low pressure drop is important, and careful attention is given to the design of superheater, dry pipes, throttles, steam pipes, and cylinders to gain this end.

The question of reducing the pressure drop through the dry pipe, superheater header, throttle, steam pipe, and valves presents no difficulty from the standpoint of design as these steam passages can be increased considerably above present practice without interfering with the fundamental design of the locomotive, or reducing the useful life of these parts.

An undue increase in the steam area through the superheater units, however, may under some conditions adversely affect the power output of the locomotive as well as the life of the units.

To reduce pressure drop to a minimum and at the same time maintain high superheat for maximum economy in the use of steam involves not only the steam passages from the boiler through the superheater to the steam chest, the valves, and exhaust passages but also the correct proportions of the cylinders to the weight on drivers.

Experience with superheater engines during the last thirty years has shown that a factor of adhesion of 4 is about the minimum for satisfactory locomotive operation with superheaters of normal pressure drop, and it is only under difficult rail conditions that such locomotives have been found to slip at high speeds.

If locomotives with factor of adhesion near the lower limit have the superheater changed to single loop, cutting the pressure drop in half, and thereby raising the mean effective pressure at high speed, such engines might prove very slippery at high speeds when using ordinary valve gears.

Under such conditions the engine must be throttled, the cylinder diameters reduced, or the initial boiler pressure cut, and this will cancel the improvement that was originally sought to be gained by the lower pressure drop at high output, and one is back where he started.

For locomotives that are undercylindered, and have a factor of adhesion larger than 4, a considerable improvement may be gained in decreased pressure drop through the use of the single-loop superheater.

Engines designed fifteen or more years ago were usually equipped with superheaters smaller than is present practice. Many of these older locomotives have been rebuilt and equipped with more efficient and powerful front ends, stokers, better grates, and valve gears. This has permitted such modernized engines to be forced to much higher rates of evaporation than originally possible and, logically, the superheater should be enlarged correspondingly both as to surface and steam area.

The greatest gain in increased boiler efficiency, higher superheat and low pressure will be obtained by installing type "E" superheaters. Whenever this is not expedient a good improvement can be obtained by the installation of a superheater unit like the "HA," which gives some 50 F higher superheat, without any increase in the pressure drop.

Another solution may be that of using a single-loop type "A" superheater. This would give less superheat, but only one third of the pressure drop of the double-loop type "A" with the same number of units.

In his fifth question Mr. Meister observes that the majority of modern locomotives have been designed with type "E" superheaters, and inquires regarding the improvements that will result from the use of this design as compared with the older type "A" superheater, or other types of superheater and boiler designs.

The type "E" superheater is a fire-tube superheater with a header in the front end of the same general design as the type "A." The difference lies in the arrangement, also the size of the superheater flues and units. The superheater flues in the type "E" superheater may vary in size from $3^1/_4$ in. OD to 4 in. OD depending upon the length of the flues. The size of the flue is selected so as to give the maximum efficiency with minimum draft loss.

Each unit is a double loop with one loop of superheater pipe in each of two superheater flues. The unit pipes are of such size as to give the highest superheat with the lowest pressure drop and draft loss. There are a number of open small tubes that do not contain superheater units.

Due to the use of the smaller size of superheater flues in the type "E" superheater as compared with the larger flues used in the type "A" it is possible to gain from 8 to 10 per cent in the total flue evaporating heating surface of the boiler for the same length of flues; this in addition to a gain of from 3 to 6 per cent in the total free gas area through the boiler.

The heating surface of the type "E" superheater is increased from 35 to 50 per cent over the type "A" superheater thus giving from 60 to 80 degrees higher superheat at maximum capacity for equal conditions of operation, and an even higher difference at the lower rates of working because of the greater surface and the more efficient disposition of same.

The steam area through the superheater is usually greater than the type "A," and is ample for normal low pressure drop.

The foregoing physical improvements in the amount and effectiveness of the heating surfaces result in a decided improvement in boiler efficiency and superheat with a resultant improvement in the over-all efficiency and capacity of the locomotive of upward of 15 per cent as compared with an old-style large-flue superheater.

With a properly proportioned grate and firebox the type "E" superheater-equipped locomotive boiler represents the most efficient concentration of boiler power that has so far been proposed for use in the conventional boiler and has proved practical in every respect.

In addition to the improvements in efficiency and capacity resulting from the use of the type "E" design there are several other practical advantages, such as a reduction in the number of unit header connecting joints to keep tight, and easier locomotive to draft because of the more even distribution of the same size of flues over the tube sheets, a larger space between the flues at the back tube sheet providing more water space and better circulation, which is of considerable importance in flue and tube-sheet maintenance.

The relative small-diameter flues permit the use of thinner flues as compared with the large flue superheater. This, together with the uniform size and thickness of the flues, equalizes the expansion strains reducing flue leakage and flue-sheet cracking.

Regarding Mr. Meister's sixth question, whether better results would be obtained with the stoker located in the front of the firebox. This question is very completely answered by Mr. Roesch's discussion on this paper; and the question of burning pulverized coal is touched upon in another place.

Mr. Meister's seventh question is of great interest to railway management. Many studies have been made on this subject, but it is apparent that sufficient experience has not yet been had to permit an accurate analysis, as suggested by Mr. Meister, from which definite conclusions could be made. This subject is of such large scope that it alone would require a separate treatise.

Mr. Ostermann's discussion on the high economy that results from the use of high superheat is valuable, and brings out the

great importance that correct principles of superheater design have upon the satisfactory operation of locomotives.

The record of locomotive construction throughout the world, during the last thirty years, amply sustains the conclusion that the fire-tube superheater has proved the only practical design for the conventional locomotive boiler so far devised to obtain high superheat. Many other types have been tried, but without success.

This record, however, although gratifying, has not stopped the research work of The Superheater Company as they for many years have been engaged in a systematic and complete program of superheater design.

Every practical form of superheater unit so far conceived has been tested by The Superheater Company to determine the form of unit that would give the maximum superheat and highest evaporation, combined with minimum draft loss, minimum pressure drop through the superheater, low weight and cost, and, at the same time, be easy to maintain.

The author's replies to several of the questions raised by Mr. Meister in his discussion will answer some of the points raised by Mr. Ostermann.

Mr. Pownall adds a valuable contribution. Based on years of experience in this field he has confirmed the importance of testing, also modification of designs to meet specific operating conditions. His work in the development and improvement of the locomotive front-end construction is well known.

Mr. Pownall suggests that the cost of boiler repairs, stated by the author to be about 30 per cent of the total cost of repairs, should not exceed 15 per cent.

The 30 per cent figure was quoted from the report of the Federal Co-Ordinator of Transportation on comparative cost of steam-locomotive repairs, dated November 7, 1935, page 82, and being of great interest is quoted below:

Boiler Repair Costs

In response to the question: "Do you have data separated so as to show what proportion of the total costs of repairs is properly chargeable to locomotive boilers? If the answer is 'yes' state the percentage," eight roads stated that they kept the data separated and showed it varied from 19.2 to 37.4 per cent of the total cost of locomotive repairs; one hundred and ten roads did not have the separation, and ninety seven made estimates that ran from one to sixty-five per cent. A summarization of their estimates showed:

Number of roads	Estimated proportion of total cost of locomotive repairs due to boilers, per cent
17	25
15	20
13	30
8	15
6	35
5	40
5	29
3	10
3	19
3	60
2	18
2	27
2	31
2	65
1	1
1	6
1	12
1	13.5
1	16
1	22
1	26
1	33
1	44
1	49
1	62
97	

Of the roads making an estimate, 68 of them, aggregating 70 per cent of their estimates, ranged from 20 to 40 per cent, so it is probably fair to assume that a mean between these extremes, or 30 per cent, would be a fair general approximation. An effort was made to develop to what extent the treatment of water had affected the cost of locomotive repairs. However, since there is such a limited knowledge with respect to what the boiler repairs cost, it was found impracticable to get much of value in this connection.

From the foregoing it will be noted that only five class 1 railroads out of 165 reporting had a boiler cost below 15 per cent of the total cost.

Mr. Roesch has submitted an interesting discussion on the subject of the great importance to locomotive-boiler operation of the problems and phenomenon of burning fuel in firebox. In the past this subject has been given much thought and study, and there is no question but that further research is necessary, also, that available test data should be published and interpreted.

There is one point in Mr. Roesch's discussion upon which further thought may be given. He states, "Needless to say, the general adoption of restricted grates was hailed by locomotive-stoker manufacturers as it fully supported their contention that stack loss was not a question of coal size as fired but rather one of air openings through the grates and draft influence."

The author feels that this statement cannot be accepted as it stands without further explanations and qualifications as it is contrary to his own experience as to the effect that the size or per cent of fineness of coal has upon stack loss or unburned fuel loss.

The author has personally conducted many fuel tests which showed that the greater the percentage of fineness in the coal as fired, the greater the stack loss, based on exactly identical locomotives, heating value of fuel, and method of firing. Many tests conducted, some within recent years, have proved this to be so.

With the permission of W. G. Knight, mechanical superintendent, Bangor and Aroostook Railroad Company, the following abstract is quoted from the test report of a recent test most carefully conducted on this road.

"In 1939 a thorough investigation was made on the Bangor and Aroostook in connection with noted increase in coal consumption.

"Every cargo of coal that this Company buys is analyzed, and a careful study made indicated that the chemical composition of the coal was good, and it was, therefore, necessary to look elsewhere for the cause.

"Stack losses were known to be excessive and tests with dynamometer cars were made under the following conditions:

"Two carloads of coal of approximately 80 tons were screened and the amount of fines removed from the coal would be everything below the 1/2" screen mesh. This coal was run through the stoker and rescreened again. From this test approximately 28 per cent fines would pass through the 1/2 in. screen.

"Two engines, identically of the same construction, one being hand-fired, and the other stoker-fired, were used for the test.

"A coal car was used behind the locomotive to catch all cinders that could be obtained for the purpose of getting samples to analyze their heat value.

"The results showed among other things that by using screened coal containing 1.24 per cent slack the saving obtained when compared with the same coal having different percentage of slack was found to be as follows:

Slack, per cent	Fuel saving lb per M.G.T.M. in per cent
12.0	8
23.8	12.2
28.0	16.0

The conditions of the locomotive and test were identical in all comparisons.

"It was further found from these experiments that the difference from the coal consumption of run-of-mine coal having 25 per cent to 30 per cent fines as compared with the 15 per cent fines amounted to approximately 10 per cent.

"Results from operation extending over a year on coal having 15 per cent or less slack have even shown on average operation slightly better than 10 per cent saving."

The foregoing quoted test results on the Bangor and Aroostook

are confirmed by recently conducted fuel tests on the New York Central Railroad.

These tests were run for the specific purpose of determining the qualities of different grades of fuel, under identical conditions, of a modern 4-6-4 type locomotive, on standing blowdown tests.

Permission has been granted to quote the following conclusions relating to the subject of the effect of fineness and slack in fuel.

"Preliminary results of tests on fuel from six different mines in which the percentage of slack in the coal varied from straight egg coal with no slack (what is commonly known as 100 per cent egg) to 40 per cent egg with 60 per cent screenings or 60 per cent slack.

"The test showed that where the slack content has been increased the coal rate was correspondingly increased for identical rates of evaporation for practically all the fuel fired.

"Coals of practically the same chemical composition and some slight difference in the B.t.u. value will result in an inferior boiler performance as the use and percentage of screenings is increased.

"The use of increased percentage of screenings, resulting in a lower boiler evaporative capacity, will affect the locomotive performance. This decrease in the boiler performance may be of sufficient magnitude to reduce the locomotive performance required for heavy trains on fast schedules 10 per cent."

From the foregoing it would appear that this question is of great importance and is worthy of the very careful study that it is now receiving at the hands of the various railway administrations.

Mr. Sillcox's comments are of great value because of the prominent part that he has taken in the development of the steam locomotive. His reference to a new approach to the use of pulverized coal and water-tube boilers is particularly timely.

Many studies have been made of this, and different types of water-tube boilers have been built in this country and in Europe. So far only a few locomotive tube boilers have operated successfully. These have been confined to good feedwater territories.

For high availability, that is, long periods of continuous service that we strive for today, it is necessary, no matter what the construction of the water-tube boiler may be, to use only fully treated water; or in conjunction with condensing operation of the engine when pure scale-free boiler feedwater will be assured.

Mr. Sillcox's reference to the use of pulverized fuel is also important. Based on various tests with burning pulverized fuel it appears practical to design a locomotive firebox for the conventional standard boiler, or water-tube boiler, in such a manner as to satisfactorily burn pulverized coal at rates that will satisfy and exceed any demands so far placed on the modern locomotive.

To do so it will necessitate pulverizing the coal very finely as this will increase the speed of the combustion process by a more rapid contact between the molecules of carbon and oxygen.

At maximum rate it should appear possible to obtain a combustion efficiency of 95 instead of 60 per cent, or less, with the present standard method of firing. This increase in the combustion efficiency, in addition to the other advantages that will accrue from burning of pulverized fuel, must pay for the total cost of pulverizing the coal.

The discussion by Mr. Wallace is welcomed indeed in view of the intimate knowledge which he has had of research problems affecting locomotives and railway operation. His comments on the necessity of reducing the delay at terminals are pertinent as every minute saved on stops and slow orders will decrease the elapsed time between terminals.

Mr. Wallace again stresses the necessity of a coordinated program of test and research for the further improvement of the steam locomotive, and that the development of a more efficient and lighter boiler must go hand in hand with the development of the prime mover as the steam consumption of the engine must be reduced substantially below the present practice.

Whether this new prime mover will take the form of a reciprocating or rotating steam engine, or turbine, can only be answered by future developments, but, in any case, it is apparent that condensing operation is a very desirable thing not only to reduce the specific steam consumption of the prime mover, but also to furnish pure condensate for the boiler feedwater.

The most recent practical development now in sight is the perfection of the Franklin improved cylinder arrangement with poppet-type steam and exhaust valves driven with a cam valve gear.

Such an arrangement is now being successfully used in the United States, and has shown a remarkable improvement in power development at high speeds.

Design Factors Controlling the Dynamic Performance of Instruments

By C. S. DRAPER,[1] CAMBRIDGE, MASS., and G. P. BENTLEY,[2] WALTHAM, MASS.

This paper presents a generalized treatment of instruments which have a single movable index, controlled by the magnitude of a single actuating quantity. Such an instrument acts as a system with one degree of freedom and is studied by the well-known methods developed for such systems. Instruments which include servomechanisms cannot be treated as systems with one degree of freedom and are therefore excluded from consideration. From the standpoint of static indications, it is shown that the essential properties of an instrument can be specified in terms of range, scale sensitivity, calibration error, environmental error, and uncertainty. The definition and use of each of these quantities is discussed.

It is shown that the response of an instrument to rapid changes in the actuating quantity can be calculated if two parameters called instrument characteristics are known. One of these parameters has the dimension of time and is called the characteristic time. The second parameter is nondimensional and is called the damping ratio. Nondimensional curves, showing instrument responses to three typical variations in the actuating quantity, are plotted for a series of values of the damping ratio. These curves are used in an illustrative example to show how the values of the instrument characteristics, required to keep dynamic errors below a given limit, can be determined in a practical case.

INSTRUMENTS must be designed to meet many types of service. Although individual instances will often present problems which call for particular construction details or special materials, certain aspects of instrumentation can be generalized to include the requirements of many practical cases. Such generalizations are useful not only in writing specifications for equipment but also in the analysis and discussion of instrument problems. The system which is outlined herewith has been developed for teaching and design purposes at the Massachusetts Institute of Technology. Emphasis is placed on the points of similarity between instrument problems rather than on the differences which appear when a comprehensive scheme of terminology is applied. For a classification of instruments from the standpoint of their use in industry the reader is referred to the works of Behar (1),[3] and Smith and Fairchild (2, 3).

Reduced to the simplest terms, an instrument is so often an arrangement in which the position of a pointer or index is controlled by some physical quantity, that instruments of other types may be considered as special cases. In the operating range of an instrument, it is usually intended that a continuous motion of the index will follow a continuous change in the actuating quantity which controls the instrument. A device in which this result has been achieved by design falls into the category of systems with 1 deg of freedom and will be called an "elementary instrument." Unless otherwise specified, the term "instrument" will always refer to an elementary instrument. One of the authors and G. V. Schliestett (4) have discussed in generalized form the mathematical analysis of elementary instruments. The analysis divides naturally into two cases, depending upon the way in which the actuating quantity changes. If the actuating quantity is constant, the index will become stationary and the instrument subjected to "static conditions." On the other hand, if the actuating quantity is varying so rapidly that the index does not follow the changes exactly, the instrument is operating under "dynamic conditions." Practical problems deal with the properties required in an instrument to meet certain static requirements and to perform satisfactorily under given dynamic conditions. The present paper suggests a method of specifying the essential features of an instrument in terms of characteristics which can be conveniently applied either for design purposes or for determining the suitability of an instrument for use in a given situation.

Static Characteristics

The essential external features of an elementary instrument are shown in Fig. 1. From the standpoint of performance, the

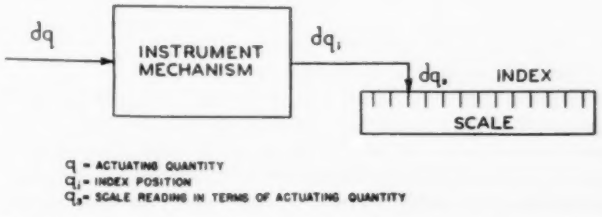

Fig. 1 Essential Features of an Elementary Instrument

mechanical details inside the case of an instrument are unimportant. It is sufficient to know that the instrument contains a mechanism of some sort which produces a change in an index when a change occurs in the actuating quantity. If the instrument belongs to the general class called "meters," a scale is attached to the structure which directly associates each position of the index with some measure of the actuating quantity. Other instruments may not include a scale and so would be disqualified as meters. However, there is always the possibility of interpreting index positions in terms of the actuating quantity by means of tables or calibration curves. For purposes of discussion, any means capable of performing the function of identifying some state of the actuating quantity with each position of the index will be called a "scale."

The general nature of an instrument mechanism is determined when the actuating quantity is given. The requirements of static performance for the mechanism and the scale may be specified in terms of the range and the scale sensitivity. Range is the difference between the highest and lowest magnitudes of the actuating quantity which the instrument is to measure.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Scale sensitivity is the ratio of a small change in scale reading to the corresponding small change in index position, i.e.

$$\text{Scale sensitivity} = S_s = dq_s/dq_i \quad [1]$$

In general S_s may be different for different parts of the scale or it may be constant throughout the range. A vapor-pressure thermometer, using a pressure gage of uniform sensitivity as the indicating system, will have a temperature scale of varying scale sensitivity.

For static conditions, an instrument with a scale perfectly suited to the mechanism, with no friction or hysteresis in the mechanism and not affected by changes in physical quantities other than the actuating quantity, would be completely specified by the range and scale sensitivity. Such an instrument would be perfectly accurate in the sense that the scale reading would always be equal to the actual value of the actuating quantity. This condition may not be fulfilled but, in any case, a small change in the scale reading may be related to a small change in the actuating quantity by the equation

$$dq_s = C dq \quad [2]$$

where C is the calibration coefficient. Obviously the condition for an ideal direct-reading instrument is for the calibration coefficient to be unity. Keeping in mind that C may vary over the range in practical cases, the scale reading corresponding to a given magnitude of q can be found by integrating Equation [2] to obtain

$$q_s = \overline{C}q + K \quad [3]$$

where K is the constant of integration and $\overline{C}$ is a proper average value of the calibration coefficient. If the zero adjustment of the instrument is set so that the scale reading is correct ($q_s = q$) at some part of the scale, the constant of integration can be eliminated from Equation [3]. The actual instrument performance can then be expressed by means of a plot of

$$\overline{C} = q_s/q \quad [4]$$

as a function of the scale reading.

In practice the variations of the calibration coefficient over the range of an instrument are so small that a plot of static corrections is more convenient for studying performance than a plot of the calibration coefficient itself. If the static correction is defined as the difference between the actual magnitude of the actuating quantity and the scale reading, Equation [3] gives

$$\text{Static correction} = q_{corr} = q - q_s = q_s\left(\frac{1-\overline{C}}{\overline{C}}\right) \quad [5]$$

or, expressed in terms of the fractional static correction

$$\text{Fractional static correction} = q_{corr}/q_s = (1-\overline{C})/\overline{C} \quad [6]$$

The fractional static correction expressed as a percentage is a measure of the inaccuracy of the scale reading in any particular case, but it is inconvenient for generalized discussions, since it varies with both the correction and the scale reading. For specification purposes, it is better to express the correction as a percentage of the highest reading on the scale. In this form the correction will be called the full-scale fractional static correction and will be given the symbol Δq_s, where

$$\Delta q_s = q_{corr}/Q_s \quad [7]$$

and Q_s is the difference between highest and lowest scale readings or total scale range.

Analysis of Static Corrections

Many instrument mechanisms are affected to some extent by changes in physical quantities other than the actuating quantity. These physical quantities together make up the environment of an instrument. The process of marking off the scale to read directly in terms of the actuating quantity is called calibration and must be carried out under some particular state of the environment which establishes the calibration conditions.

Static corrections can be broken down on the basis of the source responsible for each component. These components and a corresponding symbol in terms of full-scale fractional static correction are as follows:

1 Calibration error (Δq_c) is due to improper fitting of the scale to the instrument under calibration conditons.

2 Environmental error (Δq_e) is due to variations of the environment from calibration conditions.

3 Uncertainty (Δq_u) is due to imperfections in the instrument mechanism such as rubbing friction between solid parts, hysteresis in elastic members, etc.

Calibration errors often appear when instrument mechanisms are attached to independently graduated scales without special adjustments. The slow changes due to wear and aging effects may also produce calibration errors. Such errors may be found by experiments carried out under calibration conditions. Environmental error can sometimes be calculated but can always be determined by experiment. For any particular reading of a given instrument, the calibration error and the environmental error can be combined into a correction which removes both these errors when applied to the reading. In addition to the method of correction, environmental errors can be eliminated by designing the instrument mechanism to be unaffected by changes in the environment. An instrument constructed in this fashion is said to be compensated.

Uncertainties differ from the errors just considered in that they cannot be exactly determined for a particular scale reading and applied as a correction. Uncertainty appears when a scale reading is made from a pointer of finite width. Rubbing friction between solid parts in the mechanism is a second typical cause of uncertainty. Due to this friction, some finite change in the actuating quantity must occur before a detectable motion of the index appears. From this standpoint, uncertainty, as the word is used here, is similar to ultimate sensitivity as this term is accepted by Behar (1).

In general, it is only possible to set an upper limit for the uncertainty associated with a particular scale reading. Smith (3) has applied the term "dead zone" to a similar concept. According to Smith: "The dead zone is the extreme range of values of the variable possible without moving the indicator from a given position, in the absence of abnormal vibration; the dead zone is ordinarily twice the frictional error." Actually the uncertainty in any particular scale reading may be anything from zero to a maximum value determined by friction or the pointer width. The exact value of the uncertainty in a given instance will depend upon the previous history of the scale reading condition of the instrument mechanism, vibration, etc. Although it might be possible to estimate the uncertainty in particular cases, the usual procedure is to accept the maximum uncertainty as a fundamental limitation on the accuracy of an instrument.

Dynamic Errors

Rapid changes in the actuating quantity are accompanied by differences between instantaneous scale readings and the true values of the actuating quantity which occur at the same time. For any particular case, the static correction may be responsible for part of such differences but there will, in general, be another component peculiarly due to the fact that the actuating quantity

is changing. This latter component will be called the "dynamic error." Fig. 2 graphically illustrates the concepts of dynamic error and the corresponding time lag for a case with negligible static corrections. From Fig. 2, dynamic error is the difference between q and q_s at a given instant, while time lag is the time interval between the instant the actuating quantity passes through a certain value and the instant at which the scale reading reaches this value.

Many authors have studied the problem of dynamic errors. In the field of industrial instruments, Behar (1), and Smith and Fairchild (3) have summarized the methods of attack and have given typical results. The work of Draper and Schliestett (4), in reducing the analysis of dynamic errors to generalized nondimensional forms suited for engineering use has already been mentioned. The discussion which follows deals with a scheme for analyzing the dynamic errors of an elementary instrument

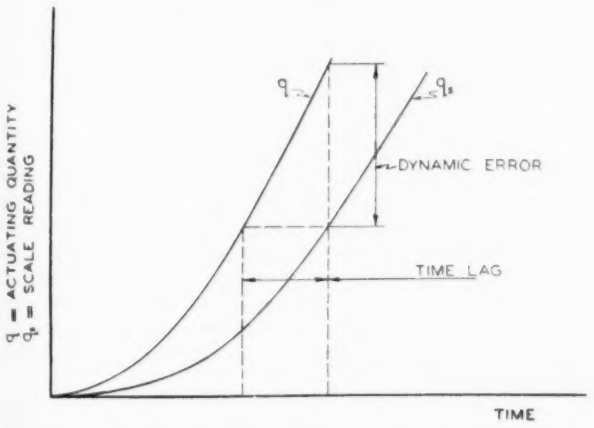

FIG. 2 DYNAMIC ERROR AND TIME LAG

in terms of two characteristic parameters. One of these parameters has the dimensions of time and will be called the "characteristic time." The other parameter is dimensionless and may be either the damping ratio or the characteristic damping number. In certain cases, the undamped natural frequency may conveniently be used as the time parameter. Methods for determining these parameters in actual cases have been described (4). The treatment which is outlined in this reference will be reviewed briefly in the present paper and extended to show how the characteristic parameters may be applied to engineering problems.

For any given instance, the dynamic error will vary with time in a manner dependent upon the characteristics of the instrument used and upon the way in which the actuating quantity changes. This means that each set of circumstances will require special treatment for an exact determination of dynamic errors. The amount of work necessary can be reduced by approximating actual variations in the actuating quantity by means of changes falling into three basic types. In the first of these types, the actuating quantity changes so rapidly between two constant values that the change is completed before the instrument reading has changed appreciably. A change of this sort is called a "step function." The second type occurs when the actuating quantity varies directly with time and will be called a "linear change." The third type is a continuous sinusoidal variation which may actually be one component of a more complicated periodic change. It will be shown how the instrument characteristics can be simply applied to predicting the dynamic errors which occur with each type of variation in the actuating quantity.

GENERALIZED EQUATION OF MOTION

Motion of an instrument index is determined by the balance between effects of four types which, for purposes of discussion, will be considered as generalized forces, as follows:

1 Restoring forces which tend to move the index toward some equilibrium position with a force magnitude proportional to the divergence of the index from that position.

2 Damping forces which resist motion of the index with a resultant magnitude proportional to the index velocity. This assumption yields useful results for many cases in which it represents an approximation.

3 Inertia forces which are proportional to acceleration of the index.

4 Forces which depend upon the magnitude of the actuating quantity. These forces are responsible for initiating changes in the index position, and for this reason, the mathematical expression which specifies the actuating quantity as a function of time will be called the "forcing function."

It has been shown (4), that the first three of these forces may be expressed in terms of the scale reading to give the equation of motion in the form

$$(a_2)d^2q_s/dt^2 + (a_1)dq_s/dt + (a_0)q_s = a_0q \ldots\ldots\ldots [8]$$

This equation can be solved by well-known methods (5) for the case in which the coefficients a_0, a_1, and a_2 are constants. When these coefficients vary either with time or with the scale reading, a solution is usually so difficult to handle that the assumption of constant coefficients is made even for cases where it is not true. The resulting solutions will not be exactly correct but will often give a picture sufficiently close to physical facts for engineering purposes. These solutions will show the way in which the scale reading varies with time for a particular instrument under given conditions. The actual value of the actuating quantity at any instant can be found from the forcing function so the dynamic error is completely determined as the difference $(q - q_s)$ or on a fractional basis as $(1 - q_s/q)$.

Two types of problems involving dynamic errors appear in practice. In the first type the coefficients associated with a given instrument are known and it is desired to find the dynamic errors existing when a particular forcing function is applied. Cases of this nature are simple in that it is only necessary to carry through straightforward solutions of Equation [8]. Problems of the second type start with requirements on the magnitude of dynamic errors accompanying certain forcing functions and lead to values of the coefficients (instrument design constants) a_0, a_1, and a_2 as the desired results. The object of generalizing the analysis of dynamic errors is to reduce the amount of effort required for solution of either type of dynamic-error problem. The method of attack is to divide Equation [8] through by a_2, so that the coefficient of the first-derivative term has the dimensions of reciprocal time, and the coefficient of the term in q_s has the dimensions of reciprocal time squared. The coefficient of the first-derivative term can be used to establish a characteristic time for an instrument. It will be shown that one additional parameter in the form of a dimensionless ratio will completely specify a given instrument. The dimensions of the actuating quantity in any particular case are immaterial since time is the only dimension involved in the characteristics. The characteristics completely define the equation of motion so it follows that all instruments with the same characteristics will have the same dynamic errors under identical forcing functions and initial conditions. Because of this fact, it is possible to plot families of nondimensional curves for the dynamic response of instruments to the three forcing-function types which have been chosen as representative practical cases. With these

curves available, it is possible to solve a wide range of dynamic-error problems by a simple inspection of the curves. The mathematical background necessary for proper use of the instrument characteristics is outlined and the use of nondimensional performance curves is illustrated by examples.

Solution of Equation of Motion in Terms of Instrument Characteristics

Equation [8] has solutions which give the variation of the scale reading q_s with time. These solutions have the general form

$$q_s = q_{s(tr)} + q_{s(ss)} \quad [9]$$

The first term on the right-hand side is called the "transient" and is the solution of Equation [8] with the forcing function taken as zero. The second term is any solution of the complete equation for a given forcing function and is called the "steady-state" solution. Physically, the steady-state solution gives the behavior of the instrument after a particular forcing function has continued indefinitely. The transient represents the period of accommodation required for the instrument to change from one steady-state condition to another.

Mathematical details required to solve Equation [8] are discussed in any course on the differential calculus but the solutions thus obtained are usually left in a form which is unnecessarily clumsy for engineering use. The treatment which follows is intended to reduce the work required to obtain quantitative results in dynamic-error problems. It is found that the transient component of the solution may be either oscillatory or nonoscillatory, depending upon the relative magnitudes of the coefficients in Equation [8]. From the standpoint of analysis, a knowledge of the quantities chosen for characteristics should make it possible to determine the dynamic behavior of an instrument directly from generalized nondimensional curves for either oscillatory or nonoscillatory transients. Reasons for the choice of characteristic time and the damping ratio, as these parameters are defined, will appear as the analysis is developed.

Instrument Transients

The nature of the characteristics can best be explained from a study of the transient component in the solutions of Equation [8]. If the forcing function is placed equal to zero and each term is divided by a_2, Equation [8] becomes

$$d^2q_s/dt^2 + (a_1/a_2)dq_s/dt + (a_0/a_2)q_s = 0 \quad [10]$$

The exponential function, the form of which is unchanged by differentiation, is particularly suited for the solution of Equation [10]. Two arbitrary constants must appear in the solution, since the original equation is of the second order. It follows that the solution may be written in the form

$$q_s = Ae^{-t/\tau_1} + Be^{-t/\tau_2} \quad [11]$$

The symbols τ_1 and τ_2 must represent quantities with the dimension of time, since the exponents must be without dimensions. Substitution of the expression given by Equation [11] into Equation [10] shows that τ_1 and τ_2 must be expressible in terms of the coefficients a_0, a_1, and a_2 by the relationships

$$1/\tau_1 = (a_1/2a_2) - \sqrt{(a_1/2a_2)^2 - (a_0/a_2)} \quad [12]$$

$$1/\tau_2 = (a_1/2a_2) + \sqrt{(a_1/2a_2)^2 - (a_0/a_2)} \quad [13]$$

The first term on the right-hand side of these equations is always real, but the quantity under the radical may be either real or imaginary, depending upon the magnitude of $(a_1/2a_2)^2$ with respect to the magnitude of (a_0/a_2). If the second of these quantities is greater than the first, the radical terms become imaginary and the corresponding motion for the transient part of the expression for q_s is oscillatory. In this case Equation [11] is usually changed from the exponential form to a trigonometric form which is more convenient for practical use. If $(a_1/2a_2)^2$ is greater than (a_0/a_2), the radical term is real and Equation [11] can be used as written. A third case exists which represents the transition condition between oscillatory and nonoscillatory transients.

For maximum usefulness the quantities chosen as instrument characteristics should be easily applied to any case whether the transient is oscillatory or nonoscillatory. The undamped natural period of an instrument is suitable for use when the transient is oscillatory or the forcing function is sinusoidal, but is difficult to interpret directly when the transient is nonoscillatory or forcing functions are not sinusoidal. On the other hand, the quantity $(2a_2/a_1)$ has the dimension of time and is so intimately associated both with the damping of transients and steady-state dynamic errors that it is particularly suitable for use as one of the instrument characteristics. For this reason the characteristic time will be defined as

$$\tau = (2a_2/a_1) \quad [14]$$

To specify completely the behavior of an instrument under dynamic conditions, another parameter is required in addition to τ. This parameter is the second instrument characteristic and can always be chosen as a dimensionless ratio. The ratio between τ_1 and τ_2, as these quantities are defined by Equations [12] and [13], is the most obvious choice for a dimensionless instrument characteristic. This ratio is especially useful for nonoscillatory transients and will be called the "characteristic damping number."

$$\nu = \tau_1/\tau_2 (\tau_1 > \tau_2) \quad [15]$$

When the transient becomes oscillatory, the characteristic damping number becomes a complex quantity which is difficult to interpret for practical purposes. A dimensionless ratio which can be conveniently applied in any case is the damping ratio. This ratio is defined as the ratio of the coefficient a_1 which actually exists to the coefficient a_{1c} which must exist for the condition which divides oscillatory from nonoscillatory transients. Mathematically this critically aperiodic condition is reached when

$$(a_1/2a_2)^2 = a_0/a_2 \quad [16]$$

For this case

$$\tau_1 = \tau_2 = \tau \quad [17]$$

and

$$\text{Damping ratio} = \zeta = a_1/a_{1c} = \nu = \tau_1/\tau_2 = 1 \quad [18]$$

It follows that when ζ is less than unity, the transient will be oscillatory, while the transient will be nonoscillatory for values of ζ greater than unity. The characteristic damping number will be unity when the transient is critically aperiodic, greater than unity for nonoscillatory transients, and complex for oscillatory transients.

In order to solve dynamic-error problems, certain definitions, in addition to those already discussed, are convenient. The "circular natural frequency" is defined as

$$\text{Circular natural frequency} = \omega = \sqrt{a_0/a_2 - (a_1/2a_2)^2} \quad [19]$$

$$\omega = 2\pi n = 2\pi/T \quad [20]$$

In Equation [20] n is the natural frequency and T is the natural period. When the coefficient a_1 is zero, the quantities thus

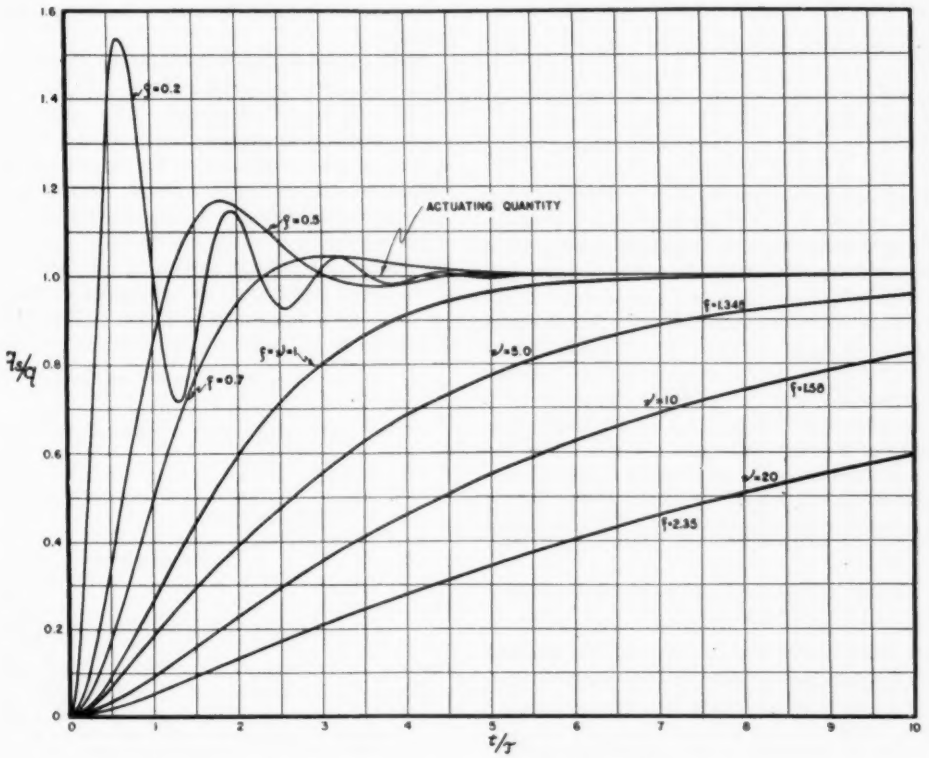

FIG. 3 INSTRUMENT RESPONSE TO A STEP FUNCTION

defined become the undamped natural circular frequency, the undamped natural frequency, and the undamped natural period, respectively. The undamped condition is indicated by a subscript n on each of the quantities so that

$$\omega_n = \sqrt{a_0/a_2} = 2\pi n_n = 2\pi/T_n \quad [21]$$

and

$$\omega = \omega_n \sqrt{1 - \zeta^2} \quad [22]$$

A convenient way of remembering the relationships between the instrument characteristics and the other essential quantities involved in the solution of dynamic-error problems is to write the original differential equation of motion in terms of the derived quantities. The result of this procedure is as follows

$$d^2q_s/dt^2 + (a_1/a_2)dq_s/dt + (a_0/a_2)q_s = (a_0/a_2)q \quad [23]$$

$$d^2q_s/dt^2 + 2\zeta\omega_n(dq_s/dt) + \omega_n^2 q_s = \omega_n^2 q \quad [24]$$

$$d^2q_s/dt^2 + (2/\tau)dq_s/dt + 1/(\zeta\tau)^2 q_s = 1/(\zeta\tau)^2 q \quad [25]$$

$$d^2q_s/dt^2 + (\nu + 1)/\tau_1(dq_s/dt) + (\nu/\tau_1^2)q_s = (\nu/\tau_1^2)q \quad [26]$$

Written in terms of the instrument characteristics, the transient can be conveniently expressed in three forms, depending upon the value of ζ.

Case 1 Oscillatory transient, ζ is less than unity, ν is complex

$$q_s = e^{-t/\tau}\left\{A \sin\left[\left\{\sqrt{1-\zeta^2}/\zeta\right\}(t/\tau)\right] + B\cos\left[\left\{\sqrt{1-\zeta^2}/\zeta\right\}(t/\tau)\right]\right\} \quad [27]$$

or

$$q_s = Ae^{-t/\tau}\cos\left[\left\{\sqrt{1-\zeta^2}/\zeta\right\}(t/\tau) + \varphi\right] \quad [28]$$

Case 2 Critically aperiodic, $\zeta = \nu = 1$

$$q_s = Ae^{-t/\tau} + Bte^{-t/\tau} \quad [29]$$

Case 3 Nonoscillatory, $\zeta > 1$, $\nu > 1$

$$q_s = Ae^{-[2/(\nu+1)]t/\tau} + Be^{-[2\nu/(\nu+1)]t/\tau} \quad [30]$$

where

$$\zeta = (\nu + 1)/2\sqrt{\nu} \quad [31]$$

In Equations [27], [28], [29], and [30], the symbols A, B, and φ represent "fitting constants" to be used for fitting the transient equations to combinations of particular steady-state solutions and given initial conditions.

DYNAMIC ERRORS PRODUCED BY A STEP FUNCTION

The step function will be treated as the first typical forcing function. For analytical purposes, a step function can be considered a case in which the scale reading is constant at zero under a zero magnitude of the actuating quantity, before the instant taken as the initial instant, followed by an instantaneous change of the forcing function to some constant value at the initial instant. Mathematically these circumstances can be expressed as

$$t = 0 \quad q = q_s = 0 \quad dq/dt = dq_s/dt = 0$$
$$t > 0 \quad q = q_s \quad dq/dt = 0$$

When the fitting constants of Equations [27] to [30] are adjusted so that the general transient equations meet the particular initial conditions of the step function, the results are

$\zeta < 1$

$$q_s/q_s = 1 - e^{-t/\tau}\left\{\left(\zeta/\sqrt{1-\zeta^2}\right)\sin\left[\left\{\sqrt{1-\zeta^2}/\zeta\right\}(t/\tau)\right] + \cos\left[\left\{\sqrt{1-\zeta^2}/\zeta\right\}(t/\tau)\right]\right\} \quad [32]$$

$$q_s/q_s = 1 - e^{-t/\tau}\cos\left[\left\{\sqrt{1-\zeta^2}/\zeta\right\}(t/\tau) - \sin^{-1}\zeta\right] \quad [33]$$

$\zeta = \nu = 1$

$$q_s/q_a = 1 - e^{-t/\tau}\,(1 + t/\tau) \quad \ldots\ldots\ldots\ldots [34]$$

$\zeta > 1,\ \nu > 1$

$$q_s/q_a = 1 - [\nu/(\nu-1)]e^{-[2/(\nu+1)](t/\tau)} + [1/(\nu-1)]e^{-[2\nu/(\nu+1)](t/\tau)} \quad \ldots\ldots [35]$$

The general nature of these transients is so well known that it is unnecessary to include a detailed mathematical discussion. From an engineering standpoint, the important point is that a family of curves can be plotted with t/τ as the independent variable and q_s/q_a as the dependent variable, each curve of the family being based on a constant value of ζ. Fig. 3 shows such a family of curves for values of ζ between 0.2 and 2.4. These curves can be applied to instruments of any type which obey the original differential equation. A useful generalization which is apparent from an inspection of Fig. 3 is that the transient is substantially over in a time interval equal to three times the characteristic time, if the damping ratio is in the range between 0.2 and 1. An example showing how the curves of Fig. 3 may be applied to practical engineering problems will be discussed later.

Dynamic Errors Due to a Linear Change of the Actuating Quantity

In many practical cases, the change in the actuating quantity can be approximated as a linear increase or decrease with time. Mathematically this is equivalent to using an expression

$$q = Mt \quad \ldots\ldots\ldots\ldots\ldots\ldots [36]$$

as the forcing function. M is the constant which can be adjusted to make Equation [36] fit the physical facts as closely as possible. The complete solution for q_s, as a function of time, depends not only upon the instrument and the forcing function but also requires that the initial conditions be specified. Out of an infinite number of possible choices, the case in which the reading is constant at zero, when the linear forcing function is applied, is most useful for generalized discussions of instrument performance. The case in which the initial reading is not zero but is constant at some other value may obviously be handled by a simple substitution of $q - q_0$ and $q_s - q_{s0}$ as variables to replace q and q_s. The equations resulting from use of the forcing function $q = Mt$ and $q_s = 0$, $dq_s/dt = 0$ when $t = 0$ are

$\zeta < 1$

$$q_s/M\tau = t/\tau - 2\zeta^2 + e^{-t/\tau}\left\{2\zeta^2\cos\left(\frac{\sqrt{1-\zeta^2}}{\zeta}\right)(t/\tau) + \frac{\zeta(2\zeta^2-1)}{\sqrt{1-\zeta^2}}\sin\left(\frac{\sqrt{1-\zeta^2}}{\zeta}\right)(t/\tau)\right\} \quad \ldots\ldots [37]$$

$\zeta = \nu = 1$

$$q_s/M\tau = t/\tau - 2 + e^{-t/\tau}(2 + t/\tau) \quad \ldots\ldots\ldots [38]$$

$\zeta > 1, \quad \nu > 1$

$$q_s/M\tau = t/\tau - (\nu+1)^2/2\nu + [\nu(\nu+1)/2(\nu-1)]e^{-[2/(\nu+1)](t/\tau)} - \left[\frac{\nu+1}{2\nu(\nu-1)}\right]e^{-[2\nu/(\nu+1)](t/\tau)} \quad \ldots\ldots [39]$$

These equations have been made nondimensional by using the amount that the actuating quantity changes in one characteristic time as the unit of scale reading. By this procedure, the equations are simplified and a single family of curves will take care of all possible cases, involving a linear forcing function acting on an instrument with a constant reading at the initial instant.

With τ used as the time unit, the time scale is not uniform as in the normal case when the damping is varied for a system which is otherwise unchanged. This effect is liable to be confusing unless it is properly interpreted. Therefore, the curves of Fig. 4 have been plotted for an instrument with constant undamped natural frequency and varying damping. By using the undamped natural period as the unit of time and the change of the actuating quantity occurring in a time interval equal to the undamped natural period, the distance associated with a given time interval or a given change in scale reading is the same for each one of the family of curves. This makes interpretation of the curves in terms of the physical facts somewhat simpler

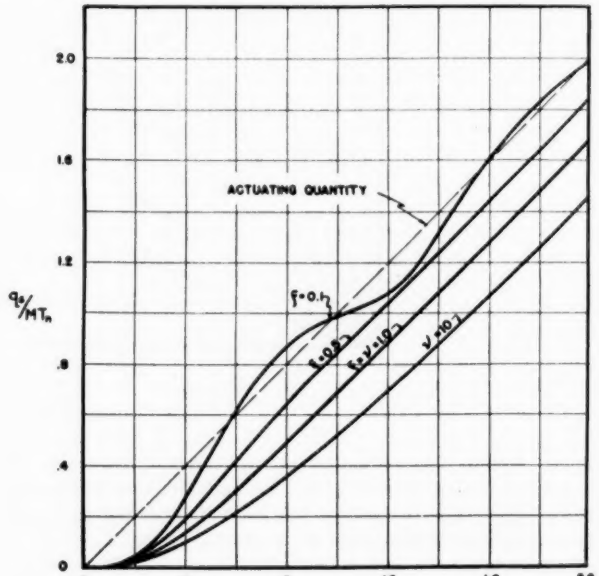

Fig. 4 Instrument Response to a Linear Forcing Function

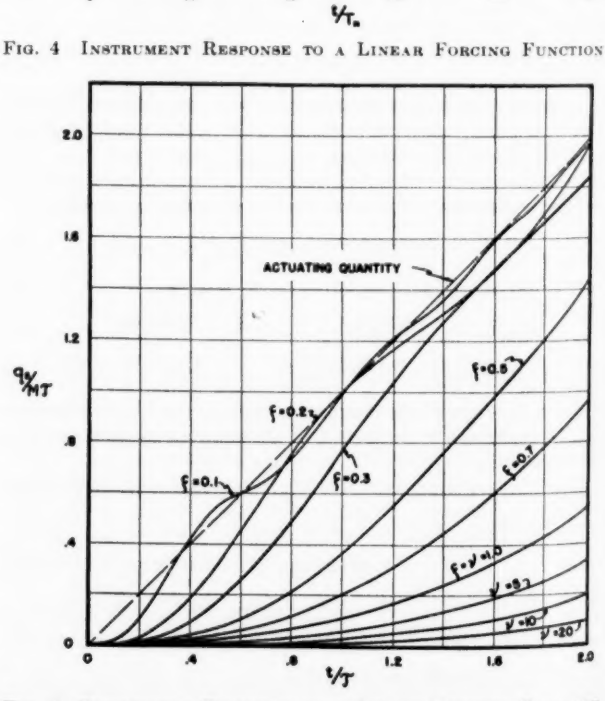

Fig. 5 Instrument Response to a Linear Forcing Function

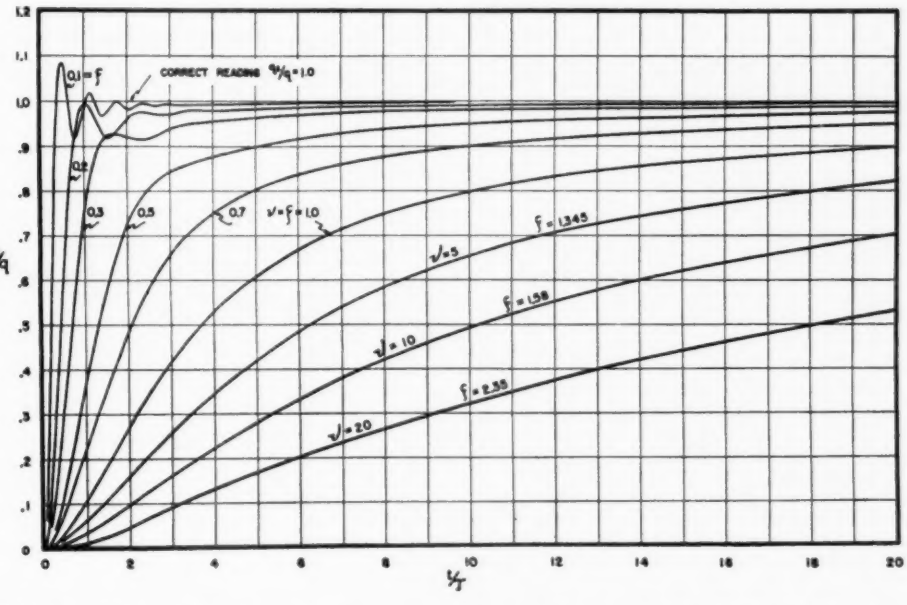

FIG. 6 LINEAR FORCING FUNCTION; VARIATION WITH TIME OF ACTUAL READING AS FRACTION OF TRUE VALUE OF ACTUATING QUANTITY

than if Equations [37], [38], and [39] had been plotted directly. The curves of Fig. 4 show that, as the transient dies out, the instrument reading differs from the true instantaneous value of the actuating quantity by an amount which tends to a constant value of $2\zeta^2 M\tau$ for oscillatory transients, $2M\tau$ for the critically aperiodic case and $[(\nu + 1)^2/2\nu]M\tau$ for the nonoscillatory case. This is an example of a steady-state dynamic error which is constant and corresponds to constant time lag in terms of T_n units. Fig. 5 shows the curves of Fig. 4 plotted directly from Equations [37], [38], and [39]. The effect of damping on the characteristic time is shown by the expanded abscissa scale as the damping ratio is increased.

Instrument engineering problems are usually concerned with the dynamic error rather than with the actual instrument reading at any instant. For generality, it is convenient to express the actual reading in terms of the correct reading at any instant. The correct reading will always be the instantaneous value of the actuating quantity and in terms of $M\tau$ units is equal to t/τ. It follows that

$$q_a/q = (q_a/M\tau)[1/(t/\tau)] \quad \ldots\ldots [40]$$

The instantaneous value of the dynamic error, expressed as a fraction of the true value of the actuating quantity, will be

$$\text{Dynamic error} = 1 - q_a/q \quad \ldots\ldots [41]$$

Curves showing the fractional reading and the dynamic error as a function of t/τ for values of ζ from 0.1 to 2.35 are plotted in Fig. 6. The use of this family of curves will be illustrated later.

STEADY-STATE DYNAMIC ERRORS DUE TO A SINUSOIDAL VARIATION OF THE ACTUATING QUANTITY

Many practical situations may be represented in terms of periodic changes in the actuating quantity. In cases where the disturbance exactly repeats itself, a Fourier series of sines or cosines will accurately describe the physical facts. Even if

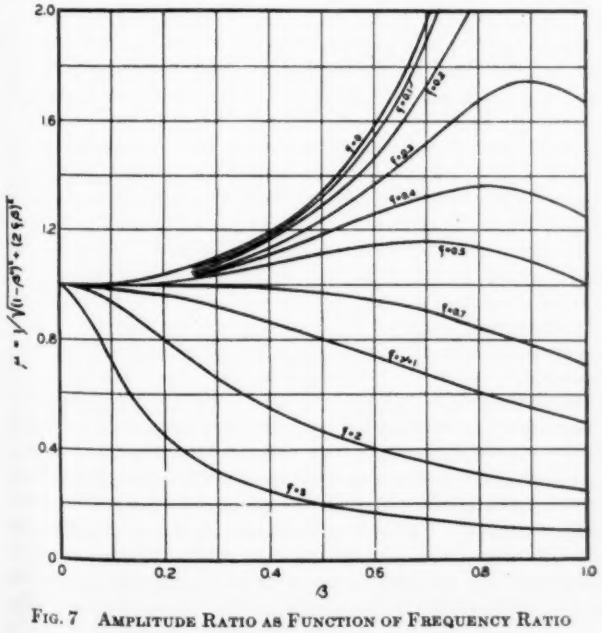

FIG. 7 AMPLITUDE RATIO AS FUNCTION OF FREQUENCY RATIO

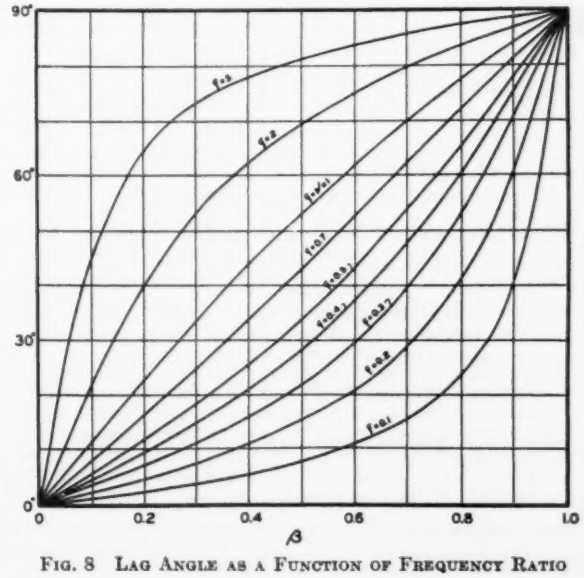

FIG. 8 LAG ANGLE AS A FUNCTION OF FREQUENCY RATIO

this condition is not precisely fulfilled, satisfactory results can often be obtained by the use of a sinusoidal forcing function to find the corresponding steady-state solution of Equation [24]. Thus if the forcing function is

$$q = q_a \sin \omega_f t \quad [42]$$

the steady-state solution as found by conventional methods (5) can be written as

$$q_s/q_a = \frac{1}{\sqrt{(1-\beta^2)^2 + (2\zeta\beta)^2}} \sin(\omega_f t - \varphi) \quad [43]$$

In Equation [43]

$$\omega_f = 2\pi n_f = 2\pi/T_f = \text{circular forcing frequency} \quad [44]$$

$$\beta = \omega_f/\omega_n = \text{frequency ratio} \quad [45]$$

$$\varphi = \tan^{-1}(2\zeta\beta)/(1-\beta^2) = \text{lag angle} \quad [46]$$

The expression

$$(q_s/q_a)_a = \mu = 1/\sqrt{(1-\beta^2)^2 + (2\zeta\beta)^2} = \text{amplitude ratio} \quad [47]$$

is very useful in connection with instrument problems involving periodic changes. A family of curves of μ against β is given in Fig. 7. Practical instrument problems usually involve values of the frequency ratio less than unity so only this range has been covered in Fig. 7. A family of curves showing the lag angle as a function of β for the same range as that of Fig. 7 is given in Fig. 8.

General Design of an Instrument to Meet Given Specifications

The ideas previously discussed are particularly useful for translating performance specifications for an instrument into terms of mechanical details. In practice every instance will present problems requiring special treatment, but the general procedure can be illustrated by an example which might reasonably occur as an actual case. This example will deal with the preliminary design of a recording pressure indicator for slow-speed steam engines or air pumps. Specifications start with the requirement that the instrument must be able to operate for reasonable periods of time under the conditions of pressure, temperature, vibration, etc., which exist in service. Beyond this necessity of satisfactory mechanical operation, the desired properties of the indicator can be defined in terms of static specifications and dynamic specifications. The specifications assumed for the present example are listed as follows:

Static specifications:

- Range—20 lb per sq in. below atmospheric pressure to 160 lb per sq in. above atmospheric pressure
- Scale sensitivity—50 lb per sq in. per in. (constant over range)
- Calibration error—2 lb per sq in. (maximum)
- Environmental error—1 per cent of range per 10 C temperature change
- Uncertainty—1 per cent of range (maximum).

Dynamic specifications:

- Step function—Indicator must give reading within 10 per cent of actual pressure, 0.05 sec after sudden pressure change (q_s/q_a between 0.90 and 1.10; $t = 0.05$ sec)
- Linear change—Gage must follow pressure increasing linearly with time with dynamic error of less than 10 per cent at end of range, when pressure change is such that range would be covered in 0.07 sec (q_s/q_a between 0.90 and 1.10; $t = 0.07$ sec)
- Sinusoidal change—Gage must follow sinusoidal pressure changes with maximum frequency of 4 cycles per sec within an amplitude error of less than 10 per cent and a phase-angle lag of less than 10 deg (μ between 0.90 and 1.10; φ less than 10 deg).

Static specifications determine several of the indicator properties. The range of 180 lb per sq in. and scale sensitivity of 50 lb per sq in. per in. require a scale length of 180/50 = 3.6 in. The pressure-sensitive element and the indicating system must operate over the range and have a spring-stiffness constant within 2/180 = 1.1 per cent if the calibration-error specification is not to be exceeded.

The idea of using sensitivities associated with the component systems of an elementary instrument, as developed (4), is useful in laying out preliminary designs. In the present case of a pressure indicator, the converter can be taken as the system which receives pressure changes and produces changes in the position of some mechanical part which can be used to operate the indicating system. The corresponding sensitivities are

$$\text{Converter sensitivity} = S_c = \frac{\text{small change in position of converter output element}}{\text{small change in applied pressure}} \quad [48]$$

$$\text{Indicating-system sensitivity} = S_i = \frac{\text{small change in index position}}{\text{small change in element connected to converter}} \quad [49]$$

From (4) for a direct-reading instrument

$$S_c S_i S_s = 1 \quad [50]$$

The converter of the indicator could be a spring-and-piston system, working in a cylinder, a metallic bellows, a diaphragm, a Bourdon tube, or any other means for converting pressure changes into mechanical displacements. If a spring-and-piston system is chosen as the converter with a converter sensitivity of 0.001 in. per lb per sq in., the necessary indicating-system sensitivity can be found by use of Equation [50], and the specified scale sensitivity as

$$S_i = 1/S_c S_s = 1/(0.001)(50) = 20 \text{ in. per in.} \quad [51]$$

Uncertainty is the result of imperfections in the indicator mechanism and the width of the recorded line. In the present case, the recording point must produce a line so fine and the mechanical details be so well worked out that the maximum uncertainty is plus or minus 1.8 lb per sq in.

The difficulty of meeting the environmental-error specification can be reduced by establishing calibration conditions as near actual service conditions as possible. In case the indicator temperature varies widely in service, it might be necessary to introduce differential expansion elements to reduce the effect of temperature upon the instrument readings. A problem of this nature must usually be handled by special methods to suit given cases.

Dynamic specifications determine the instrument characteristics τ and ζ. Theoretically, there is an infinite number of characteristic combinations which will satisfy the dynamic specifications. Practical mechanical considerations will determine the particular combination to be selected. For an engine indicator, as in many simple instruments, no benefit is to be gained by using a damping ratio in excess of unity ($\zeta = 1$). On the other hand, values of the damping ratio less than 0.1 ($\zeta < 0.1$) will permit excessive natural-frequency components in the index motion.

With these facts in mind, it is reasonable to survey the range of possibilities by selecting damping-ratio values of 0.2, 0.5, 0.7, and 1 for trial purposes. The dynamic specifications will then place limiting values on the ordinates of Figs. 3, 6, 7, and 8, so that critical values of t/τ can be found for each value of the damping ratio. The spring stiffness of the mechanism has already been determined by the value of S_c. From the standpoint of design it is often desired to find the maximum permissible inertia or mass of the instrument parts. For a constant value

of the spring stiffness, this means that the natural undamped period of the system will be a maximum. For a given damping ratio, the characteristic time is proportional to the undamped natural period, so the general problem can be resolved into finding the minimum value of t/τ for which the dynamic-error specification is not exceeded. For steady-state sinusoidal changes, a minimum value of the frequency ratio β corresponds to a minimum value of t/τ for the other cases.

Table 1 gives a summary of the numerical work required to solve the problem discussed in the preceding paragraphs. For low values of ζ where oscillation is noticeable, the minimum value of t/τ must be selected so that the specified ordinate limits are not exceeded for any greater value of t/τ. For example, in Fig. 3 the curve for $\zeta = 0.2$ crosses the 10 per cent error line several times, but the critical value is the last crossing at $t/\tau = 2.1$.

TABLE 1 SUMMARY OF NUMERICAL WORK USED TO SOLVE TYPICAL PROBLEM

(a) Step-function analysis (Fig. 3)
$t = 0.05$ $q_0/q_a = 0.90 - 1.10$

ζ	$(t/\tau)_{crit}$	$\tau_{crit} = \frac{0.05}{t/\tau\ crit}$
0.2	2.1	0.0238
0.5	2.3	0.0217
0.7	1.8	0.0278
1.0	3.8	0.0131

(b) Linear-pressure-increase analysis (Fig. 6)
$t = 0.07$ $q_0/q_a = 0.9 - 1.10$

ζ	$(t/\tau)_{crit}$	$\tau_{crit} = \frac{0.07}{t/\tau\ crit}$
0.2	0.7	0.1000
0.5	5.0	0.0140
0.7	10.0	0.0070
1.0	20.0	0.0035

(c) Frequency-response analysis (Figs. 7 and 8)
$\omega_f = 4 \times 2\pi$ $T_f = 0.25$ sec $\mu = 0.90 - 1.10$ $\varphi < 10$ deg

ζ	Frequency criterion, β_{crit}	Phase criterion, β_{crit}	Critical, T_n	τ_{crit}
0.2	0.32	0.375	0.0800	0.0638
0.5	0.47	0.175	0.0440	0.0140
0.7	0.72	0.125	0.0308	0.0070
1.0	0.33	0.082	0.0207	0.0033

TABLE 2 SUMMARY OF POSSIBLE INSTRUMENT DESIGN CONSTANTS

(Determined by minimum value of τ from *a*, *b*, *c*, Table 1)

ζ	τ_{max}	$T_{n_{max}}$	$N_{N(min)}$ (cycles per sec)	Critical specification
0.2	0.0238	0.0299	33.5	Step function (*a*)
0.5	0.0140	0.0440	22.7	Phase angle (*c*)
0.7	0.0070	0.0308	32.5	Linear change (*b*)
1.0	0.0033	0.0207	48.3	Phase angle (*c*)

Values of ζ and τ, which meet the dynamic specifications are listed in Table 1. In order to satisfy all the conditions, the shortest characteristic time required for any of the three forcing functions with a given value of ζ must be chosen. Table 2 is a summary of the critical conditions established in Table 1. The critical values of the characteristic time have been converted into values of undamped natural frequency and undamped natural period by the relation

$$T_n = 2\pi\zeta\tau = 1/n_n \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots [52]$$

From Table 2, it is seen that, for low values of the damping ratio, the step function establishes the critical condition, since the low damping permits several natural-frequency oscillations before the reading will remain below the specified error limit. As the damping ratio is increased, the transient component of the step-function response becomes of reduced importance, while the steady-state time lag for the other two forcing functions is increased. In the present case, the steady-state time lag, during a linear change, and the phase-angle lag for a sinusoidal change introduce limitations which are almost identical.

In general as the steady-state-lag specifications are made more severe (specified lags are made smaller), the required undamped natural frequency is increased for a given value of ζ, or the damping ratio must be decreased for a given natural frequency. For the step function, the reverse is true, since the response to such a change is more accurate, as ζ is increased to about 0.7. It follows that the characteristics selected for an instrument must be a compromise between conflicting trends. In many cases, it is mechanically easier to construct an instrument with a low rather than a high undamped natural frequency. This will probably be true for a spring-and-piston engine indicator like that of the present discussion, so the results summarized in Table 2, which are based on the assumption of a critical lower limit to the undamped natural frequency, represent at least one reasonable engineering solution to the original problem. It follows that an indicator with a damping ratio of 0.5 and a characteristic time of 0.0140 sec will be satisfactory. The corresponding undamped natural frequency will be 23 cycles per sec.

After an analysis of dynamic performance has been carried out along the lines suggested in the foregoing discussion, it may be found very difficult to obtain the required characteristics in practice. For example, an engine indicator would probably not have a damping ratio of 0.5 without including some special damping system in the mechanism. In such a case, the original specifications must be relaxed or the expense of building a more than usually complicated instrument accepted. It is evident that the dynamic-error specifications, which can actually be fulfilled by a given indicator, may be found by using the dynamic-performance curves in a process which reverses the method described.

Discussion

K. J. DeJuhasz.[4] This paper represents a noteworthy endeavor to coordinate the scattered information on the dynamic behavior of instruments into a coherent whole and make it more readily available and understandable for students and practicing engineers. In view of the magnitude of the task, it is no detraction from the value of this paper to state that this objective has been only partially attained. The following remarks are intended to complement the paper in some respects and to call attention to some aspects in which further elucidation would be desirable.

The title of the paper suggests a broader scope than is actually the case, as the treatment does not include discussion of seismographic-type instruments which depend for their function on a low natural period of the actuating member, such as seismographs, vibrographs, and torsiographs. A more detailed treatment of Coulomb friction and backlash also would be desirable, as these enter into the functioning of most engineering instruments.

[4] Professor of Engineering Research, The Pennsylvania State College, State College, Pa. Mem. A.S.M.E.

The writer questions the usefulness of the concept of "time lag" when dealing with transient changes. The "lag angle" in measuring a sinusoidally varying actuating quantity is a well-established and useful concept. The time lag of a transient change has no meaning in cases in which the scale reading cannot follow rapidly enough the increase and decrease of the actuating quantity, hence, some values of the actuating quantity are not indicated at all by the scale reading. Furthermore, it may happen that a scale reading is shown before the actuating quantity attains the corresponding value, i.e., the time lag is negative. This would be tantamount to saying that the instrument knew beforehand, and predicted what was going to occur in the future, which is of course absurd. Therefore the writer suggests that the concept of time lag be dropped altogether when dealing with transient changes, and the performance of the instrument be characterized solely by the "dynamic error," i.e., the difference between the actuating quantity and the scale reading at a given instant, which has a real meaning in all cases. Attention should be focused on the concept of "maximum dynamic error," i.e., the maximum difference between actuating quantity and scale reading.

It would be highly desirable to elucidate the various abstract concepts.

As examples, the writer suggests:

(*a*) The undamped natural period of an instrument is equal to the period of a simple pendulum having a mass equal to that of the instrument, and a length equal to its static deflection under its weight.

(*b*) The maximum dynamic error decreases with the decrease of the natural period.

(*c*) The critical damping is brought about by a damping force which is just sufficient to dissipate the potential energy of the instrument.

Possibly these definitions could be further elucidated or improved, in order to reduce to the minimum the mental effort necessary for their understanding.

The writer cannot call to mind any instrument in which the concept of "error after the elapse of a given time" would be of advantage, or could be stipulated in advance. In most cases the requirements are as follows:

(*a*) That the natural period and damping be as low as possible. This is the case with engine indicators, in which the "maximum error" is proportional to the natural period, and the superimposed waves can be allowed for by simple inspection, or more accurately, deducted from the curve by graphical differentiation. An uncertain amount of damping (or friction) is far more difficult to take into account.

(*b*) That the damping be the lowest causing the instrument to "dead-beat," i.e., critical damping. This is the case with quick-weighing scales, in which the overshooting of the pointer is prevented by a dashpot. In such cases it is farfetched to stipulate, and hardly feasible to design in advance, a definite damping ratio. Such dashpots are designed by a rough advance calculation, relying on the fortunate fact that the final adjustment can be readily made by means of a needle valve.

In view of the ever-increasing importance of instrumentation, and corresponding attention given to the theory and design of instruments, further investigations in this field are greatly to be desired, and the authors' paper is welcomed for stimulating thought in these problems.

E. S. Smith.[5] Figs. 7 and 8 and their context, dealing with "steady-state dynamic errors due to a sinusoidal variation of the actuating quantity," offhand appear to this writer to comprise the novel portions of the paper and as such should be useful to engineers working in this art. Nothing that appears anywhere in this discussion is to be taken as minimizing the value of the authors' contribution which unquestionably involved the expenditure of a considerable amount of effort with a corresponding reduction in the work which others in this special field must do.

The treatment is not in fact general, as stated in the summary, since it is not applicable to common servo-operated measuring and controlling instruments which move at constant speed from one position to the next or are intermittently actuated; instead, it seems to be limited to a special (lineal-law) sort of self-operated meter. The treatment does not fit even the ordinary flowmeter which responds to a differential pressure which increases with the square of the velocity of flow.

The terminology of the paper unfortunately differs radically from any of those in common use in this country. The American Society of Mechanical Engineers' Committee on Industrial Instruments and Regulators is endeavoring to develop an authoritative and generally acceptable terminology which should do much to lessen the effort required in digesting papers such as this one, in which the points of possible originality may be obscured by unusual expressions.

As to discussion in the present paper, of papers (2, 3) by Fairchild and the writer and the use of the term "dead zone" in paper (3), it is regretted that such discussion was not made as such, at the time the papers in question were presented, so that the usual closure could have covered it adequately. In view of such belated discussion, the following brief answer may be in order: The papers were presented with controlling (or regulating) as well as measuring in mind, and the treatment of measuring instruments was intended to be suitable for the metering portions of controlling (or regulating) instruments. They were presented to cover the basic theory involved in an introductory manner and with the use of the unavoidable minimum of mathematics; however, such papers are believed to be more than mere "classifications" and to cover much of the material in the present paper. In this paper, the use of numerous Greek letters and the presentation of lengthy mathematical restatements of generally known material are objectionable, in so far as they exceed a reasonable requirement of completeness. However, such repetition may be defensible as making such material more readily available to mechanical engineers.

The term "dead zone" was intended by Fairchild and the writer to cover the maximum disturbance of the measured variable which cannot affect the meter and, hence, alter the position of a controller, instead of referring to the error of a particular reading. Such a definition of this expression still appears to be substantially correct, with usual ratios of starting friction to running friction, although an attempt was made to attain clarity rather than to sponsor an unassailable definition.

The DeJuhasz treatment of the engine indicator in his book[6] on that subject appears to the writer to be essentially similar to that of the present authors on the linear change of the actuating quantity, although it includes a more limited treatment of the amplitude of the response with sinusoidal variations with, offhand, no treatment of lag in such case.

The authors might well test the usefulness of their two criteria on the design of a commercially needed, reliable, and accurate pressure indicator for hydraulic transmissions of the multiple-piston type using, e.g., a working pressure of about 1500 lb per sq in., a frequency of 12,000 cycles per min, and an unsymmetrical wave form (rounded tops and V-troughs).

[6] "The Engine Indicator," by J. K. DeJuhasz, Instruments Publishing Company, Pittsburgh, Pa., 1934.

Authors' Closure

Professor DeJuhasz and Mr. Smith have based their major criticism upon their opinions that the principles discussed in the paper could not be applied to instrument problems of certain types and have advanced examples to prove their claim. The authors feel that this criticism is due to a lack of understanding of the manner in which generalized reasoning in terms of nondimensional variables can be applied to specific problems. When such a method is used, a large part of the mathematical work can be carried out once and for all to produce results in the form of curves which may be applied to any physical case described by the differential equation used as the basis for the analysis. To use such curves intelligently and to be able to handle cases which may fall outside the range of available plots, it is only necessary for an engineer to have a general understanding of the steps followed in order to obtain the final results. For this reason, the analysis has been presented in some detail at the risk of "lengthy mathematical restatements of generally known material." It was the authors' intention to offer the possibility of a saving in time and effort on the part of workers in the general field of instrumentation.

In considering an instrument problem, it is only necessary for the practicing engineer to satisfy himself that the behavior of a given instrument can be described by a second-order differential equation with constant coefficients. When this requirement is fulfilled, ability to use the curves of the present paper will provide an engineer with specific information directly applicable to many problems which could be duplicated from papers similar to references (2, 3), cited by Mr. Smith, only after many hours of detail work. Mr. Smith shows some recognition of this fact in his statement, ". . . such repetition may be defensible as making such material more readily available to mechanical engineers."

The particular objection of Professor DeJuhasz that the method of analysis described in the paper is not general, because it does not apply to the seismographic type of instruments for measuring vibration, is definitely unjustified. As a matter of fact, the method of analysis as presented was largely worked out during the design of a line of vibration-measuring equipment for aircraft which has been commercially available for some time. A detailed discussion of the manner in which the methods explained in the present paper can be applied to vibration-measuring instruments was given by C. S. Draper and Walter Wrigley at the 1940 Annual Meeting of the Institute of the Aeronautical Sciences.[7]

Mr. Smith states that the method of analysis discussed in the present paper does not apply to the case of an instrument such as a flowmeter which involves a square law between the actuating quantity and the reading of an indicator which responds to pressure changes. As a matter of fact, the authors anticipated this objection by defining the sensitivities in terms of differential changes. Where nonlinear laws are required to express the relationship between the actuating quantity and the index position, the coefficients of Equation [8] are actually differential coefficients which can be treated as constants over small ranges of operation. The sentences, which follow Equation [8] in the paper, discuss the case in which the analysis will not produce accurate results due to variations of the coefficients with scale position. In practice, the analysis has been found adequate to handle the case of dynamic errors in air-speed meters for aircraft when relatively small fractional changes in speed are involved. The assumptions are similar to those used by electrical engineers in treating circuits containing vacuum tubes and are subject to the same limitation, namely, that the results will have increasing errors as the magnitude of the changes is increased.

The contention that the analysis does not include the case of systems which contain servomechanisms is only partially correct. Actually, the courses on theory and practice of servomechanisms taught by Professors Hazen and Brown at the Massachusetts Institute of Technology use the same general method of nondimensional analysis as that described in the present paper. For analytical purposes it is convenient to consider any servomechanism as made up of a series of systems with 1 deg of freedom. Frequently, the analysis of the performance of a complete servosystem involves only a second-order differential equation. Even where equations of higher order than the second are required, it has been found helpful to use the ideas of damping ratio and undamped natural frequency. The example of a servosystem of the relay type, as suggested by Mr. Smith, may be analyzed in a particularly simple fashion by use of the ideas discussed in the present case, but the method requires the application of a sequence of forcing functions acting upon the individual 1-deg-of-freedom systems (elementary instruments) which make up the servomechanism.

The criticism of the authors for failing to use a system of terminology which as yet has not been published cannot be given much weight. Surely it is granted that, until a system is unanimously adopted, the opportunity to present the arguments in favor of one which has been evolved through many exhaustive tests should not be denied. The terminology used in this paper has been developed over a period of about 10 years by the students and teachers interested in instrumentation at the Massachusetts Institute of Technology and is certainly familiar to and endorsed by a considerable number of engineers who at present are working in the field of aircraft instruments and vibration analysis. The reason underlying development of the terminology has been the lack of a generally accepted system which could be applied to dynamic problems of any type. The authors' system has facilitated the solution of many problems. Furthermore, the time and effort required to teach or to acquire a knowledge of instrument analysis have been reduced, as compared with the work required by an approach based entirely upon the contemporary treatments available in the literature.

The authors feel that the use of Greek letters in the list of symbols is a definite advantage in forming a systematic nomenclature. The general scheme is to use Greek letters for nondimensional quantities and quantities with the dimensions of time, small Roman letters for variables or directly measured quantities, and capital Roman letters for undetermined coefficients. This system has certainly justified its use by reducing the time required for an engineer to understand the results of the analysis from an unfamiliar project.

The authors disagree with Professor DeJuhasz that the quantity defined as "time lag" is unimportant. Time lag is the essential design variable in any instrument which must disregard small instantaneous variations of a quantity and indicate an average value. For example, the artificial horizon used as an aircraft instrument must have a time lag of such magnitude that it will substantially disregard deviations of the resultant-force vector from the true vertical. The requirement of a short time lag in a rate-of-climb meter used for maintaining level flight is obvious. Another application of the concept of time lag occurs when an elementary instrument is used to detect changes in the physical quantity actuating an automatic control system, short time lag being essential in order to start the system functioning soon after a change has occurred. The importance of "error after the elapse of a given time" is also apparent in this case. The existence of a negative time lag, as suggested by Professor

[7] "Instruments for Measuring Low-Frequency Accelerations in Flight," by C. S. Draper and Walter Wrigley. Presented at the Meeting of the Institute of the Aeronautical Sciences, Jan. 25, 1940. To be published in an early issue of the *Journal of the Aeronautical Sciences*.

DeJuhasz, is a physical possibility and is merely an indication that the elementary instrument is oscillating.

The concept of time lag, as the term was used in the paper, is useful and should certainly be retained in any comprehensive system of instrument analysis. On the other hand, the term "time lag" appears to be unsatisfactory and should probably be replaced by other words to describe the same concept. Professor Brown of the Massachusetts Institute of Technology has suggested the term "response delay" to replace time lag. This term is descriptive of the concept involved and will be adopted by the authors for future work.

A discussion of Coulomb friction and backlash effects as suggested by Professor DeJuhasz should certainly be included in any complete instrument analysis. One of the authors has included these effects in teaching instrumentation for some years. A reasonable generalized treatment would have been too long for inclusion in the paper. A study of Coulomb friction is included by Den Hartog in his book (5).

The use of analogies has not been found particularly helpful. It is better to allow an individual to apply theoretical results to whatever electrical, mechanical, acoustical, hydraulic, or other system which he judges to be most readily understandable. For this reason, the authors have omitted any attempt to make particular applications of the generalized results in a fashion which might be useful in explaining the theory to a given group of listeners. Mechanical analogies are readily accessible in books on mechanical vibrations, while electrical analogies are discussed in many electrical-engineering texts.

The authors have had some difficulty in recognizing the usefulness of the pendulum analogy suggested by Professor DeJuhasz, inasmuch as the mass of an instrument is largely case structure, which is not the mass of interest in this discussion. Furthermore the period of a pendulum is independent of the pendulum mass. Of course, any pendulum of a length equal to the static deflection of a 1-deg-of-freedom system will have the same period as the system, but the advantage of this type of analogy is open to question.

The maximum dynamic error normally decreases with decrease of the natural period, but it is possible to show that this statement is not general. For example, if an instrument period is originally longer than the fundamental forcing frequency, reducing the natural period will cause the system to pass through resonance when the dynamic errors increase.

The statement that the natural period should be as low as possible and the damping near critical is unnecessarily restricting. One of the particular advantages of a generalized set of curves is that, when mechanical considerations limit the natural frequency which may be realized in practice, and hence limit β, a satisfactory instrument may be obtained by a suitable choice of the damping ratio. These considerations are clearly brought out by a study of Fig. 7 of the paper, and further by the following discussion of the instrument problem proposed by Mr. Smith. As noted in the paper, there is usually an infinite variety of combinations of β and ζ which will satisfy specified instrument performance conditions. Therefore, it is the designer's responsibility to select that combination leading to the simplest and most reliable mechanical construction.

The hydraulic pressure indicator, proposed by Mr. Smith as a design problem, cannot be analyzed by any methods without a full performance specification. The word "accurate" is not an engineering specification per se, it must include the acceptable numerical tolerance range. It is this lack of reduction of instrument specifications to numerical terms that leads to many of the instrument designer's headaches. It is also not quite clear whether Mr. Smith intended the quantity to be measured accurately as the mean steady working pressure or the instantaneous variations of pressure throughout the cycle. If the latter were the problem in mind, the unsymmetrical wave form must be broken down into a Fourier series. The predominant term will be the fundamental frequency of 200 cycles per sec. To indicate the pressure variations to any degree of accuracy whatsoever, an instrument must respond to frequencies as high as the fundamental, with an accuracy at least equal to the numerically specified tolerance. When higher frequency components are present in the forcing function, the frequency range for linear response must extend to higher frequencies, if the response is to be a true picture of the forcing function.

In the particular problem at hand, where higher harmonics will be present in the instrument forcing function and no numerical accuracy has been specified, a fundamental response accuracy of at least 5 per cent might reasonably be assumed. Furthermore, to avoid resonant magnification by higher frequency components, μ (Fig. 7) must be kept reasonably close to unity by selection of a ζ of approximately 0.6. From Fig. 7, a β of 0.25 and a ζ of 0.6 will fulfill the accuracy requirements for the fundamental up to the fourth harmonic and will record within 15 per cent accuracy. These harmonic components will undergo a phase shift which is linear with frequency within the frequency range over which the magnitude response is satisfactory (Fig. 8). This means that the first four harmonic terms of the Fourier series will be reasonably well recorded with respect to the magnitude, and the shift along the time scale, due to phase shift, will be the same for all these components, thereby retaining the true wave form of the forcing function. For $\beta = 0.25$ a natural frequency of the indicator of 800 cycles per sec is necessary. It should be noted that the use of critical damping in this case would reduce the accuracy of amplitude recording, Fig. 2, of the paper.

If the desired indicator were to measure the mean pressure only, then β must have some value in excess of unity. This is similar to the case of a seismograph and has been covered in earlier papers.[8] For an indicator reading to oscillate less than 5 per cent, any value of ζ can be used if β is greater than 5 (natural undamped frequency is less than 40 cycles per sec).

The methods of this paper permit the critical instrument constants β and ζ to be evaluated quickly. The problem of achieving these constants in the instrument is the responsibility of the mechanical designer, but it is certain that the desired response cannot be obtained unless the graphically obtained constants β and ζ are actually realized in the completed indicator.

Thermostatic Bimetals

By S. G. ESKIN,[1] PITTSBURGH, PA., and J. R. FRITZE,[2] CHICAGO, ILL.

The use of thermostatic bimetals has increased rapidly during the last fifteen years. In this period, considerable study has been given the subject. The present paper reviews the available information dealing with the theory and practice in the application of bimetals. A lack of essential data concerning various pertinent properties of the material is indicated. Basic principles are thoroughly considered, as in the analysis of the mechanics by Professor Timoshenko and in the properties of nickel-iron alloys. However, a considerable fund of useful data is also presented in the form of curves and tables which give the properties of representative bimetals.

Introduction

DURING the last few years, the demand for automatic methods of control in regulating devices has expanded in proportion to the ease and comfort enjoyed by mankind. All concerned have increasingly realized the importance and convenience of automatic regulation and the complete satisfaction with which it may be used. Many automatic regulating devices, in which temperature can be used for controlling the regulation, depend for their successful operation on thermostatic bimetal.

In general, automatic control effects considerable savings in fuel cost. It also acts to safeguard the equipment on which it is used. Such equipment normally is left to operate unattended with full confidence that nothing is likely to happen to it. Whether in factory or home, whether to engineer or housewife, automatic control creates a peace of mind in our complex civilization which cannot otherwise be obtained.

Since the use of thermostatic bimetal has so greatly increased in recent years and is so vital to much automatic regulation, considerable work has been done on its theory and application. In this paper, the authors present a review of the available information on thermostatic bimetals which at present is scattered throughout numerous publications.

Definition of Thermostatic Bimetal

Thermostatic bimetal is a metallurgical product made from two metals which have widely different coefficients of thermal expansion and which have been firmly bonded at their face of contact. When subjected to a change in temperature, the composite material will change shape, which change of shape is utilized for control purposes. In addition to having widely different coefficients of expansion, the components must have mechanical properties suitable to minimize hysteresis and provide adequate strength. For example, lead cannot be used as a component. The two component metals are usually of equal thickness and joined together in a firm bond by brazing or welding.

History and Manufacture

Thermostatic bimetals were known for many years as laboratory curiosities. Their first known application was in balance-wheel compensators, supposed to have been used as early as 1775. As far back as 1858, Wilson obtained U. S. patent No. 24,896 covering a thermostatic bimetal. In 1863, in France, Villarceau published an analysis of thermostatic bimetal in the Annales de L'Observatoire Imperial de Paris. Wilson's patent covered a bimetal consisting of brass and steel and, since the difference in the coefficients of expansion of the two metals was not very large, the movement of the bimetal was so limited that its practical value was small. With the discovery by C. E. Guillaume in 1898–1899 of the low-expanding alloy known as "invar," consisting of 36 per cent nickel and the remainder iron, a new impetus was given the work on bimetals.

At the present time, the manufacture of bimetals is still an art rather than a science and the processes involved constitute closely guarded secrets. In one plant thermostatic bimetals were made by brazing two blocks of the component metals in a furnace in which a reducing atmosphere was maintained to prevent oxidation of the surfaces which were to be joined together. Sometimes blocks were used which were $^1/_2$ in. thick, 4 in. wide, and 12 in. long. Prior to brazing, one of the blocks was machined on both surfaces to a thickness of exactly $^1/_2$ in., while the other block was machined only on one surface. While the blocks were being brazed in the furnace, they were subjected to pressure by means of a hydraulic press to obtain a sound joint. It was very important to keep the metal surfaces clean before brazing. The blocks were usually kept in carbon paper, which prevented their oxidizing.

After the brazing operation, the exposed unfinished side of one of the blocks was machined to produce a total thickness of exactly 1 in., thereby assuring that each component was of equal thickness before reduction by rolling. The blocks were then rolled down to the desired thickness, annealing being required at a number of stages. Special rolling mills were used for this work and those in the last stages needed to be extremely accurate to finish the product to within very close tolerances.

In general, the thickness variation of bimetals cannot exceed plus or minus 0.001 in. for thickness above 0.040 in. and plus or minus $2^1/_2$ per cent below this thickness. These close tolerances are necessary to obtain uniform performance since the thickness enters into the deflection equation.

It is interesting to note that, in most cases, the final thickness of each component is very close to $^1/_2$ of the total thickness, even though in some bimetals the hardness of the separate components differs materially.

During the rolling processes, it is necessary to anneal the strips a number of times which it has been found most convenient to do by heating the strips electrically in the flat condition.

Properties of Invar and Related Alloys

As defined, thermostatic bimetals consist of two metals, having widely different coefficients of thermal expansion, which are joined together at their surfaces. The effectiveness of a given bimetal will depend upon the difference in thermal expansivity of the two components. Although numerous alloys now on the market have varying degrees of high expansivity, there are only a few alloys with thermal expansion sufficiently low for commercial use in bimetals.

In making a study of the iron-nickel series, Guillaume discovered that some of these alloys possessed low expansivity at

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

ordinary temperatures, the composition corresponding to minimum expansivity being in the vicinity of 36 per cent nickel. This alloy maintained its dimensions so nearly constant with ordinary variations in atmospheric temperature that he gave it the appropriate name "invar."

Since Guillaume's work, the entire iron-nickel series has been so explored that the engineer can now use an alloy with any desired coefficient of linear expansion between zero and that of nickel. With such a range of low-expansion alloys available, the development of bimetals followed as a matter of course.

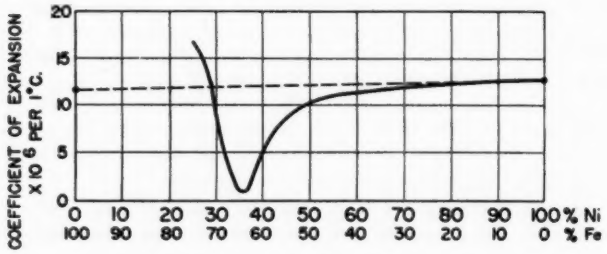

FIG. 1 TRUE COEFFICIENT OF LINEAR EXPANSION AT 20 C OF TYPICAL NICKEL-IRON ALLOYS, CONTAINING 0.4 PER CENT MANGANESE AND 0.1 PER CENT CARBON (GUILLAUME)

In Fig. 1, the coefficient of linear expansion at room temperature of iron-nickel alloys is plotted against nickel content (1).[3] The composition corresponding to the minimum point on the curve is that of invar. As the nickel content varies from the invar point the expansion coefficient increases continuously but not uniformly. Fig. 1 is representative of typical alloys containing 0.4 per cent manganese and 0.1 per cent carbon which have been cooled in air after being hot-rolled. The point on the left edge of the grid shows the value of the coefficient of expansion of pure iron as 11.9×10^{-6} per C, while on the right edge is the point giving the value of pure nickel as 13×10^{-6} per C. The dotted line on the curve connecting the values of the coefficients for pure iron and pure nickel, represents the theoretical results obtained from the law of mixture in a condition stable at low temperatures. However, the true coefficients of the various mixtures are far from following this law, as the curve shows.

The point of low expansivity shown in Fig. 1 holds true only in an alloy in which the proportion of elements other than iron and nickel are also fixed, as has been stated. The position of the minimum is changed considerably when other elements are present.

Fig. 2 shows the change in the expansivity of nickel steels produced by the addition of 1 per cent manganese or chromium.[4] The solid curves give the change in the expansivity due to the addition of the foregoing elements, while the dotted curve gives the actual expansivity of nickel steels. The effect of these additions is to increase the expansivity of invar very considerably.

All thermal or mechanical treatment given such an alloy changes its expansivity. When such an alloy has been heated and then slowly cooled, its expansivity rises. However, its expansivity falls if the cooling has been rapid. When such an alloy is cold-rolled or drawn, its expansivity will decrease still more. By first quenching and then drawing a rod to the limit, it is possible to reduce the expansivity to such an extent as to reach a negative value. Reheating at 100 C for several hours brings the value up to substantially zero. However in processing invar for bimetal applications, advantage is not taken of this property, since reheating to higher temperatures will cause its expansivity to revert to the higher minimum.

[3] Numbers in parentheses refer to the Bibliography.

[4] Bibliography (1), Fig. 24, p. 38.

In Fig. 3 are reproduced curves showing the variation of the true coefficient of linear expansion with temperature for nickel steels varying in composition from 33.8 per cent nickel to 64.8 per cent nickel.[5] The values of the coefficient of expansion are plotted against temperature. The curves show invar (35.4 per cent nickel) to be the most desirable for temperatures from 100 to 300 F. From this point up, the coefficient of expansion greatly increases, thus making such an alloy useless for bimetal applications at higher temperatures if uniform rates of movement are desired over the entire range. Fig. 3 also shows that the alloy of 42 per cent nickel, although having a considerably higher coefficient of thermal expansion than some other alloys at room temperatures, develops only a slight increase in the coefficient with an increase in the temperature and maintains a uniform coefficient over a rather wide range of temperature. It has been found that alloys of 40 and 42 per cent nickel are particularly suitable for bimetals operating in the medium and high temperature ranges and they are used extensively for this purpose.

In an attempt to explain the expansion anomaly of invar several theories were evolved. Some of the earlier views attributed the nonexpansion to an inner molecular change. Another theory expressed the view that the nonexpansibility was caused by the high nickel content bringing the temperature of the A_3 transformation to the vicinity of room temperature, which made the

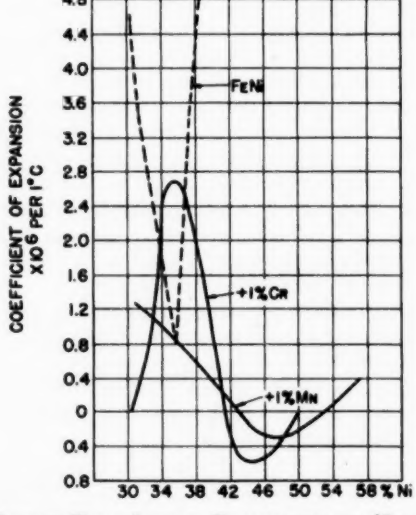

FIG. 2 EFFECT UPON LINEAR EXPANSIVITY OF NICKEL STEELS PRODUCED BY ADDING 1 PER CENT MANGANESE OR CHROMIUM (GUILLAUME)

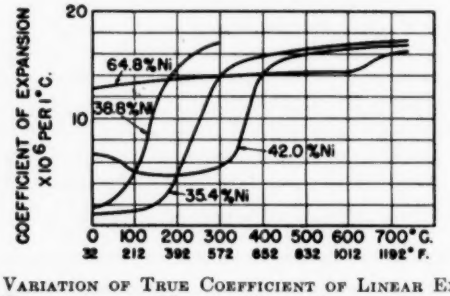

FIG. 3 VARIATION OF TRUE COEFFICIENT OF LINEAR EXPANSION WITH TEMPERATURE IN VARIOUS NICKEL STEELS (CHEVENARD)

[5] Bibliography (1), Fig. 28, p. 44.

transformation of γ into α progressive. However, it was shown that the position of Ac_3 for 36 per cent nickel is about +400 C and that of Ar_3 about —100 C, thus making impossible an equilibrium at ordinary temperature and the invar would be in a decidedly unstable condition.

Benedicks (2) in developing a theory for the expansion of invar, reasoned that the alloy was in reality a two-phase system instead of being homogeneous. He proved his theory by a careful microstudy of the alloy which led him to four conclusions:

1 Strictly local, deep-etching spots occurred regularly throughout the metal.

2 These spots were often more concentrated at definite places, at which points considerably more iron goes into solution.

3 In an unetched surface, a darker, finely divided structure could be made visible in red light.

4 The deep-etching spots of invar presented the same general characteristics as those observed in a larger proportion in a 30.5 per cent nickel alloy where a two-phase microstructure was already known to occur.

From the foregoing evidence, Benedicks concluded that invar possessed a duplex structure. As he was certain that invar contained two phases, he reasoned that, since every transformation between two phases requires a definite time for its completion, by heating invar quickly, sufficient time would not elapse for the transformation between the two phases to take place. In that event, the initial expansion would be a normal one and the coefficient would lie between that of iron (12×10^{-6}) and that of nickel (13×10^{-6}). However, when sufficient time is allowed,

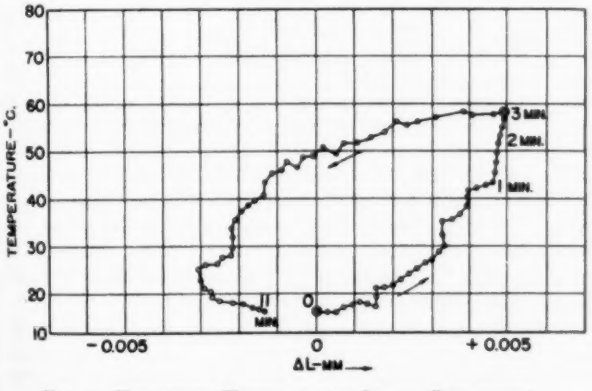

FIG. 4 EXPANSION HYSTERESIS OF INVAR (BENEDICKS)

the change caused by the two-phase transformation will become noticeable. In other words, since invar is a two-phase alloy, quick heating should show a thermal hysteresis, while if invar were a one-phase alloy, no thermal hysteresis would be detected. Consequently, the high-expansion coefficient should be expected to occur at quick temperature changes if the alloy had two phases.

To prove his theory, Benedicks conducted an experiment in which the thermal expansion of invar was measured as a function of time. He developed special equipment whereby measurements of expansions were made with an apparatus which amplified the movement 14,000 times, time being measured simultaneously.

Fig. 4 shows the results of Benedicks' experiments.[6] As expected, the thermal hysteresis was very pronounced. For a given temperature change (42 C), a sample of invar wire had an initial expansion coefficient of 13×10^{-6} or about the normal value for iron or nickel. The coefficient then diminished continually until, after 3 min heating, a considerable contraction had set in. Due to this, the resulting length diminished so much after a lapse of about 11 min as to give an expansion coefficient of 0.2×10^{-6} to 0.6×10^{-6}. This is the same magnitude established for invar by previous workers (0.4×10^{-6}).

In other words, invar upon heating first expands the same average amount as the separate constituents would expand for the same temperature change and then, after a lapse of a few minutes, contracts to show a coefficient of expansion considerably less than that of the two elements.

In applications of thermostatic bimetals where rapid rates of heating or cooling are encountered, this temperature-time hysteresis of invar may affect the deflection of bimetals by an appreciable amount. The present methods of testing bimetals result in data giving the "static" (constant-temperature-deflection) properties only. In order to detect this hysteresis effect, a "dynamic" (temperature-time-deflection) test must be used.

SUMMARY OF PROPERTIES OF INVAR

Invar is a nickel steel made either in the open hearth, crucible, or electric furnace, containing about 36 per cent nickel, 0.1 per cent carbon, and 0.5 per cent or less of manganese with negligible quantities of sulphur, phosphorus, and other elements.

It can be forged, rolled, turned, filed, and drawn into wire. It is very strong and ductile and takes a high polish, giving an excellent surface on which extremely fine lines may be ruled. It is generally ferromagnetic but becomes paramagnetic in the vicinity of 165 C.

Some of the physical properties of invar in the hot-rolled or forged conditions are given in Table 1 (3).

TABLE 1[a] PHYSICAL PROPERTIES OF INVAR

Melting point	1425 C (2600 F) (melts sharply)
Density	8 g per cc
Tensile strength	65000–85000 lb per sq in.
Yield point	40000–60000 lb per sq in.
Elastic limit	20000–30000 lb per sq in.
Elongation	30–45 per cent
Reduction in area	55–70 per cent
Scleroscope hardness	19
Brinell hardness	160
Modulus of elasticity in tension	21400000 lb per sq in.
Thermoelastic coefficient[b] (thermal coefficient of Young's modulus)	500×10^{-6} per C
Electrical resistance	75–85 microhm-cm
Thermal coefficient of electrical resistance	1.2×10^{-3} per C
Specific heat between 25–100 C	0.123 cal per g per C
Thermal conductivity 20–100 C	0.025 cal per sec per cm² per cm thickness per C temperature difference
Linear coefficient of expansion (annealed)	1.7×10^{-6} per deg C

[a] Bibliography (3).
[b] W. G. Brombacher (21) gives 480×10^{-6} per C, in range —50 to 50 C.

The amounts of carbon, manganese, and chromium present appear to exercise considerable influence on the expansion. Above 200 C, the expansion of invar is nearly that of steel.

MATERIALS FOR HIGH-EXPANDING SIDE

It has been pointed out that commercially useful bimetals must consist of two metals having widely different coefficients of thermal expansion. In the previous section, the properties of low-expansion alloys have been described in detail. Materials for the high-expansion side, in addition to having a high coefficient of expansion, should have good brazing or welding properties, should develop high elastic properties as a result of cold-working, and should have high heat-resisting properties.

Initially, brass used in combination with invar resulted in a satisfactory bimetal for low-temperature applications up to approximately 300 F. Further development led to the adoption of monel for high-temperature bimetals, but the deflection constant when using monel was rather low. To meet the requirements for high-temperature, high-deflection bimetals of good constancy,

[6] Bibliography (2), Fig. 63, p. 141.

various nickel-chrome alloys have been adopted for the high-expanding side. Representative analyses contained from 18 to 27 per cent nickel and from 3 to 11 per cent chromium.

Developments in high-temperature bimetals have been mainly in connection with the high-expanding side. Most of the patents taken out recently on bimetals of improved properties cover modifications of the high-expanding side made to obtain the desired performance.

Mechanics of Thermostatic Bimetals

Efficient and economical design of elements of mechanisms requires, first, the knowledge of stresses to which these elements will be subjected under various conditions of service; and second, data giving the physical properties of materials which may be used for these elements. This is particularly the case when controlling or indicating devices are designed, employing thermostatic bimetals, since thermal and residual stresses are present in bimetals in addition to the mechanically induced stresses. Where cost may be a primary consideration, the size of bimetal elements has to be considered, since bimetals are relatively expensive due to the involved fabrication processes. Consequently, a knowledge of the properties of bimetals and an understanding of the stress conditions in sensitive elements made of this material are essential to the most advantageous use thereof.

The first experimental investigation known to the authors of the thermal properties of bimetal strips was made in the laboratories of the General Electric Company. The results of this investigation, published in 1920 (4), were that:

(*a*) For strips, the deflection with change in temperature is given by the relation

$$D \approx \frac{(T_2 - T_1)\, L^2}{t} \qquad [1]$$

where D = deflection
$T_2 - T_1$ = change in temperature of the strip
L = length of strip
t = thickness of strip

The relation given by Equation [1] is in agreement with more recent investigations and theory.

(*b*) The deflection is not affected by changes in width of the strip. Later investigations showed this to be generally true if the width of the strip is less than 20 times its thickness. If the width of the strip is greater than this ratio, cross buckling may take place, reducing the deflection of the strip.

(*c*) The force exerted by the strip varies as the square of the temperature difference and is not affected by changes in length, a conclusion which is erroneous. A simple analysis of the mechanics involved, using the relation of Equation [1], requires that the force vary directly as the change in temperature, inversely as the strip length, directly as the square of the thickness, and directly as the width.

In 1925, S. Timoshenko published a complete analysis (5) of the mechanics of thermostatic bimetals. In this analysis, he developed, in a clear and concise manner, the equations giving the change in curvature of a bimetal strip upon a rise in temperature. The relative effects of variation in the thickness of the two components of the bimetal strip and the difference in the values of their moduli of elasticity were shown; equations being derived for thermal stresses in heated bimetallic strips. In 1934, T. A. Rich presented a similar analysis (6), using a well-planned group of diagrams for visualization of the stress conditions which produce a change in curvature of a bimetallic strip upon an increase in its temperature. The following analysis of the mechanics of bimetals follows closely the analysis of Timoshenko (5).

The method of visualization (6) introduced by Rich has been used in a modified form in Fig. 5 to show the effect of expansion stresses in the two components of an invar-brass bimetal strip on its curvature when heated from a temperature T_1 to a temperature T_2. Assuming that the two separate components of the strip are of the same length at some temperature T_1, the lengths will increase in both cases when the temperature is raised to T_2. The invar will increase in length only slightly, while the brass will expand considerably. Next, the lengths of the two components are equalized by elongating the invar strip with the tensile forces P_1, and compressing the brass strip with oppositely applied compression forces P_2. While under the action of these two sets of forces, the two separate strips are joined over their surfaces by either brazing or welding. The bimetal strip thus

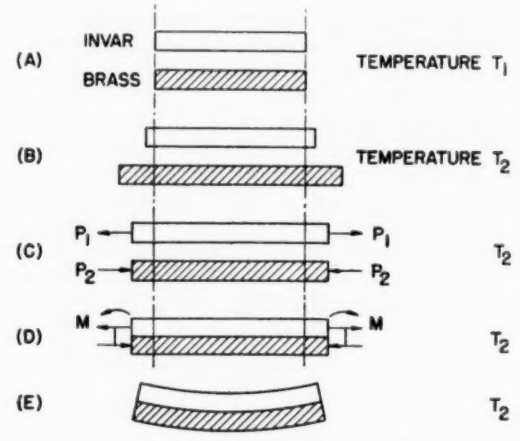

Fig. 5 Diagrams of Forces Which Produce Change in Shape of Bimetal Strip Upon Heating

formed will be straight as long as it remains under the action of the forces P_1 and P_2 applied at the ends. Upon the removal of forces P_1 and P_2, the strip will assume the form of an arc of a circle due to the action of internal moments M, which, in the straight strip, were balanced by external moments of the same magnitude, resulting from the forces P_1 and P_2.

The expression for the radius of curvature of a bimetallic strip subjected to a temperature rise of $T_2 - T_1$ deg can be obtained from the condition that, at the joint of the two components of the strip, the unit elongation is equal in each of the components. The following derivation will be carried through on the basis that the thicknesses of the two components are not equal, which makes it possible to determine the effect of differences in the relative thickness of the components. The width of the strip will be taken equal to unity, since, within certain limits, the width does not affect the deflection. The following notation will be used:

P = force
M = moment of force
α_1 = coefficient of expansion of component having low expansion
α_2 = coefficient of expansion of component having high expansion
a_1 = thickness of the low-expansion component
a_2 = thickness of the high-expansion component
E_1 = modulus of elasticity of the low-expansion component
E_2 = modulus of elasticity of the high-expansion component
I_1 = moment of inertia of the low-expansion component
I_2 = moment of inertia of the high-expansion component
t = total thickness of strip
ρ = radius of curvature, due to temperature rise $T_2 - T_1$

m = ratio of thicknesses of low- to high-expansion components

n = ratio of moduli of elasticity of low- to high-expansion components

Since no external forces are present in a freely supported heated bimetallic strip, all internal forces must be in equilibrium at every section of the strip. This condition makes it possible to establish the relations

$$P_1 = P_2 = P \quad [2]$$

and

$$M = M_1 + M_2 = \frac{Pt}{2} \quad [3]$$

Since

$$\rho = \frac{E_1 I_1}{M_1} = \frac{E_2 I_2}{M_2} \quad [4]$$

$$\frac{Pt}{2} = \frac{E_1 I_1 + E_2 I_2}{\rho} \quad [5]$$

The force P can now be eliminated from Equation [5] by determining its value from the condition that unit elongation of the two components is equal at the joint. This results in the equality

$$\alpha_1(T_2 - T_1) + \frac{P_1}{E_1 a_1} + \frac{a_1}{2\rho} = \alpha_2(T_2 - T_1) - \frac{P_2}{E_2 a_2} - \frac{a_2}{2\rho} \quad [6]$$

By substituting the value of $P_1 = P_2 = P$ from Equation [6] in Equation [5], the expression for the radius of curvature is obtained

$$\frac{1}{\rho} = \frac{(\alpha_2 - \alpha_1)(T_2 - T_1)}{\frac{t}{2} + \frac{2(E_1 I_1 + E_2 I_2)}{t}\left(\frac{1}{E_1 a_1} + \frac{1}{E_2 a_2}\right)} \quad [7]$$

Replacing moments of inertia I_1 and I_2 with their respective values $\frac{a_1^3}{12}$ and $\frac{a_2^3}{12}$, considering unit width, and taking the ratio of thicknesses equal to m and ratio of moduli of elasticity equal to n, Equation [7] reduces to the form

$$\frac{1}{\rho} = \frac{6(\alpha_2 - \alpha_1)(T_2 - T_1)(1 + m)^2}{t\left[3(1 + m)^2 + (1 + mn)\left(m^2 + \frac{1}{mn}\right)\right]} \quad [8]$$

From Equation [8], the effect of the variation in the thickness of the two components of the strip may be determined. Generally the thicknesses of the two components are the same so that $m = 1$. Equation [8] thus simplifies into more useful form

$$\frac{1}{\rho} = \frac{24(\alpha_2 - \alpha_1)(T_2 - T_1)}{t\left(14 + n + \frac{1}{n}\right)} \quad [9]$$

Equation [9] shows that the ratio n of the moduli of elasticity can vary over a rather wide range without affecting to any extent the radius of curvature of a heated bimetallic strip. In most bimetals, the moduli of elasticity of the two components are of the same order of magnitude so that the ratio n can be taken equal to unity. Equation [9] with this approximation reduces to its final form

$$\frac{1}{\rho} = \frac{3}{2}\frac{(\alpha_2 - \alpha_1)(T_2 - T_1)}{t} \quad [10]$$

From Equation [10] it is possible to determine the deflection of strips of various forms supported in a number of different manners. The case of a narrow strip supported on two knife-edges will be illustrated. Referring to Fig. 6, for the case of small deflections

$$1/\rho = 8D/L_2 \quad [11]$$

Eliminating ρ from Equations [10] and [11], the deflection at the center of a freely supported strip will be

$$D = \frac{3}{16}\frac{(\alpha_2 - \alpha_1)(T_2 - T_1)L^2}{t} \quad [12]$$

Usually the difference of the coefficients of expansion for a given pair of metals formed into a thermostatic bimetal is determined experimentally and combined with the $^3/_{16}$ factor into the deflection constant for the bimetal. The common form of the equation for the deflection of a bimetal strip is

$$D = \frac{k(T_2 - T_1)L^2}{t} \quad [13]$$

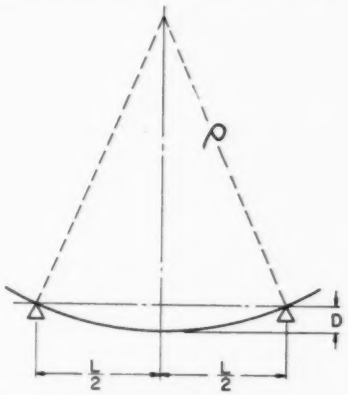

FIG. 6 RELATION OF RADIUS OF CURVATURE TO DEFLECTION OF BIMETAL STRIP

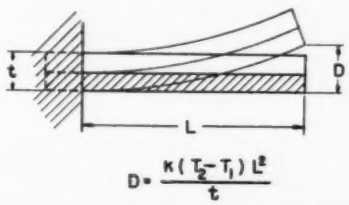

FIG. 7 DEFLECTION OF BIMETAL STRIP MOUNTED AS CANTILEVER BEAM

The deflection constant k is given in this paper for the case of a narrow strip clamped at one end and free to deflect at the other end, as shown in Fig. 7. The force necessary to return a heated bimetallic strip to its initial position is obtained by substituting in Equation [13] the value for the deflection of a cantilever beam with the force concentrated at the free end. The following relation gives the force in terms of the temperature change

$$F = \frac{c(T_2 - T_1)t^2 w}{L} \quad [14]$$

The constant c is known as the force constant and is usually determined experimentally.

STRESSES IN THERMOSTATIC BIMETALS

Bimetals free to deflect upon heating are subjected to internal stresses which at high temperatures may assume large values. If, in addition to internal stresses, bimetals are subjected to stresses due to restraints, loads, etc., their performance may be critically

FIG. 8 THERMAL STRESSES IN BIMETAL STRIP

affected if these stresses exceed the elastic limit of the material at high temperatures. Thus, it is necessary to evaluate stresses for applications involving high temperatures and loadings or restraints. In this paper, only the analysis of internal stresses due to heating will be presented. Stresses due to external forces will vary, depending upon the application. A few simple cases of combinations of internal stresses and stresses due to external forces have been analyzed by Timoshenko (5) and Rich (6).

The strains produced in a freely supported heated bimetallic strip are given in Equation [6] and consist of elongation due to thermal expansion, strains due to axial forces and strains due to bending. The stress at the joint will thus be given by the expression

$$p = P/a + Ea/2\rho \quad \ldots\ldots\ldots\ldots\ldots\ldots [15]$$

assuming equal thicknesses of the two components of the bimetallic strip and equal moduli of elasticity. For this case the value of the force P from Equation [5] is

$$P = \frac{4EI}{t\rho} = \frac{Et^2}{24\rho} \quad \ldots\ldots\ldots\ldots\ldots\ldots [16]$$

Substituting this value of the force into Equation [15] and remembering that $2a = t$ we obtain for the stress

$$p = \frac{Et}{12\rho} + \frac{Et}{4\rho} = \frac{1}{3}\frac{Et}{\rho} \quad \ldots\ldots\ldots\ldots\ldots\ldots [17]$$

The value of the radius of curvature ρ is given by Equation [10] so that the stress in terms of the difference in coefficients of expansion of the two components of the bimetal and the temperature rise will be

$$p = E/2\,(\alpha_2 - \alpha_1)\,(T_2 - T_1) \quad \ldots\ldots\ldots\ldots\ldots\ldots [18]$$

The maximum stress will occur at the joint of the two components as shown in Fig. 8. The stresses at the surfaces will be half as high as those at the joint.

For a temperature rise of 300 C (540 F) the maximum stress will have approximately the following value

$$p = \frac{20 \times 10^6}{2}\,(15 - 5) \times 10^{-6} \times 300$$

$$= 30000 \text{ lb per sq in}$$

THERMAL PROPERTIES OF THERMOSTATIC BIMETALS

The primary function of thermostatic bimetals is to produce a deflection or a rotation when heated. In many applications, such as thermometers, the bimetal does not have to do any work, except that of moving an indicating pointer, the bearings of which may have some friction. But there are other numerous applications where the bimetal is called on to do considerable work such as lifting parts of mechanisms or overcoming stored energy in spring or magnetic systems to obtain snap action. In the case of those applications where the function of the bimetal is mainly to provide an indication of the temperature change only, the deflection constant has to be considered. On the other hand, in cases where the bimetal is expected to do work, the force constant is of importance and has to be investigated to obtain a design of maximum efficiency.

The important thermal properties of a number of representative bimetals are illustrated in Fig. 9, the data for which were obtained from catalogs. The bimetals selected for this chart characterize the three general groups into which a number of commercially available bimetals may be classified, depending upon the temperature range of application, low, medium, and high. The bimetals selected for this illustration are made by the three largest manufacturers of this material in the United States: The H. A. Wilson Company, W. M. Chace Company, and General Plate Company. In the upper part of the figure, deflection and force constants are given as defined in Equations [13] and [14]. The lower part of the figure shows the temperature ranges for which the deflection is directly proportional to the temperature change and temperature ranges for which these bimetals have a maximum useful deflection. As will be noted, the three largest manufacturers of bimetals produced materials of practically identical thermal properties. Fig. 9 simplifies the problem of the selection of a bimetal for any specific purpose. By extending this chart to include all the available bimetals, it should be of value to designers of devices employing thermostatic bimetals. In addition to the bimetals selected for illustrative purposes in Fig. 9, a large number of other bimetals is available having widely different properties. Manufacturers' literature contains complete descriptions of these bimetals and gives their complete properties in full detail.

In order to prevent changes in calibration of devices using bimetals upon initial heating, it is necessary to anneal the bimetal carefully. During the rolling operation stresses are set up which can be relieved by a proper annealing procedure. High-temperature thermostatic metals should be annealed by, e.g., heating at 600 F for 1 hr if the material is to be used for any temperature below 550 F. In cases where the bimetals are to be used above 550 F, annealing should be done at a temperature 50 deg higher than the maximum temperature encountered in service. Low-temperature bimetals should be annealed at 350 F.

The deflection constant of bimetals changes as a result of annealing. Generally, different bimetals will show a varying degree of change in constant due to annealing. Manufacturers provide data on the effect of annealing on their respective products.

PHYSICAL PROPERTIES OF BIMETALS

In many applications the actuating bimetallic element is used

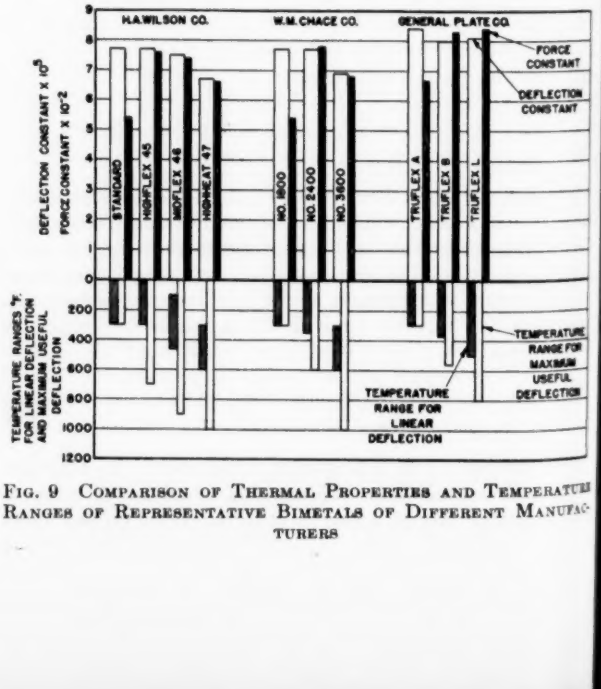

FIG. 9 COMPARISON OF THERMAL PROPERTIES AND TEMPERATURE RANGES OF REPRESENTATIVE BIMETALS OF DIFFERENT MANUFACTURERS

in a manner similar to that of a spring; it is subjected to large deflections or rotations. It is expected, and usually it is essential, that the element should return to its initial position upon the removal of the restraining forces. The design of bimetallic elements, where large deflections occur and permanency of calibration is necessary, requires the knowledge of the stresses involved and the tensile properties of the material. The authors were unable to find in the available literature on thermostatic bimetals any data on the tensile properties of bimetals. Neither have the manufacturers of bimetals published information regarding the tensile properties of their products. In some cases, the moduli of elasticity have been determined and given in the catalogs.

One of the authors, S. G. Eskin, during a study of bimetals eleven years ago, measured the tensile strength and the elastic limit of metals available at that time. The results of these measurements are given in Table 2. Bimetals available at present probably have higher tensile properties than those shown in Table 2. With the exception of the brass-invar type of bimetals, all other bimetals can be subjected to tensile stresses of the order of 70,000 lb per sq in. at room temperatures. Manufacturers generally recommend stresses not exceeding 30,000 lb per sq in. which value allows a very wide margin of safety and makes necessary the use of more bimetal than with a less conservative value. Stresses must be considerably lowered due to "creep" which occurs at high temperatures. Table 3 shows the "safe working" stresses recommended by two manufacturers at various temperatures.

For the calculation of forces exerted by bimetallic strips when subjected to deflections, the moduli of elasticity must be known. The brass-invar type of bimetal has a modulus of elasticity approximately 17,500,000 lb per sq in. and most of the medium- and high-temperature bimetals have moduli of elasticity close to 25,000,000 lb per sq in. These values are for room temperatures; at elevated temperatures, the moduli of elasticity will be lowered from 10 to 20 per cent, depending upon the metal and the temperature rise.

Hardness of bimetals varies considerably with analysis, degree of rolling, and the heat-treatment. In general, bimetals are relatively hard, the low-expansion side varying from 205 to 260 Vickers or Brinell, while the high-expansion side of medium- and high-temperature metals varies from 230 to 300 Vickers or Brinell. These hardnesses are of the same order as those of medium-hard cold-rolled spring materials.

TABLE 2 TENSILE PROPERTIES OF THERMOSTATIC METALS

Metal and treatment	Tensile strength, lb per sq in.	Elastic limit, lb per sq in.	Elongation,[a] per cent
Wilson standard, as rolled	86000	75000	5.0
Wilson standard, annealed at 350 F	86000	75000	11.1
Wilson high-temp. constant, as rolled	110000	95000	3.5
Wilson high-temp constant, annealed at 750 F	110000	85500	12.9
Chace No. 2600, annealed	109000	94000	1.1
Chace No. 2800, annealed	105000	91000	4.0

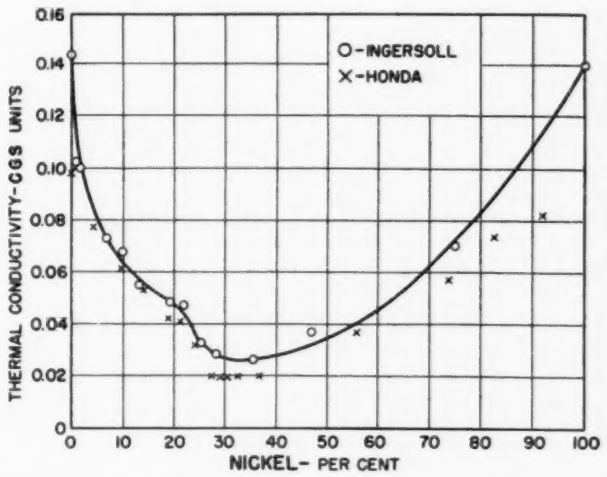

FIG. 10 THERMAL CONDUCTIVITY OF PURE NICKEL-IRON ALLOYS (INGERSOLL)

With the exception of brass-invar and some special bimetals, most high-temperature, high-deflection constant bimetals have very low thermal conductivity. This is due, first, to the fact that invar is a very poor conductor of heat. Fig. 10[7] shows that the lowest thermal conductivity of the nickel-iron alloys is in the range of their lowest thermal expansion, this latter property making them of particular value for bimetal applications. Second, heat-resisting chrome-nickel steels and similar alloys are also very poor conductors of heat. Since this is the case, most high-temperature bimetals are very poor conductors of heat. This should be borne in mind by designers of devices in which the bimetal is to be heated by conduction.

METHODS OF TEST

All manufacturers and most large users of bimetals have developed methods of test which meet their own particular requirements. While there may have been some similarity in the general test procedure, there usually existed enough difference to cause discrepancies in results when testing identical materials. To eliminate this difficulty, the American Society for Testing Materials formed Subcommittee VII, under Committee B4, to study bimetals and set up methods of test. Their latest work may be found in Tentative Standard B106–39T entitled "Tentative Method of Test for Flexivity of Thermostat Metals."

APPLICATION OF THERMOSTATIC BIMETALS

Space limitations do not allow enumeration of the very extensive uses of thermostatic bimetals. Suffice it to state that one manufacturer of bimetals lists in his catalog 60 general industrial applications and 15 automotive, aviation, and marine applications. A number of articles have been written on the application of bimetals, showing the more common forms in which bimetal elements are used; i.e., spirals, helices, disks, flat and U-shaped strips, and also special shapes to meet various unusual requirements. These references are listed in the Bibliography.

Recently two new bimetal units have been introduced which are shown in Figs. 11 and 12. The triple helix shown in Fig. 11 was developed by the Weston Electrical Instrument Corporation and is being used extensively in dial thermometers. By this method of winding a very sensitive element requiring small space is obtained. The double-helix coil shown in Fig. 12 is a product of the General Plate Company. This coil is made by winding a relatively long small diameter helix into a much shorter

helix of a considerably larger diameter. Upon heating, this helix produces a linear deflection along the main axis of the coil.

ACKNOWLEDGMENTS

The authors are indebted to W. M. Chace Company, General Plate Company, and The H. A. Wilson Company, for valuable information in regard to bimetals and their properties. They are grateful to members of the A.S.M.E. Committee on Industrial Instruments and Regulators for many helpful suggestions in connection with this paper. Their appreciation also extends to J. C. Sharp, chief engineer of the Edison General Electric Appliance Company for making the preparation of this paper possible.

Discussion

J. B. DOWDEN.[8] Fig. 11 of the paper shows a Weston triple-helix bimetal coil and a short discussion of its characteristics may be informative. These multiple-helix coils are made with 2 to 4 helices. A very stable self-supporting mechanical form is obtained by this construction so a long length of bimetal may be wound in a small space. A bimetal strip 25 in. long can be readily wound in a cylindrical form 0.32 in. diam × 0.50 in. long without any one convolution touching another. The combined axial expansion of the helices is practically canceled out since alternate helices are wound in opposite directions. Also there is no side thrust as in a spiral. The maximum accuracy in measuring the temperature of a small portion of a temperature gradient is secured by the most concentrated temperature-sensitive element as in this multiple-helix coil.

With regard to the expansion of invar, Benedicks (2) showed that invar has a two-phase structure and a hysteresis loop of thermal expansion if one considers the changes which occur during the heating cycle. His final experimental proof was obtained by taking many points rapidly on the temperature-expansion curve of an invar bar 80.05 mm (3.15 in.) long as it varied over the temperature range 16 to 58 C. He explained that the length of the invar changed as the material changed from one phase to the other and this counteracted the normal temperature-expansion change which was assumed to be that of iron or nickel, and thus produced an extremely small net linear-expansion coefficient.

Benedicks' experiment was chosen as being most suitable for demonstrating his theory regarding the expansion anomaly. To be directly applicable to the practical use of bimetals, similar tests would have to be made with a variety of heating rates and differently treated invar samples. It would seem from our experience with invar that the size and shape of the hysteresis loop are affected by the rate of heating (or cooling) and the condition of the invar as regards its treatment and composition. We find that bimetal coils with a small heat capacity, having one element of invar, when suddenly changed from one well-stirred liquid bath to another differing by 50 to 90 C, will register a maximum and final change in 10 to 25 sec, as nearly as can be read on a practical scale which is readable within 0.25 per cent. This would indicate that the effect of this hysteresis is negligible in practical applications with good material and design.

[8] Thermometer Division, Weston Electrical Instrument Corporation, Newark, N. J.

H. D. MATTHEWS.[9] Caution should be used in connection with the use of the word "annealing" in reference to thermal elements. Annealing is usually associated with softening the material by the use of elevated temperatures. The words "heat-treatment" are more commonly used rather than "annealing," and the heat-treating temperature should be a value slightly above the maximum value to which the material would be subjected while in service. An appreciable softening of the material will occur at temperatures above 1000 F and, if the material is annealed in the usual sense of the word, the strength would be considerably reduced. Heat-treatment relieves stresses which exist in the material, due to the fact that it is finished by cold-rolling. If the finished elements are formed in any way from strip material, additional stresses are set up, which are also relieved by the heat-treatment. Another very important factor in connection with heat-treatment is that the nickel steels which are used for the low expansive side of bimetals have an expansion value the magnitude of which is determined by the temperature history of the material. When bimetal is finished by cold-rolling, the nickel-steel components have minimum expansion values. During the first heating of the material, the expansion value is raised, depending upon the time of heat-treatment, as well as the exact temperature used. The increasing of the expansion coefficient of the nickel-steel side, due to heat-treatment, therefore, reduces the deflection constant of the finished bimetal element. This change in deflection constant can amount to a value as high as 10 per cent in some bimetals and, if an accuracy of 2 or 3 per cent is desired after being placed in service, it is necessary, of course, that the heat-treatment be given to the finished piece before determining the calibrated scale in the finished instrument. In ordinary air furnaces it requires from 2 to 3 hr properly to stabilize the elements rather than 1 hr, as mentioned in the paper.

In connection with the exact value of the deflection constant, this is affected to some extent by the relation of the thickness to the width of the strip. A change in deflection constant may be as great as 10 per cent if the width of the strip is out of proportion to the thickness. Therefore, for strips of unusual width or thickness, it is desirable to determine from tests the actual resulting deflection constant, as general formulas in use do not make any definite reference with respect to width.

The use of the phraseology "low- and high-temperature bimetals" is becoming more or less obsolete. Up to about 1915, the bimetal in general use was made of brass and invar, and was recommended for temperatures up to 300 F. Since that time a great advance has been made in heating elements, so that with the growth of the electrical heating industry, higher-temperature bimetals were necessary, resulting in the use of monel and nickel-chrome alloys for the high-expansive side. Due to our present wide range of temperature calibrations, the words "high- and low-temperature bimetals" are not particularly significant.

In connection with the theoretical deflection of bimetal as published in 1863 by Villarceau, it is interesting to note that, with present manufacturing methods of direct welding of bimetals, no slippage occurs. The actual deflection of the material agrees with the theoretical values.

The authors refer to other qualities of bimetals besides deflection as being of importance. These might be briefly enumerated as follows: Noncorrosive bimetal; bimetals with low and high resistivity; nonmagnetic bimetals; bimetals with small and large temperature coefficients.

Through several years of field experience, the writer has found that the stresses recommended by bimetal manufacturers referred to in Table 3 are extremely favorable for actual use in design work.

[9] Minneapolis-Honeywell Regulator Company, Minneapolis, Minn.

S. R. HOOD.[10] Based on Benedick's experiments (2) with invar, it is assumed that "where rapid rates of heating or cooling are encountered, the temperature-time hysteresis of invar may affect the deflection of bimetals by an appreciable amount." With all the progress in metallurgy since Benedick's work in 1926, there is still no adequate explanation of the thermal expansion anomaly of invar. The conclusions in Benedick's exposition are based on premises which cannot be verified by tests. In 1928, Howard Scott reported[11] no detectable hysteresis and suggested "the effect described by Benedick must therefore be attributed to temperature lag between his specimen and the temperature-measuring device."

An example of the rapidity with which thermostatic metal will respond to a change in temperature is best shown by the 5000 amperes test given by the Underwriters' Laboratory to domestic circuit breakers. One of the thermostatic metals for this application has a high expansive component with an expansion rate slightly lower than that of invar when the latter is heated to temperatures above 500 F. Therefore, at the beginning of a rapid temperature rise, if the initial expansion rate of the invar were high as stated, no deflection would result in the bimetal. However, in this device, the elapsed time between closing the circuit and its subsequent interruption is 0.010 sec. Only 0.003 to 0.004 sec is required for the deflection of the bimetal and the remaining 0.006 to 0.007 sec is consumed by the remainder of the mechanism. Therefore, it is safer to say that there is no temperature-time hysteresis in thermostatic metals but that their deflection depends upon the rate at which they are heated; they respond as any other metal to radiation, conduction, and convection.

It is also stated that, if the width is greater than 20 times the thickness, the resulting cross-buckling reduces the deflection of a strip. Actually, the deflection of a cantilever, either tapered or rectangular, increases with an increase of the width of the base when the length and thickness are held constant. This variation depends upon the width-length ratio, but for commercial sizes is of the order of 5 per cent.

R. G. WALTENBERG.[12] The writer believes this to be the first paper dealing with the properties of thermostatic bimetal presented before a technical society in this country, and the authors are to be commended for this initial step. There are some features of this paper which it appears desirable to amplify and there are some statements which may be questioned.

It should be noted that the data on the low-expanding nickel steels reviewed in this paper deal mainly with steels which have been cold-worked much less than the usual thermostatic bimetal.

It is surprising that anyone who has worked with thermostatic bimetal would accept without question Benedick's conclusions (2) on the expansion hysteresis of invar. There are millions of devices operated by thermostatic bimetal containing 36 per cent nickel steel which must respond to temperature changes in fractions of a second. The statement, that invar, when subjected to a temperature change from 16 to 58 C, expands for a few minutes at about the rate of iron or nickel, can be proved erroneous by plunging a thin strip of any of the common thermostatic bimetals into hot water. The bimetal will change form immediately. No time lag between change in form and change in temperature will be noticed.

We have attempted to determine expansion hysteresis by tests on thermometal composed of Armco iron against a 36 per cent nickel steel. The test specimen was a loosely wound spiral made

[10] Chief Engineer, W. M. Chace Company, Detroit, Mich.

[11] "Low Expansion Nickel Steels," by Howard Scott, Trans. American Society for Steel Treating, May, 1928, pp. 829–847.

[12] The H. A. Wilson Company, Newark, N. J.

from strip 0.006 in. thick, 1/8 in. wide, and 12 in. long. This would rotate 1.12 angular deg per deg F. The spiral was held at 75 F (24 C), then immersed in oil at 200 F (93 C) and the amount of rotation was automatically recorded at intervals of 0.1 sec. The results were as follows:

Time after immersion, sec	Rotation, deg
0.1	22
0.2	32
1.0	90
4.0	140
No further rotation	

During the first 0.1 sec, the coil rotated 22 deg and in 1 sec it had rotated 90 deg. These rotations correspond to temperature changes of 75 to 95 F and 75 to 155 F with the coil in equilibrium at those temperatures. The temperature change of the bimetal could not have been much faster so there could have been little, if any, time lag between the temperature of the 36 per cent nickel steel and the corresponding expansion for equilibrium conditions. Certainly there was no hysteresis of the order discussed by the authors.

The properties of the components which affect the change in curvature of a bimetal may be combined into what is known as a deflection constant and a theoretical derivation of this constant K is given. The numerical value of K can be determined by temperature-deflection observations on a suitable specimen. Consistent results may be obtained on a beam specimen tested in the manner proposed by the American Society for Testing Materials (A.S.T.M.) and cited by the author in the section, "Methods of Test." The values of K observed by this method agree closely with the values derived from a theoretical analysis based upon the properties of the components.

A rate of deflection may also be determined by observations on the temperature rotation of spirals and helices, but the rate of rotation determined in this manner may vary 20 per cent on a given bimetal, because the amount of rotation depends upon the form and relative dimensions of the bimetal strip, particularly the ratio of width to thickness. The latter method of test is mentioned because some of the deflection constants shown in Fig. 9 were obtained in this manner. A comparison with deflection constants obtained by the A.S.T.M. method leads to erroneous conclusions.

This paper contains an analysis of stresses introduced by a change in temperature of a bimetal. This analysis gives changes in stress, not the actual value of the stress. The amount and distribution of the stresses in any part depend upon its previous history. It is possible to distribute stresses advantageously in a bimetal part by a suitable heat-treatment. Heat-treatment of a finished bimetal part is necessary if uniform and unchanging performance is desired. In most applications the treatment described by the authors is sufficient. In a few applications, it is necessary to carry the assembled thermostat over the entire temperature range, above the maximum and below the minimum temperature it will meet in service.

Authors' Closure

The authors regret that due to lack of space they were unable to give a detailed description of Benedicks' ingenious apparatus for determining the manner in which invar expands on fast heating and to describe more clearly and in greater detail results of Benedicks' experiments. Mr. Hood cited the work of Howard Scott[11] in which Scott was unable to check results previously obtained by Benedicks. The authors have studied the method used by Scott and it seems that, having been designed primarily for the purpose of obtaining easily and quickly a large amount of data, Scott's apparatus may not have been particularly suited to determine an effect which requires extremely high magnification. Scott's conclusion to the effect that Benedicks' results were incorrect was based on the premise that temperature lag existed between the test specimen and the platinum rod used as a thermometer. The authors do not agree with this conclusion but, even assuming that a temperature lag may have existed, it could not have changed the general aspects of Benedicks' investigation. The fact that at the start of heating the expansion of the invar rod was of the order of the expansion of either iron or nickel indicates that the temperature-measuring arrangement was satisfactory.

The authors were quite interested in data presented by Messrs. Hood and Waltenberg, showing that bimetals made with commercial invar give a deflection immediately upon heating. It was thus assumed that, since bimetals containing invar perform in a manner which does not follow from the results of Benedicks' researches, his work was wrong. While the authors have no definite data to explain the seemingly contradictory situation which exists, they feel that these discussers have erred in arriving at their conclusions, having approached the problem too much from the commercial point of view. A careful study of Benedicks' work would show the tremendous importance of the analysis of the invar rod on its hysteresis effect. Fig. 65 in Benedicks' book (2) shows that, while an alloy containing 36 per cent nickel will have a hysteresis effect, an alloy containing 36.9 per cent nickel will not show it. This in itself may be indicative that commercial invar may not have a hysteresis effect and, therefore, bimetals with it will respond instantaneously to temperature changes, as the results of Messrs. Hood and Waltenberg's tests indicate. The authors agree with Mr. Dowden that the entire subject requires further investigation, particularly from a purely scientific point of view.

It may be pointed out that the hysteresis effect theoretically would initially reduce the deflection of a piece of bimetal containing pure invar when heated at a fast rate by about 10 per cent. This amount of reduction in deflection requires careful measurements and may not be apparent when investigated by methods described by Messrs. Hood and Waltenberg.

The authors are grateful to Mr. Matthews for amplifying their comments in regard to annealing of thermostatic bimetals. They have used the term "annealing" in a broader sense, as defined by the American Society for Testing Materials (A.S.T.M.) in Standard A119–33.

Mr. Hood brings out the point that a bimetal strip when used as a cantilever will show a greater deflection with increases in the width. While this may be true in one particular case, generally, the contrary will occur. The authors would like to refer him to an A.S.T.M. treatise,[13] which gives the following formula as a correction for cross-curvature of a freely supported strip of thermostatic bimetal, where w is width of strip and L the distance between supports $1/\{1 + (w/L)^2\}$.

Mr. Waltenberg points out that, in Fig. 9 of the paper, the deflection constants of the General Plate Company's bimetals are higher than they should be, due to the fact that the company used coils rather than strips to determine deflection constants. It was pointed out in the paper that the data for this figure were taken from catalogs of manufacturers, assuming that the manufacturers were familiar with methods for determining accurately the deflection constants of their materials. At the request of the authors, the General Plate Company rechecked the deflection constants of their bimetals shown in Fig. 9 using strips, and found them to check very closely with constants given in the figure.

While it is quite possible that erroneous results may be obtained, when deflection constants of coils of certain geometry are recalculated to obtain deflection constants for strips, it is conceivable that a coil can be used of such a size that its deflection constant would be quite comparable with that obtained with a strip.

The Significance of, and Suggested Limits for, the Stress in Pipe Lines Due to the Combined Effects of Pressure and Expansion

By D. B. ROSSHEIM[1] AND A. R. C. MARKL,[2] NEW YORK, N. Y.

This paper has been prepared as a vehicle for discussion of the following basic problems, on which agreement must be reached to establish a satisfactory working-stress basis for pipe lines:

1 Proper allowable stresses for combined pressure and expansion effects.

2 Influence of and limits for localized stresses under static and repeated loading.

3 Capacity of bolted joints to withstand expansion effects without leakage or damage to flanges, bolts, or gaskets.

4 Effect of prespringing, self-springing, creep, and yielding on operating and off-stream stresses.

An attempt has been made to point out various aspects of each issue, rather than limit the presentation to the personal views of the authors.

DURING the last decade, economic considerations and new processes in the power, oil-refinery, and chemical industries have produced a trend toward large-scale units and high operating temperatures and pressures. With the attendant increase in line sizes and wall thicknesses, the subdivision of pipe lines into convenient runs with expansion bends soon proved entirely inadequate; instead, today most piping for severe service is carefully analyzed for forces and stresses, full advantage being taken of the inherent flexibility by minimizing the number of anchors, guides, or other restraints. A natural consequence of this improved accuracy in evaluating thermal effects is the necessity for a review of stress limitations as they apply to expansion stresses alone and in combination with internal pressure. This problem has received the active consideration of Subgroup No. 3 on Expansion and Flexibility, Subcommittee No. 8 on Fabrication Details of the Code for Pressure Piping (ASA B31) who, functioning with the Applied Mechanics and Power Divisions of the A.S.M.E., have sponsored this symposium.

This paper has been prepared as a vehicle for discussion of the following basic problems, on which agreement must be reached to establish a satisfactory working-stress basis for pipe lines. An attempt has been made to point out various aspects of each issue, rather than limit the presentation to the personal views of the authors.

1 Proper allowable stresses for combined pressure and expansion effects.

2 Influence of and limits for localized stresses under static and repeated loading, such as in bends and corrugated pipe.

3 Capacity of bolted joints to withstand expansion effects without leakage or damage to flanges, bolts, or gaskets.

4 Effect of prespringing, self-springing, creep, and yielding on operating and off-stream stresses

Résumé of Simple Stresses Involved

A pipe line is essentially a pressure vessel, the internal pressure causing a radial stress at the inner face which is converted into circumferential stress on the way through the wall, leaving zero radial stress at the outer surface; at any point the sum of the radial and hoop stresses varies inversely as the radius, while their difference is the same at all points. These are the laws of Lamé which involve the assumption of a uniform or zero longitudinal stress. Following this reasoning, in a closed cylinder the longitudinal stress equals the product of the pressure and the internal area divided by the cross-sectional area of the wall, and has the same value throughout the thickness. While most runs of piping are not technically closed cylinders, the same longitudinal stresses occur due to pressure effects on the projections of elbows, there being a complete absence of longitudinal pressure stress only in straight runs between vessels of infinite rigidity and such including frictionless expansion joints.

Under temperature changes with free expansion no stresses are introduced. However, ordinarily, expansion is restrained by the equipment to which the pipe line is attached, as well as anchors, guides, solid hangers, or supports.

In calculating a line for expansion, the ends are commonly assumed completely fixed; this connotes three forces and an equal number of moments in the case of a problem in space, resulting in longitudinal bending stresses in two mutually perpendicular planes and torsional stress about the pipe axis, as well as two shears and a normal stress. With the assumption of hinged ends, the end moments reduce to zero, a condition which would be fully realized only in a frictionless ball-and-socket joint. Actually, an intermediate condition of restraint will prevail in practice due to sympathetic deflections, rotations, or distortions of the equipment to which the pipe is attached. On the other hand, cases will arise where external movements of the ends tend to increase rather than decrease their degree of fixity; in addition, guides, solid or spring supports, and hangers often inhibit free deformation of the line and thus add to the stresses.

To avoid additional complexity, the weight of the piping is commonly neglected in flexibility calculations. In heavy pipe lines spring hangers are often used to balance the dead-load effects when the line is at working temperature, and solid hangers can be similarly employed in neutral locations. Properly designed supports appear to offer the most suitable means for handling this effect, which can then be disregarded in the stress analysis of most lines.

Where piping is not insulated, the heat loss from the exposed surface produces a temperature drop through the metal thickness causing longitudinal and circumferential stresses of equal magnitude which may be evaluated by the formulas of Lorenz (1).[3] Since the outside surface is relatively colder, tensile

stresses will result there while the inner face will be in compression. Where conditions are not conducive to rapid heat loss, or where there is insulation even though of low thermal efficiency, these stresses are not of sufficient magnitude to warrant consideration.

Stress Intensifications and Their Significance

The Intensifications. A pipe being a simple cylinder is in itself free of secondary effects if we neglect nonuniform thickness and defects. However, most runs of piping contain joints, intersections, valves, and fittings, or may be fabricated into special shapes, which introduce differences in rigidity or changes in contour with the result that localized bending stresses must occur to preserve the continuity of the structure. It is our purpose to list the sources of stress intensifications, and briefly discuss their significance under static and repeated loadings.

When a pipe is curved into a torus shape (pipe bend or welding fitting), increased flexibility results under moments in the plane of the bend as a result of flattening of the cross section toward the neutral axis. The effect of this ovalization is to produce circumferential bending stresses of a relatively high order, and also to increase the longitudinal stress in proportion to the added flexibility. This distortion of the cross section is resisted at the ends of the bend by the straight tangents which probably tends to reduce the out-of-round shape of the curved pipe in this area and introduce corresponding ovalization into the straight pipe for a short distance.

All intersections or outlets involve bending effects due to the transmission of direct stress around the opening and the directional change at the sharp corners. In consideration of these effects, standard fittings are increased in thickness and branch connections are provided with reinforcement which, while lessening these influences, on the other hand introduces discontinuity effects due to the additional stiffness. The distortion produced by circumferential welds is in effect a corrugation which, with present-day welding technique, is probably so slight as to be of little or no consequence. In welds, as well as hot or cold bends or other fabricated parts, residual stresses are encountered which are probably reduced to an insignificant level where stress-relieved.

To secure added flexibility, straight and curved pipe are sometimes provided with circumferential corrugations which behave analogous to a bellows; as a result, appreciable longitudinal bending stresses are introduced while the circumferential stresses are probably reduced. Creased bends involve somewhat the same consideration. No adequate analytical analysis has been made of the stresses in corrugated or creased-bend pipe although some experimental research on full-size specimens has been done at the Navy Experimental Station at Annapolis by Dennison (2) and this has been supplemented with tests on 2-in. pipe by the M. W. Kellogg Company. Details of these tests and a summary and discussion of the Dennison and Kellogg data are given in Appendix 1.

In recent years the trend in high-pressure piping has been toward the omission of bolted joints wherever possible. On the other hand, such connections have performed satisfactorily in oil-refinery service under extremely high pressures and temperatures, involving in some cases frequent cycles of application. Pressure discontinuity stresses occur at the back of the flange due to the differences in stiffness, and bending stresses result from the bolt load. Due to the importance of this subject on pipe design, a detailed discussion is considered advisable and this has been incorporated into Appendix 2 to avoid overburdening the body of this paper.

Static Loading. It is generally conceded that, under static loading, localized stresses do not necessarily influence the failure load of a structure. Tests on plain pipe with stiffening rings usually result in failure in the pipe beyond the influence of the ring and not in the zones of high bending stress adjacent thereto. Similarly, many tests on unreinforced openings in pressure vessels and pipe have shown a bursting strength comparable with that of the plate or piping material, unless the openings were large with comparable distortion, in which case the effect is no longer local and failure is a function of the shape involved. Many structures have to undergo a considerable degree of cold working in manufacture and nevertheless give satisfactory service in the absence of stress relieving; for instance, the A.S.M.E. Pressure Vessel Code permits unstress-relieved vessels up to $1^1/_2$ in. plate thickness in proportion to the diameter for U-69 construction, and in most of these vessels the plates are formed cold. With the present safety factor of 5, many stress intensifications are countenanced such as the knuckle stress on relatively shallow dished heads and unreinforced openings of limited size. In the API-ASME Unfired Pressure Vessel Code, an attempt has been made to reduce the degree of possible stress intensification in view of the safety factor of 4, but here also these stress raisers are present although to a lesser degree.

In connection with transverse stresses in curved pipe, Hovgaard (3) has made tests which show that for low-carbon steel, with a minimum yield point of 25,000 lb per sq in., appreciable permanent set would not be obtained until the longitudinal stress as calculated with the longitudinal-stress coefficient derived by him exceeded 20,000 lb per sq in.

With bolted joints, the trend at the present time is to permit an overstress in the hub in proportion to the capacity of the flange proper to take additional stress, that is, the mean of the hub and flange stress must not exceed the allowable. Flanges calculated in this manner have given satisfactory performance on hundreds of heat exchangers. There is the additional consideration of maintaining a tight joint and this aspect is covered in Appendix 2. It would appear that with ASA standard flanges the bolt area is sufficient to transmit bending stress of ordinary magnitude without lowering the gasket pressure beyond the minimum required so that the flange and bolting would not be unduly overstressed. At the same time the bolt load is able to withstand appreciable torsion by means of friction between the gasket and flange faces although to a lesser degree than applies to bending, and caution must be exercised where high torsional moments are involved.

In so far as static stresses are concerned, it would, accordingly, seem to be entirely proper to permit principal stresses in the line which closely approach the yield point and to neglect the influence of highly localized stresses. This is particularly true where the distortion due to the stress intensification tends to result in a shape of increased stiffness.

Cyclic Loading. The problem of establishing suitable allowable stresses becomes more involved in the case of cyclic loading. There are some cases where load variations will definitely exist such as in discharge lines from reciprocating pumps or compressors; more often the number of stress cycles and magnitude of alternating stresses during operation are a matter of conjecture. There is little doubt as to the limitations that should be imposed for applications definitely involving alternating stresses. On the other hand, for average applications, the question whether and to what extent fatigue should be considered is not readily answered. This is particularly true in view of the large amount of pipe which is giving satisfactory service in proportion to the relatively few fatigue failures which have been encountered. Alternating stresses may also be a source of fatigue corrosion which might occur as accelerated attack in corrosive media, and is sometimes present in applications where the type of material is considered fully resistant.

In Appendix 1 the available data on fatigue tests of different types of tubular members are given and an attempt has been made to correlate this information to determine what relation, if any, exists between the flexibility factor and the useful life as indicated by the number of cycles to failure. It is regrettable that the information available is exceedingly meager; on the other hand, we believe that the data indicate a definite trend between the resistance to fatigue and the stress intensification, of which the flexibility factor is a rough measure.

Subzero Temperatures. Occasional failures are sometimes encountered in subzero piping and usually occur in an area of localized stress which might be only a flaw or scratch in the pipe. At the present time, resistance of materials to impact is compared on the basis of a Charpy keyhole-notch bar test, although attempts have been made to correlate similar information from tension impact tests. In the absence of a better explanation, failures of this nature are connected entirely with the composition and the physical properties of the material involved, although stress may be found to be a factor when our knowledge of this subject is further expanded.

Stresses Beyond Yield Point and Creep

The stresses in a pipe wall, being the superposition of individual effects following individual laws of distribution, are by no means uniform over the cross section or length of the pipe. The longitudinal pressure stress is assumed constant; the radial and circumferential pressure stresses are a function of the radius; the bending stresses due to expansion are a maximum at the extreme fibers and zero at the neutral axis of the section, and vary over the length of the pipe; the discontinuity stresses at flanges and intersections, the effects of ovalization in plain bends, and the stress concentrations at corrugations follow laws peculiar to themselves.

Local yielding, where overstress occurs in restricted areas, will effect a redistribution to adjacent fibers. When the load is removed, the fibers which have undergone permanent set will assume a negative strain, the net result being an increase in the elastic range of the structure. As an extreme condition, and neglecting increase in yield point due to strain hardening, it is possible to visualize a line carrying a negative strain with stresses at the yield point in the unloaded condition, and deflecting under expansion forces and moments until an equal positive strain is produced, with stresses again at the yield point but of opposite sign. This increase in elastic range could also be obtained by prespringing the bend to the yield point cold and then applying displacements twice as great as the prespringing but of reversed sign. The difference between "self-springing" and "prespringing" structures would be that in the first case the bend has undergone permanent deformation of certain areas which combine to shorten the distance between the ends while in the latter case no yielding was necessary.

Normally the entire elastic range (from the positive to the negative yield point) will not be utilized, and self-sprung bends will operate hot with a yield-point stress, with an off-stream stress somewhat lower. The same bend with 50 per cent prespringing will have equal stresses hot and cold, both below the yield point, or the prespringing could be up to the yield point with a low operating stress.

We next consider the effect of time and temperature on this problem. Prolonged loading at room temperature will result in a slightly lowered yield point, and as we go to higher temperatures the short- and long-time yield points decrease. This fact is the basis of stress relief at temperatures below the critical range, the procedure being to select a corresponding temperature and soaking time to yield all locked-up stresses to a desired level. This effect probably extends down to room temperature although the soaking time rapidly increases below 1000 F for carbon steel. The first effect of time and temperature therefore is to lower the stress-carrying capacity to the level of the long-time yield point at that temperature.

The yielding which occurs during the period just described is so-called "first-stage creep." Subsequently, the structure will continue to elongate under second-stage creep analogous to decreasing load or relaxation tests, the rate diminishing rapidly as the load is reduced. In time, a stress is reached which will be practically maintained over an extended period, which is commonly called the "relaxation strength." Consequently the second effect of time and temperature is to reduce the stress level to the relaxation strength of the material at that temperature.

With this reasoning, an unstressed bend will first assume elastic stresses proportional to the deflections; subsequently, first-stage and second-stage creep will reduce the stress to the relaxation strength, given sufficient time, so that there appears no possibility of more than initial overstress. The strain corresponding to the overstress will reappear when the off-stream condition obtains, so that the bend has self-sprung itself to this degree. For high-temperature piping, the self-springing therefore provides an expansion range from the desired stress cold to a relaxation stress of reversed sign. If the bend is presprung the period of adjustment is reduced and, if the prespringing is 100 per cent, there would be no bending stress due to expansion under operation.

It is evident that prespringing is beneficial and should be encouraged since it maintains the stresses in a more favorable range. Calculations should have for object the determination of the elastic range rather than the maximum stress. The average stress level should be considered in setting the allowable range, a procedure which also recommends itself from fatigue considerations. For high-temperature piping in the creep range the off-stream stress becomes significant as relaxation occurs, so that calculation for stresses at room temperature is indicated, since the maximum high-temperature stress is regulated at the relaxation-stress level for that temperature. This involves the room-temperature elasticity modulus.

Where the thrusts and moments in operation are significant, calculations at operating temperatures are also necessary. For these the reduced moduli of elasticity at the line temperature are used. In all calculations Poisson's ratio is assumed constant since few data are available on its variation.

Methods of Combining Stresses

A pipe line in space is subjected to flexural and torsional stresses as well as normal stresses and shears due to expansion effects in addition to circumferential, longitudinal, and radial stresses caused by pressure. This connotes a triaxial state of stress which must be correlated with the uniaxial failure stress obtained from the standard tensile test. The three better-known criterions of elastic failure (4) are the principal-stress theory (Rankine), the maximum-shear theory (Coulomb-Guest), and the maximum-shear strain-energy theory (Hencky-Mises). The first, although still widely applied on account of its simplicity, has been discredited, while the results of the other two theories agree fairly well among themselves and with elastic-limit tests. The Hencky-Mises theory is generally conceded to predict yielding most closely.

Neglecting, as of little practical significance, such effects as the radial pressure stress, the circumferential bending stress (which occurs in curved members), the normal stresses, and shears due to expansion, and assuming that stress-intensification factors, where applicable, have already been included in the stress components, the simple stresses which remain to be considered as acting in the extreme tensile fiber are

f_L = longitudinal pressure stress plus extreme-fiber stress due to bending
f_C = circumferential pressure stress
f_S = shear stress due to torsion

The resulting principal stresses can be written as

$$f_1 = \tfrac{1}{2}\{f_L + f_C + \sqrt{[4f_S^2 + (f_L - f_C)^2]}\} \quad [1]$$

$$f_2 = \tfrac{1}{2}\{f_L + f_C - \sqrt{[4f_S^2 + (f_L - f_C)^2]}\} \quad [2]$$

$$f_3 = 0$$

In the principal-stress theory, f_1 is directly compared with the allowable stress f and the two lower principal stresses are disregarded.

In the maximum-shear theory, the difference between the two extreme stresses governs. If both f_1 and f_2 are positive, the same criterion is obtained as for the principal-stress theory. If, on the other hand f_2 is negative, a different limitation applies. Accordingly, the following two conditions must be satisfied

$$f_1 = \tfrac{1}{2}\{f_L + f_C + \sqrt{[4f_S^2 + (f_L - f_C)^2]}\} \leqq f \quad [3]$$

$$f_1 - f_2 = \sqrt{[4f_S^2 + (f_L - f_C)^2]} \leqq f \quad [4]$$

Finally, for the Hencky-Mises theory, the failure criterion can be written as

$$\sqrt{(f_1^2 + f_2^2 - f_1 f_2)} = \sqrt{(3f_S^2 + f_L^2 + f_L^2 - f_L f_C)} \leqq f \quad [5]$$

With steady creep, the maximum-shear theory is commonly used, although Bailey (5) has developed a formula analogous to the Hencky-Mises equation, involving constants which are evaluated from the creep properties of each material. Before selecting a theory, some thought should be directed at criteria of failure. The stress theories mentioned predict yielding, not ultimate failure and, with extensive yielding or creep, the elastic theory no longer controls the stress distribution. In thick cylinders under pressure the Hencky-Mises theory would no doubt predict the yielding of the innermost fibers, but general yielding of the cylinder is probably best predicted by the simple stress theory, and the same is true of failure.

Where stresses are calculated according to the elastic theory, the principal-stress theory could be safely continued in use since it is in step with present-day safety factors. In fact, the Barlow or outside-radius formula of the Piping Code already penalizes piping in comparison with pressure vessels (A.S.M.E. and API-ASME Codes both use the Lamé formula which follows Rankine's theory for thick pressure vessels). If stresses are to be evaluated more closely and the safety factor reduced, then the Hencky-Mises theory should be used if yielding destroys the utility of the structure. If some yielding is not considered detrimental, then further studies and tests are desirable to correlate combined loads with rupture.

Where stresses are calculated under conditions of steady creep rather than the elastic theory, the maximum-shear theory is used by Bailey (5). Norton (6) has made creep tests on tubular specimens which indicate similar rates where the average simple circumferential stress and the simple tensile stress in the cylinder and test bar were the same, although with longer tests there are indications that the creep rate would decrease for the cylinders. Bailey establishes the ratio of diametral to tensile creep as $\frac{1}{2}$ to $\frac{1}{3}$ for the same shear stress. Norton's tests would indicate that the use of the average stress from the elastic theory (Lamé—mean of outside- and inside-diameter stresses) is entirely safe for a hydrostatic loading.

Suggested Design Assumptions and Stress Limits

Up to this point, we have been concerned with the presentation and discussion of the data and reasoning affecting the problem of pipe lines under expansion, and have found the subject to be quite complex. It is obvious that considerable simplification must be introduced in order to establish rules suitable for general application. In the following, basic assumptions for use in evaluating stresses and limits for the combined stresses resulting from pressure and expansion are suggested.

Evaluation of Expansion Thrusts and Stresses. The calculation of the line for expansion serves the purpose of establishing the range over which stresses vary rather than the maxima and minima, and accordingly consideration of the amount of prespringing required can be deferred to the end of the calculation. Since the relaxation stress definitely limits the hot condition, both prespringing and self-springing will tend to make the room-temperature condition the controlling one and calculations accordingly should be based on the elasticity modulus at room temperature rather than the reduced value in operation. Where a close estimate of thrusts in operation is desired, a simple conversion by the ratio of the hot to the cold elasticity moduli will give the required results.

Simple Stresses to Be Considered. In arriving at the principal stresses, consideration should be given in all problems to the following stresses at the outside surface of the pipe:

Simple pressure stresses:
- Circumferential
- Longitudinal

Line expansion stresses:
- Longitudinal bending (two planes)
- Torsion

Local stresses:
- Longitudinal bending in curved pipe and creased ells
- Longitudinal bending in corrugated pipe.

The radial pressure stress is zero at the outer surface. Direct stress due to the axial force and shearing stresses caused by transverse forces need be calculated only where the piping is extremely stiff. The local stresses are evaluated conveniently by using stress-intensification factors which are discussed later. We believe that the circumferential bending stress (curved pipe) and other local stress raisers, such as branch connections, may be neglected, although the use of unreinforced openings and reinforcement details should be more closely controlled where service conditions involve distinctly cyclic loading. Bolted joints will be commented on as a separate item.

Stress-Intensification Factors—Fatigue. In addition to the ordinary usage of the term "stress-intensification factor," it will here also be applied as a correction factor reducing the elastic range of stresses where cyclic loading is involved. The values given in Table 1 are suggested as a working basis.

TABLE 1 SUGGESTED STRESS-INTENSIFICATION FACTORS

Shape	Stress-intensification factor: Noncyclic stresses	Stress-intensification factor: Cyclic stresses
Plain tangents	1	1
Plain bends and creased bends	β	k
Corrugated tangents and bends	$2\frac{1}{2}$	5

Cyclic stresses would be considered to obtain where service conditions involve pulsating loads or frequent temperature changes; a closer definition should be considered, although it cannot be expected to relieve the designer entirely from a consideration of the merits of each case.

The factors for plain tangents require no comment. In the case of plain bends, k and β are the familiar Kármán or flexibility factor and Hovgaard's longitudinal stress-intensification factor, respectively. Both are applied to flexure stresses in the plane of the bend only. Creased bends are realized to occupy an inter-

mediate position between plain and corrugated pipe, but are usually classed with the former in the absence of reliable data. For straight and curved corrugated pipe, stress calculations are based on the moment of inertia of the pipe before corrugating, and the stress-intensification factor is applied to the longitudinal pressure stresses and the bending stresses. It is realized that the moment transverse to the plane of a bend can vary from pure bending to pure torsion with an intermediate range where both effects are present, and that the true state of stress is not evaluated by present methods; however, this and kindred problems can be considered as future refinements as our knowledge of this subject expands.

For noncyclic stresses, we have used the endurance properties of 20,000 cycles as a rough guide; for cyclic loading, 500,000 stress reversals have been considered as fairly representative of the endurance limit.

Combination of Stresses. If failure is associated with yielding, the Hencky-Mises theory most accurately predicts the elastic limit under combined stresses, although the maximum-shear theory offers sufficiently close results and is somewhat easier to apply. On the other hand, present-day safety factors for pressure stress are predicated on the principal stresses (Rankine theory) and, since local yielding results in stress redistribution with no loss in utility, average stresses are probably the best over-all strength index. For the present, we would favor the continued use of the principal-stress theory for calculations based on the elastic theory. Where stresses under steady creep (5) are being considered, the maximum-shear theory may be used.

Suggested Stress Limits. Using as a basis the allowable stress established in the codes for calculating pipe wall thickness under pressure, the following limits for the available stress range (already discussed as a suitable criterion for stress-deflection comparison) are suggested:

For no prespring

$$\text{Allowable stress range} = 0.75\ (S_A + S_A') \quad [6]$$

and for 50 per cent prespring

$$\text{Allowable stress range} = S_A + S_A' \quad [7]$$

where S_A = allowable stress at room temperature and S_A' = allowable stress at operating temperature, both to be introduced with their algebraic values so that they will always be numerically additive.

As an illustration, the allowable ranges obtained for combined pressure and expansion stresses in accordance with formulas [6] and [7] are listed in Table 2 for various line temperatures, as based on allowable pressure stresses for seamless low-carbon steel piping (48,000 lb per sq in. minimum ultimate tensile strength) to A.S.T.M. Specification A-106 as proposed for the ASA Code for Pressure Piping.

TABLE 2 ALLOWABLE RANGES FOR COMBINED PRESSURE AND EXPANSION STRESSES AS OBTAINED WITH FORMULAS [6] AND [7]

Line temperature, F	Allowable stress range			
	Oil-piping section		Power-piping section	
	No prespring	50% prespring	No prespring	50% prespring
Up to 650	18000	24000	14400	19200
700	17663	23550	14100	18840
750	17175	22900	13740	18300
800	16500	22000	13200	17600
850	15413	20550	12330	16440
900	14250	19000	11400	15200
950	12563	16750	10050	13400
1000	10875	14500	8700	11600

For any intermediate degree of prespring, the relation

$$\text{Allowable stress range} = (0.75 + s/2)\ (S_A + S_A') \quad [8]$$

could be used, where s = percentage of prespring expressed as a fraction = 0.50 maximum.

A higher degree of prespring than 50 per cent is beneficial at elevated temperatures in establishing the piping nearer equilibrium, thus reducing the amount of permanent set necessary to bring stresses to the relaxation limit. However, this will not affect long-time conditions, and is therefore not considered to warrant an increase in the elastic range.

Investigation of Bolted Flanged Joints. The rules suggested in the preceding apply to pipe and do not consider joints. These are properly investigated after the completion of the line calculations. We have already indicated that ASA standard flanges are probably sufficiently strong to take any bending stresses ordinarily encountered and, at least with ring-type gaskets, possess a fair resistance to torsion. In doubtful cases, and where special flanges are used, an investigation analogous to that carried out for two flanges in Appendix 2 will be indicated. The ASA flanges should probably be explored more thoroughly, and definite limits imposed on the allowable bending and torsion moments depending on the type of gasket used.

Appendix 1

TESTS OF PLAIN, CORRUGATED, AND CREASED-BEND PIPE UNDER CYCLIC VARIATION OF STRESS

Few, if any, pipes break in service due to the application of a steady load or but a few repetitions. Since the common pipe materials are quite ductile, under steady stress a small amount of yielding ordinarily will relieve highly localized overstress and effect a redistribution without hazard of failure, provided the average stress does not already exceed the yield point. Where, on the other hand, repeated stress variations are incurred due to temperature or pressure changes, or vibration, an entirely different situation arises. The application of a large number of stress cycles of sufficient amplitude will cause fatigue failure, which is accelerated by flaws in the material or surface irregularities.

The fatigue properties of a metal are characterized by the endurance limit which is the stress below which no fracture will occur even after an indefinite number of stress reversals, and is usually derived from cyclic flexure tests in which the extreme fibers are alternately subjected to maximum tensile and compressive stresses of equal magnitude. It has been found that the ratio of endurance limit to ultimate strength, or so-called endurance ratio, ranges between 40 and 50 per cent. Where stresses are not completely reversed, but vary about a definite mean, the limiting stress is raised. For a variation from zero to a maximum, an approximately 50 per cent higher limit is found comparing to between 60 and 75 per cent of the ultimate strength. A general formula covering any arbitrary stress range has been suggested by Moore and Kommers (7), as

$$S_{max} = \frac{3S_L}{2 \pm (S_{min}/S_{max})} \quad [9]$$

where S_L is the endurance limit for complete reversal, and the sign of the ratio of minimum to maximum stress is negative where both stresses act in the same sense, and positive where one is tension and the other compression. In the absence of corrosion, cycle frequency appears to have no influence on fatigue-resisting properties, the number of cycles alone controlling.

TESTS OF CORRUGATED AND CREASED-BEND PIPING BY DENNISON (2)

Realizing the advantages offered by corrugated and creased-bend piping, particularly in confined spaces, and at the same time noting the lack of concise information on the characteristics of such piping, the Bureau of Engineering of the Navy Department

authorized large-scale flexibility and fatigue tests on which Dennison (2) reports. The information contained in this valuable paper is summarized briefly below.

Standard commercial products were used, the specimens including tangents, square and offset quarter bends, and expansion U-bends of 6-in. standard-pipe-size seamless tubing of carbon steel to A.S.T.M. Specification A106–33T, with different heat-treatments. The ultimate tensile strength of the various pieces ranged from 51,500 to 72,600 lb per sq in.; the yield point, from 33,400 to 46,000 lb per sq in.; the elongation in 2 in. from 25.5

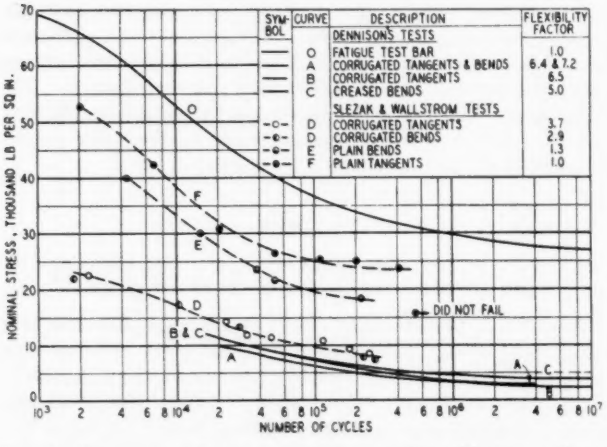

FIG. 1 ENDURANCE LIMITS FOR PIPE AND PIPE MATERIAL FROM DENNISON'S AND M. W. KELLOGG COMPANY'S DATA

to 48.0 per cent; and the reduction in area from 33.5 to 75.1 per cent.

The corrugations showed a $2^1/_2$-in. pitch and $^3/_4$-in. height. The creased bends were made on a 15-in. radius, the creases being on approximately 11 deg 15 min pitch and extending around two thirds of the circumference. For the corrugated tangents, a flexibility factor of 6.4 was established, and for the corrugated arcs, a value of 7.2 (as compared with 2.8 for plain pipe bent to the same radius); for the creased bends the flexibility factor was 5.0 (as compared with a theoretical value of 3.8 for plain pipe of the same radius).

Two types of fatigue-testing equipment were used—the one, a rotating-beam machine, producing a specific stress in the specimen while the other applied a definite deflection through a crank mounted on an eccentric. Tests made with complete stress reversal were correlated with tests where the stress ranged from zero to a maximum by application of formula [9] Moore and Kommers (7); this simply requires reducing the stresses for the second form of loading in the ratio of 2 to 3 before plotting.

Dennison's results are reproduced in the three lower curves on the fatigue graph shown in Fig. 1. Curve *A* includes corrugated arcs and tangents. Curve *B* applies to corrugated tangents of slightly different thickness and shape, and curve *C* to creased bends. Curve *O* gives the results of a standard fatigue test on the material itself which had an ultimate strength of 63,000 lb per sq in. and an endurance limit of 27,000 lb per sq in. or an endurance ratio of 0.43.

The presentation used is the customary semilogarithmic graph in which the logarithmic scale of abscissas measures the number of cycles to failure; it makes little difference whether this is defined as the ultimate fracture or the point at which slightly eccentric rotation heralds the end of a test, since the intervening interval is extremely brief. The vertical scale reads the "nominal" stress calculated for the point of fracture in accordance with the common or Rankine theory based on the pipe dimensions before the corrugations or creases are formed; in other words, the "nominal" stress equals the bending moment divided by the section modulus of the original pipe.

Space does not permit a detailed discussion of the interesting analysis and conclusions offered in Dennison's paper (2). Instead, we will conclude with a few notes on the type of failure experienced. With a single exception the corrugated pipe always failed at the crest of a corrugation, the cracking progressing from the inside out. On the other hand, the creased pipe invariably failed through the trough between two creases, with the cracks starting at the outer surface and proceeding inward; the same was true of the corrugated pipe cited previously as an exception, which was bent to a short radius so that it assumed an intermediate shape between corrugation and creasing. Dennison points out that the failure in all instances starts at the surface of sharpest curvature which is the inside of the crest for corrugated pipe and the outside of the trough for creased pipe.

TESTS OF PLAIN AND CORRUGATED PIPING BY E. J. SLEZAK AND H. WALLSTROM OF THE M. W. KELLOGG COMPANY

While Dennison has admirably achieved his immediate objective of developing information on the endurance of corrugated and creased-bend piping and correlating this with the endurance limit of the parent metal as obtained from a standard fatigue-test specimen, the authors have been reluctant to accept fully the conclusions he derives therefrom in the absence of a parallel investigation on plain piping with which a wealth of service experience is associated. It is felt that comparison with plain pipe would furnish a better yardstick for the appraisal of the limits within which corrugated or creased pipe should be stressed in actual installation. In order to supply such a basis, a simple series of tests were projected which have recently been completed by E. J. Slezak and H. Wallstrom under the authors' supervision. A description of the tests follows:

A 24-in. lathe was transformed into a rotating fatigue-testing machine of the specific-strain variety. The size of the model bends was restricted by available clearance; also, by the force applied, due to the construction of the lathe, in particular the feedscrew. Since the tests were intended to give results representative of commercial pipe and the corrugating processes used for the larger pipe cannot be properly extended to too small a diameter, 2-in. nominal-size standard-weight seamless pipe was used throughout. In setting up for a test, the model was rigidly attached to the chuck of the lathe at one end after the outstanding leg had been carefully aligned to revolve on the dead center of the tailstock. A self-aligning roller bearing attached to the cross-feed mechanism was then advanced over the end of the pipe which, owing to the difference between the size of the bearing and the pipe, was fitted with a reducing collar. Next, a predetermined amount of deflection was applied by means of the transverse feedscrew; as an additional precaution, this was checked against a dial gage mounted on the lathe bed. In order to be able to dispense with an accurate determination of the moment arm and obviate the necessity of complicated deflection calculations (made uncertain by variations in stiffness introduced by the reducing collar as well as the varying flexibility of the corrugated sections), the stress introduced by the applied deflection was directly gaged by means of an accurately calibrated Huggenberger extensometer attached to the plain pipe tangent provided at the chuck end. Both the dial and extensometer were, of course, removed before the lathe was started up. The number of revolutions was recorded by a mechanical counter attached to the shaft. The test arrangement is shown in Figs. 2, 3, and 4.

The material for the 2-in. seamless pipe was taken from stock and was manufactured to A.S.T.M. Specification A53-36. After fabrication, the pipe received a stress relief at 1150 F with

FIG. 5 MICROGRAPH OF PIPE MATERIAL USED IN M. W. KELLOGG COMPANY'S TESTS

subsequent furnace cooling to 600 F. A tensile test gave an ultimate strength of 59,400 lb per sq in., a yield point of 36,700 lb per sq in. (as obtained by the drop of the beam), and an elongation of 45.6 per cent in $1^1/_4$ in. gage length. Satisfactory bend and flattening tests were made. A micrograph is shown in Fig. 5 which reveals the pearlite nearly completely dispersed, with cementite particles well spheroidized.

A number of tests were run with each of the four types of models shown on the right-hand margin of Fig. 6; these include tangents and offset quarter bends of plain and corrugated pipe. The corrugations used had an average pitch of $1^9/_{16}$ in. and a depth of slightly over $^3/_8$ in. As was demonstrated by a series of load-deflection tests, this contour does not offer the degree of flexibility common to the larger pipe sizes, averaging 3.7 for the tangents and 2.9 for the arcs. This was the first 2-in. pipe corrugated by our shop; the flexibility probably could be improved by changing the corrugations. For the plain offset quarter bend, calculations give a flexibility factor of 1.3 and a (static) stress-intensification factor of 0.9; following the established theory, the bend actually would be stressed lower than an equivalent tangent.

The results of the fatigue tests are plotted in Fig. 1 on the same basis as Dennison's data. In addition to the average curves marked *D*, *E*, and *F*, the values of each individual test are shown by a circle, different symbols being used for each of the four test

authorized large-scale flexibility and fatigue tests on which Dennison (2) reports. The information contained in this valuable paper is summarized briefly below.

Standard commercial products were used, the specimens including tangents, square and offset quarter bends, and expansion U-bends of 6-in. standard-pipe-size seamless tubing of carbon steel to A.S.T.M. Specification A106–33T, with different heat-treatments. The ultimate tensile strength of the various pieces ranged from 51,500 to 72,600 lb per sq in.; the yield point, from 33,400 to 46,000 lb per sq in.; the elongation in 2 in. from 25.5

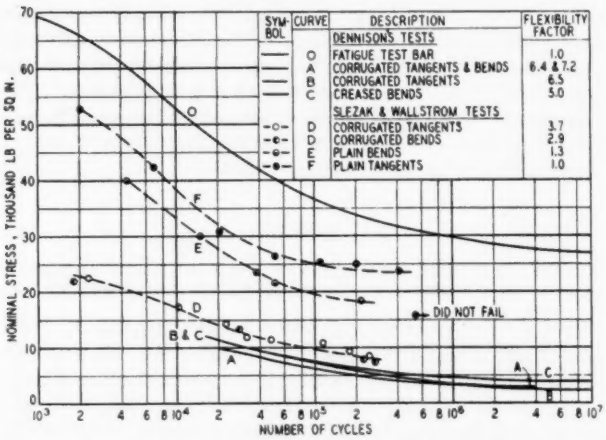

FIG. 1 ENDURANCE LIMITS FOR PIPE AND PIPE MATERIAL FROM DENNISON'S AND M. W. KELLOGG COMPANY'S DATA

to 48.0 per cent; and the reduction in area from 33.5 to 75.1 per cent.

The corrugations showed a $2^1/_2$-in. pitch and $^3/_4$-in. height. The creased bends were made on a 15-in. radius, the creases being on approximately 11 deg 15 min pitch and extending around two thirds of the circumference. For the corrugated tangents, a flexibility factor of 6.4 was established, and for the corrugated arcs, a value of 7.2 (as compared with 2.8 for plain pipe bent to the same radius); for the creased bends the flexibility factor was 5.0 (as compared with a theoretical value of 3.8 for plain pipe of the same radius).

Two types of fatigue-testing equipment were used—the one, a rotating-beam machine, producing a specific stress in the specimen while the other applied a definite deflection through a crank mounted on an eccentric. Tests made with complete stress reversal were correlated with tests where the stress ranged from zero to a maximum by application of formula [9] Moore and Kommers (7); this simply requires reducing the stresses for the second form of loading in the ratio of 2 to 3 before plotting.

Dennison's results are reproduced in the three lower curves on the fatigue graph shown in Fig. 1. Curve *A* includes corrugated arcs and tangents. Curve *B* applies to corrugated tangents of slightly different thickness and shape, and curve *C* to creased bends. Curve *O* gives the results of a standard fatigue test on the material itself which had an ultimate strength of 63,000 lb per sq in. and an endurance limit of 27,000 lb per sq in. or an endurance ratio of 0.43.

The presentation used is the customary semilogarithmic graph in which the logarithmic scale of abscissas measures the number of cycles to failure; it makes little difference whether this is defined as the ultimate fracture or the point at which slightly eccentric rotation heralds the end of a test, since the intervening interval is extremely brief. The vertical scale reads the "nominal" stress calculated for the point of fracture in accordance with the common or Rankine theory based on the pipe dimensions before the corrugations or creases are formed; in other words, the "nominal" stress equals the bending moment divided by the section modulus of the original pipe.

Space does not permit a detailed discussion of the interesting analysis and conclusions offered in Dennison's paper (2). Instead, we will conclude with a few notes on the type of failure experienced. With a single exception the corrugated pipe always failed at the crest of a corrugation, the cracking progressing from the inside out. On the other hand, the creased pipe invariably failed through the trough between two creases, with the cracks starting at the outer surface and proceeding inward; the same was true of the corrugated pipe cited previously as an exception, which was bent to a short radius so that it assumed an intermediate shape between corrugation and creasing. Dennison points out that the failure in all instances starts at the surface of sharpest curvature which is the inside of the crest for corrugated pipe and the outside of the trough for creased pipe.

TESTS OF PLAIN AND CORRUGATED PIPING BY E. J. SLEZAK AND H. WALLSTROM OF THE M. W. KELLOGG COMPANY

While Dennison has admirably achieved his immediate objective of developing information on the endurance of corrugated and creased-bend piping and correlating this with the endurance limit of the parent metal as obtained from a standard fatigue-test specimen, the authors have been reluctant to accept fully the conclusions he derives therefrom in the absence of a parallel investigation on plain piping with which a wealth of service experience is associated. It is felt that comparison with plain pipe would furnish a better yardstick for the appraisal of the limits within which corrugated or creased pipe should be stressed in actual installation. In order to supply such a basis, a simple series of tests were projected which have recently been completed by E. J. Slezak and H. Wallstrom under the authors' supervision. A description of the tests follows:

A 24-in. lathe was transformed into a rotating fatigue-testing machine of the specific-strain variety. The size of the model bends was restricted by available clearance; also, by the force applied, due to the construction of the lathe, in particular the feedscrew. Since the tests were intended to give results representative of commercial pipe and the corrugating processes used for the larger pipe cannot be properly extended to too small a diameter, 2-in. nominal-size standard-weight seamless pipe was used throughout. In setting up for a test, the model was rigidly attached to the chuck of the lathe at one end after the outstanding leg had been carefully aligned to revolve on the dead center of the tailstock. A self-aligning roller bearing attached to the cross-feed mechanism was then advanced over the end of the pipe which, owing to the difference between the size of the bearing and the pipe, was fitted with a reducing collar. Next, a predetermined amount of deflection was applied by means of the transverse feedscrew; as an additional precaution, this was checked against a dial gage mounted on the lathe bed. In order to be able to dispense with an accurate determination of the moment arm and obviate the necessity of complicated deflection calculations (made uncertain by variations in stiffness introduced by the reducing collar as well as the varying flexibility of the corrugated sections), the stress introduced by the applied deflection was directly gaged by means of an accurately calibrated Huggenberger extensometer attached to the plain pipe tangent provided at the chuck end. Both the dial and extensometer were, of course, removed before the lathe was started up. The number of revolutions was recorded by a mechanical counter attached to the shaft. The test arrangement is shown in Figs. 2, 3, and 4.

The material for the 2-in. seamless pipe was taken from stock and was manufactured to A.S.T.M. Specification A53–36. After fabrication, the pipe received a stress relief at 1150 F with

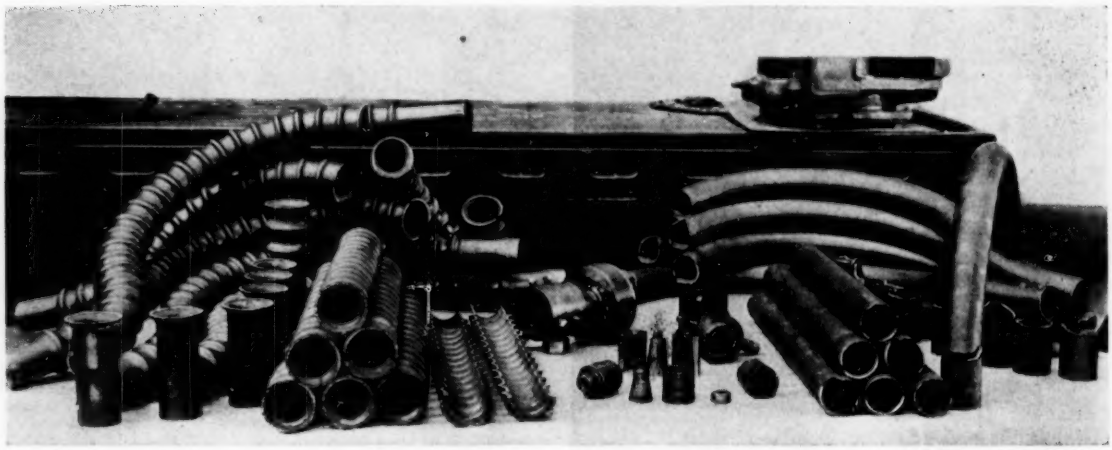

FIG. 7 FAILED SPECIMENS, PARTS OF TESTING APPARATUS, AND CORRUGATED TANGENTS CUT TO ILLUSTRATE THE SHAPE OF THE CORRUGATIONS

series; the arrow attached to the point furthermost to the right denotes a test which was discontinued without failure. Since the results for the corrugated tangents and bends were in close accord, a single curve, marked *D*, was drawn for both series. It should be noted that there is quite a reduction in endurance for the plain tangents (curve *F*) as compared with the metal itself. (Since the ultimate strength of the pipe material in the present tests is close to that obtained for the material in Dennison's tests, it is assumed that curve *O* can serve as a parameter for both investigations.) A further reduction in fatigue properties is found for the plain arcs (curve *E*) despite the reduced theoretical stress.

A short note may be in order on the type of cyclic variation of the stresses applied. While the stress curve for each point on the circumference of the tangents follows a sine wave, this is not true for the offset quarter bends shown in Fig. 6. The curves of both flexural and torsional stress are given at three points on the circumference for the location of maximum stress near the fixed end; point *A* is on the inside of the bend in the plane of its center line, and points *B* and *C*, respectively, are 45 and 90 deg distant therefrom. Only point *A* and a point diametrically opposite are subjected to stress reversal of the maximum amplitude. Despite this fact, and the added complication of a cyclic torsional stress, the corrugated arcs behaved similarly to the tangents, and the conclusion, also implied in Dennison's presentation (2), can be drawn that the highest stressed point controls failure provided average conditions are not too dissimilar.

Examination of the failed specimens of corrugated pipe confirms the observations of Dennison (2). In the case of plain pipe it was natural to expect a more jagged break since there is no sharp concentration of stresses; here surface markings and weak ligaments dictate the path of least resistance. Fig. 7 shows all the failed specimens assembled, with corrugated bends and tangents at the left, and plain bends and tangents at the right; in the center, the roller bearing, reducing collar, and various parts of the clamping devices are shown, together with the two halves of a corrugated tangent cut through longitudinally to illustrate the shape of the corrugations.

DIGEST OF RESULTS OF FATIGUE TESTS

In order to review the results of both the Navy (2) and the Kellogg tests for the purpose of formulating rules suitable for general application to the practical problem of pipe-line design,

[a] Series *A*, *B*, *C*, and *O* are Dennison's tests. Series *D*, *E*, and *F* are Kellogg's tests made by Slezak and Wallstrom.

So = Limiting stress using standard fatigue-test bar, test series *O*.
S_F = Limiting stress using plain straight pipe, test series *F*.
UTS = Ultimate tensile strength.

all the pertinent information on each separate series has been assembled in Table 3. The listing follows the order of increasing flexibility of the significant part of each bend model. Limiting stresses have been read from the original fatigue curves for 20,000, 100,000, 500,000, and 2,500,000 cycles and these are correlated to the ultimate tensile strength in column 7. In column 8, the limiting stresses obtained for the pipe for each number of cycles are compared with the corresponding stresses for the standard fatigue-test bar. In column 9, the limiting stresses for the plain bends, creased bends, and corrugated tangents and corrugated bends are correlated with those applying to the plain pipe tangents.

A relationship can be established between the flexibility factor and the endurance of the material, which appears to be independent of the source of increased flexibility (whether flattening of the cross section, as in the case of plain bends, or partial or complete corrugation, as in the case of creased or corrugated pipe). This will be illustrated by reference to the 20,000-cycle and 500,000-cycle stresses, for which the following formulas permit a reasonably close estimate of the limiting stresses for pipe of varying flexibility. For 20,000 cycles

$$S_{k20} = S_{20}/\sqrt[3]{k^2} \quad \ldots\ldots [10]$$

and for 500,000 cycles

$$S_{k500} = S_{500}/k \quad \ldots\ldots [11]$$

where k is the flexibility factor of the pipe; S_{20} and S_{500} are the "virtual" endurance limits, or limiting stresses for pipe of unit flexibility at 20,000 and 500,000 cycles, respectively; and S_{k20} and S_{k500} are the "virtual" endurance limits for pipe of a flexibility factor k at 20,000 and 500,000 cycles, respectively. Values computed in accordance with formulas [10] and [11] are compared in Table 4 with those obtained by test.

If the exponents of k were changed to 0.65 and 1.04, respectively, for the 20,000- and 500,000-cycle stresses, the difference would be reduced considerably. However, formulas [10] and [11] should be viewed as rough guides in the interpretation and extrapolation of these tests only, and additional refinement appears unwarranted in view of the meager basis on which they are founded.

In the tests, the endurance of the plain tangents was between two thirds and three quarters that of the test bar and, by introducing a factor approximately 0.7, an estimate of the virtual endurance limit for pipe of any flexibility can be derived from the fatigue characteristics of the material.

TABLE 4 ENDURANCE LIMITS COMPUTED FROM FORMULAS [10] AND [11] COMPARED WITH TEST RESULTS

Flexibility factor, k	Virtual endurance limit S_{k20}			Virtual endurance limit S_{k500}		
	Computed	From test	Difference, % of computed stress	Computed	From test	Difference, % of computed stress

Appendix 2

THE PROBLEM OF BOLTED FLANGED CONNECTIONS

A study of the effects on bolted flanged joints of eccentric loading introduced by the expansion of a pipe line cannot be properly undertaken without a reasonably correct understanding of the fundamental problem of the action of flange and gasket under the bolt load required to produce a tight seal under internal pressure. While thousands of bolted flanged connections are in continuous successful use in an ever-widening variety of services, surprisingly little precise knowledge of the stresses and deformations of the component parts is available. It is only the recent trend toward higher temperatures and pressures in the steam power plants and chemical industries which has forced a reconsideration of the entire basis of design and lent impetus to research which is already yielding valuable returns. We refer in particular to the work of the British Pipe Flanges Research Committee (8) which operates on a broad basis, to the improved

approaches to flange design published by Waters, Wesstrom, Rossheim, and Williams (9), as well as Bailey's (10) contribution to our understanding of the behavior of flanges under conditions of creep, and the many individual investigations made in recent years here and abroad with reference to the performance of gaskets.

The complexity of the problem involved will be apparent from a consideration of the variables. In general, the shape of a flange does not readily lend itself to accurate mathematical analysis, particularly since the method of its attachment to the pipe, by welding, rolling, screwing, or otherwise, affects the stress distribution. The effects of bolt holes and the gasket groove are difficult to include. Serious uncertainties are introduced by the necessity of making assumptions for the locations of the bolt and gasket reactions which depend on the stiffness of the flange. While a formidable number of test results are available on a wide variety of gasket shapes and materials, no entirely satisfactory correlation of the data has yet been presented and opinions regarding the gasket contact pressures required to seal a joint under varying conditions show considerable divergence. The share of the elastic deformation of the compound system assumed by the bolting depends on the material, size, length, and spacing of the bolts, on the development of the shank and type of thread used, on the material and height of the nut and, to a small extent, even on the compressibility of the washer. Allowable design stresses have to consider the yield strength as well as the fatigue properties and are affected by the manufacture and heat-treatment of the steel.

Conditions are further aggravated in the case of hot lines where the problems of creep and relaxation make it extremely difficult, if at all possible, to develop an accurate analysis of the behavior of a bolted joint. In addition, the different expansions of the component parts must receive consideration and this, in turn, presupposes at least an approximate knowledge of the temperatures assumed by the flange, bolting, and gasket in operation and during starting up and shutting down. The question arises whether flanges should be insulated. If lagging is provided, the metal temperatures can be maintained more nearly uniform and sudden failure due to change in operating or atmospheric conditions or thermal shock is less likely to occur; on the other hand, the life of an uninsulated connection will probably be greater due to the reduced temperatures.

In view of the multiplicity of considerations entering into the design of an ordinary bolted flanged connection it is comforting to be able to state that, in general, a few relatively simple rules supported by experience and good judgment will enable a designer to proportion the parts in such a way that the joint will perform satisfactorily in operation, at any rate under conditions which do not involve excessive temperatures or rapid fluctuations.

Both the A.S.M.E. Code and the API-ASME Code for Unfired Pressure Vessels have adopted the flange formulas developed by Waters and Taylor. An extension of the method to include shear and to cover tapered hubs has been published recently (9); this new derivation also permits the evaluation of the effects of internal pressure by a secondary investigation while the earlier analysis restricted itself entirely to the bolt moment. While the present paper is not concerned with flange design proper, a brief exposition of certain phases will be necessary in order to show how the effects of expansion of a pipe line on the bolted flanged connection can be taken into account.

The following forms of loading must be considered in the design of bolting for a flange:

1 The internal pressure load, which is usually taken over the circular area bounded by the center line of the gasket.

2 The minimum load required to set the gasket in the cold condition. It has been found that, up to certain pressures, the force required to maintain a tight seal is independent of the internal fluid or gas pressure; this limit varies for different materials and shapes of gasket and also depends on the flange facing. The minimum contact load can be interpreted as the load required to establish line contact around the circumference for the harder gaskets; for the softer packings, it probably signals a sufficiently intimate contact over a larger area so that the gap between the gasket and flange faces is reduced to such minute dimensions that crossflow cannot occur.

3 The minimum load required to maintain the joint tight under operating pressures exceeding the limit mentioned in 2. For such pressures the required gasket force appears to be a direct function of the internal pressure. The value of the gasket-contact ratio is dependent on the type of gasket and facing.

4 A sufficient additional compressive load to allow for the reduction in gasket pressure caused at the joint by direct tensile stresses and tensile bending stresses due to thermal expansion of the line, the fundamental idea being that this pressure under no circumstances can be allowed to drop below the minimum required to preserve a tight joint.

5 A sufficient total load to prevent rotation in the joints due to torsional stresses induced by the line expansion. These are taken in friction which is a direct function of the bolt load.

6 An adequate initial load to compensate for yielding of any part of the assembly due to suddenly applied pressure or temperature loads.

7 For service at elevated temperatures a design load which does not stress the component parts beyond their relaxation strength, so that the required gasket compression will be maintained for the desired period.

While the conservation of a sufficiently high gasket load under all conditions of operation is the primary concern in the design of the bolting, care should be taken to proportion the gasket so that overpulling of the bolts or the application of expansion thrusts or compressive bending stresses will not lead to its failure by crushing. Furthermore, the effect of internal pressure on the gasket in producing excessive hoop stresses and the danger of blowouts must be considered. The flanges of course, must be able to withstand the maximum bolt moment exerted, and, while ordinary allowable stresses need not apply, the proportions must be such as to prevent excessive distortion.

Disregarding the effects of line expansion, cold design stresses between 20,000 and 25,000 lb per sq in. have been used rather widely in this country for alloy-steel bolting; these are stresses maintained in operation, although the initial stresses required to set the gasket are very often much higher. For elevated temperatures where creep controls, stresses producing 1 per cent strain in 100,000 hours are applied; as determined by investigators in this country, such stresses will remain below the relaxation strength. In England, Bailey (10) from a test on carbon-molybdenum steel arrives at the conclusion that the relaxation limit for 100,000 hours corresponds to the stress causing 0.1 per cent creep in that period (11). For the flanges, the applicable code stresses are used except that it is not uncommon to allow a 50 per cent higher limit for the hub stresses which are of a highly local nature and easily relieved.

With the introduction of a more accurate analysis of a stress problem, it is common practice to reconsider safety factors. In the past, flanges have withstood stresses in excess of those calculated considering the bolt load required for tightness only, and accordingly a precedent is established for permitting higher design stresses where the effects of line expansion are included. Before we suggest any new stress limits, it will be in order to form an estimate of the magnitude of the hitherto uncalculated expansion stresses in a bolted flanged connection.

A review of a large number of stress calculations involving

TABLE 5 RESULTS OF INVESTIGATION ON TWO ASA WELDING NECK FLANGES WITH STANDARD RING JOINTS FOR THE CONDITION WHERE THE BENDING MOMENT DUE TO EXPANSION IS HIGH ENOUGH TO PRODUCE A STRESS OF 15000 LB PER SQ IN. IN THE ADJOINING PIPING

	Pipe data:		
1	Line size, in.	4	24
2	Flange series, lb	300	1500
3	Pipe schedule	40	160
4	Bending moment producing a stress of 15000 lb per sq in. in the pipe, in-lb	48200	11730000
	Limits for unit gasket compression based on gross width of ring:		
5	Minimum pressure required to set the gasket with no internal pressure (1/8 ring width × 18000 lb per sq in. yield point), lb per sq in.	2250	2250
6	Minimum pressure required to maintain tightness under operation (1/4 ring width × 5.5 × internal pressure), lb per sq in.	413	2063
7	Maximum pressure to prevent crushing gasket, lb per sq in.	30000	30000
	Bolt stresses for various conditions:		
8	Minimum stress required to set gasket with no internal pressure, lb per sq in.	7500	1900
9	Minimum stress to hold internal pressure plus gasket pressure under operation, lb per sq in.	4750	7950
10	Stress required to withstand moment causing a stress of 15000 lb per sq in. in the pipe, lb per sq in.	10100	8600
11	Minimum stress required for tightness (item 8 or 9, whichever is higher), lb per sq in.	7500	7950
12	Minimum stress required for tightness and bending moment (item 10 + item 11), lb per sq in.	17600	16550
13	Probable limit to which bolt may be pulled without control, lb per sq in.	31800	20000
	Flange stresses for various conditions:		
	For minimum bolt load required for tightness (item 11):		
14	Longitudinal hub stress, lb per sq in.	3300	5300
15	Radial flange stress, lb per sq in.	3700	6500
16	Tangential flange stress, lb per sq in.	2800	6200
	For minimum bolt load for tightness and bending moment (item 12):		
17	Longitudinal hub stress, lb per sq in.	6900	10000
18	Radial flange stress, lb per sq in.	7900	12200
19	Tangential flange stress, lb per sq in.	5900	11700
	For condition where bolts are pulled up to limit (item 13):		
20	Longitudinal hub stress, lb per sq in.	12000	11800
21	Radial flange stress, lb per sq in.	13600	14400
22	Tangential flange stress, lb per sq in.	10300	13900
	Maximum gasket compression on gross width:		
23	For minimum bolt load required for tightness (item 11), lb per sq in.	2250	9500
24	For minimum bolt load for tightness and bending moment (item 12), lb per sq in.	5300	19750
25	For condition where bolts are pulled up to limit (item 13), lb per sq in.	9550	23800

pipe lines connecting to pumps gave the following averages for the end reactions:

Vertical thrust plus weight of pump riser including valves and fittings, lb $= 3.25\ D^3$

Lateral thrust in any direction, lb $= 1.50\ D^3$

Bending or torsional moment, in-lb $= 60\ D^3$

where D equals the outside pipe diameter increased by 3 in. The corresponding bending or torsional stresses in the pipe due to expansion ranged from 1000 to 6000 lb per sq in. It has been our practice to limit the total stresses in pipe lines to 1.5 times the allowable code stresses, one third of which is absorbed by the longitudinal pressure stress; accordingly, some carbon-steel installations below 750 F based on the API-ASME Code with material of 60,000 lb per sq in. ultimate strength must have supported up to 15,000 lb per sq in. bending stress due to expansion. Since the ends of a line usually are locations of maximum stress and normally will be flanged for attachment to a nozzle provided on the vessel, there will probably always be one or two flanges which are subject to the maximum moment.

In order to appraise conditions at a joint under such circumstances, two ASA welding neck flanges with standard ring joints will be investigated for the conditions where the bending moment due to expansion is high enough to produce 15,000 pounds per square inch stress in the adjoining piping; the data are given in Table 5. It will be noted by referring to Tables 6 and 7 that the examples selected are fairly representative of the range of conditions met with in ASA flanges.

[a] Root areas of bolts are computed for V-threads with 8 threads per inch, minimum. In calculating the section modulus of the bolting, it has been considered permissible to assume the bolt area uniformly distributed over the bolt circle.

[b] The approximate formulas $A = 2\pi rw$ and $SM = \pi r^2 w$ have been used in calculating the ring-gasket areas and section moduli, respectively, where r = radius of the pitch circle and w = gross width of the ring.

[c] Proposed.

TABLE 8 INVESTIGATION OF ASA FLANGES (TABLE 5) EXTENDED TO COVER TORSION EQUAL IN MAGNITUDE TO THE BENDING MOMENTS INVESTIGATED[a]

Line size, in.	4	24
Flange series, lb	300	1500
Pipe schedule	40	160
Torsion moment, in-lb	48200	11730000
Vertical thrust required $P = M/(f \times$ gasket radius), lb	82500	4290000
Corresponding bolt stress = (P/bolt area), lb per sq in.	34000	30600
Required minimum gasket compression = P/gasket area, lb per sq in.	10200	36500

[a] A friction factor of $f = 0.20$ is assumed.

This investigation would tend to show that the ASA flanges, at least where used with ring joints, have a sufficient margin of strength in all parts to take considerable bending moments without danger of overstress. In both examples, the check against overpulling of bolts, to which the authors subject each flange as a routine precaution, gives higher values than the computation including an unusually high bending moment. It is a well-

known fact that ASA flanges are overbolted in order to allow for high gasket contact ratios required on some forms of gaskets. This is no longer true of the proposed 4000-lb standard, which is intended for ring joints only or alternate gaskets requiring a low sealing force. The 4-in. 4000-lb size actually has the same bolting as the 4-in. 1500-lb size, and correspondingly the margin for bending stresses is considerably reduced; also, the gross ring area is by no means in proportion to the rating, and accordingly caution must be exercised in the use of such flanges where line stresses are high.

Where torsion moments are applied to a joint and no mechanical means for absorbing them are provided, these must be transmitted through friction between the gasket and the flange faces. Our study of representative ASA flanges was extended to cover torsion equal in magnitude to the bending moments investigated; the data are given in Table 8. A friction factor of $f = 0.20$ is assumed.

Neither flange can be considered adequate to withstand the torsional moments applied. While it is true that the assumptions used are extremes, the investigation clearly indicates the need for caution where torsion is concerned. This is even more true for gaskets other than metal rings with a lower degree of rigidity particularly such that suffer from abrasion.

Similar lines of reasoning can also be applied to shear effects and pipe thrusts, although it is believed that neither ordinarily will be significant.

Concerning the calculation of flanges under the conditions of creep and relaxation obtaining at elevated temperatures, the reader is referred to an interesting article by Bailey (10). Unfortunately, a large degree of uncertainty attaches to the creep constants and temperature assumptions which must be made, and present experience at high temperatures is insufficient to permit of correlating theory and practice. As far as superimposed stresses due to line expansion are concerned, Bailey suggests that these tend to diminish rapidly and need not be considered in connection with the ultimate steam tightness of the joint.

Discussion

WILLIAM HOVGAARD.[4] This paper is very suggestive and affords a good basis for a discussion of the many difficult questions which arise in the design of pipe lines. The problem presented may be summarized as that of the determination of factors of safety for pipe stresses.

It is necessary to distinguish between the states of stress which exist locally and those which exist generally throughout the pipe. In the former class belong the longitudinal stresses denoted by f_L in the paper and stresses localized near the ends of the pipe. These stresses combine with hoop stresses and torsional stresses, creating a state of stress which should not be allowed to approach the condition of plasticity. If flow does occur locally, a permanent set is liable to occur, although the safety of the pipe may not be endangered. It is believed that this state of stress is best measured by the Hencky-Mises formula, given as Equation [5] in the paper. The expression on the left side of the equation does not represent an actually existing stress, although it has the dimensions of a stress. It is simply a function of the component stresses, so constructed that when it reaches the value of the yield point, flow of the material will occur. This function the writer has called the "equivalent stress" in various papers, and has denoted it by f_{eq}. It is suggested that the equivalent stress should not exceed one half of the stress at the yield point; that is, the factor of safety, in case of the stresses here under consideration, should be at least 2 relative to the yield point. It is found that then with all ordinary values of the circumferential or hoop stress, f_C, the longitudinal stress, f_L, can be from 1000 to 2000 lb per sq in. higher than the equivalent stress.

In the latter class of stresses, which are general over the entire pipe, belongs the hoop stress, f_C, caused by the steam pressures. It has a special significance, because it cannot be relieved by a change of form of the pipe or by a readjustment of the strains. When the pressure is associated with high temperatures, creep has to be considered and, due to our incomplete knowledge of this phenomenon, it is advisable to use a relatively high factor of safety. Hitherto, it appears that, in the case of the hoop stress, the factor of safety has been ordinarily related to the ultimate strength. This was quite satisfactory so long as the ratio between the ultimate and the yield strength was fairly constant, but in modern alloy steels, where this ratio may vary widely, it seems safer and more rational to relate this factor to the yield point, which determines incipient breakdown. It is of interest to note that Lloyd's Rules, for instance, prescribe a thickness of the pipe wall, which, including the additional increment of 0.12 in., gives a factor of safety of about 7 relative to a yield point at 500 F of 27,000 lb per sq in. This is obtained, assuming a steam pressure of 400 lb per sq in., a wall thickness of 0.319 in., and a hoop stress of 3750 lb per sq in. An analysis of other rules representing ordinary practice seems to indicate that the factor of safety of the hoop or "bursting" stress relative to the yield point should not fall below 6.

A. E. R. DE JONGE.[5] The authors should be highly commended

[4] Professor Emeritus, Massachusetts Institute of Technology; address, Brooklyn, N. Y. Mem. A.S.M.E.

[5] Mechanical Engineer, The Babcock & Wilcox Company, New York, N. Y. Mem. A.S.M.E.

for having undertaken the arduous task of outlining the problems encountered in determining the stresses in pipe lines. As their paper is intended to be a "vehicle for discussion" of these problems to supply material for a new piping code, it offers an occasion to stress the difficulties of this undertaking.

As the total stress can only be arrived at by a combination of the individual stresses, the latter have first to be considered separately before they can be combined.

With regard to internal pressure, the Lamé formula for thick-walled cylinders is probably the best to use as it gives results which agree fairly well with practical measurements. It might be said that an attempt should be made to obtain uniformity in all codes concerning pressure vessels with respect to the use of this formula.

Expansion stresses, on the other hand, provide a very different problem. First, the fundamental assumption made in their determination is that the ends of the pipe line are rigidly fixed. This assumption, however, is rarely if ever correct. It is therefore necessary to begin with the investigation of the rigidity of the various apparatus connected by pipe lines and to classify them with regard to the "degree of fixedness" assigning definite percentage values or percentage limits to them. For instance, a pressure vessel supported on a high gantry will offer but a slight degree of fixedness in the horizontal plane while it must be considered more or less rigid in the vertical direction. This investigation and classification has not only to be extended to linear displacements, but also to rotations.

However, even when disregarding all considerations of partly fixed ends, the problem of calculating stresses in pipe lines in space is by no means solved as yet with anything approaching accuracy. The theoretical values for the deflections and rotations in pipe bends, subjected to torsion, transverse bending, and transverse forces, do not check with the test results, differing in some cases by more than 50 per cent, the error being systematic, i.e., always in the same direction. Even straight pipe lines do not seem to follow the laws of ordinary beams any better. Thus, compound pipe lines in space exhibit quite different flexibilities from those usually assumed in the calculations, although it should be stated that these values could be allowed for in the calculations if they were known with any degree of certainty. Dead weight and local stresses at hangers, anchors, etc., are usually neglected and so are temperature stresses. In heavy pipe lines, however, deadweight should not be neglected. With all this uncertainty, it does not seem to be of much use to lay down fixed rules for maximum stresses.

Fortunately, pipe lines are generally more flexible than assumed, and this factor works in the direction of lower stresses. In addition, should overstressing occur, the usual materials for pipe lines exhibit the useful property of ductility and thus automatically lower the stresses in the pipe line by local yielding. The same holds with respect to creep. Prespringing is another uncertain factor, and so is the fact that load variations or load alternations occur. In combining the stresses obtained for these individual effects, it is clear that the end result will be even more uncertain.

Taking all these factors into consideration, the fixing of stress limits can only be regarded as a very rough approximation which of necessity must prove to be highly controversial. The actual approach to the subject obviously lies in investigating all of the different factors separately and more carefully than has hitherto been done, to fix for each one the limits within which theory and measured results agree, and then to compound these limit factors into a common limit factor. It is apparent that, for this purpose, experimental investigations on the flexibility of actual large-size pipe lines are required, and while such investigations have probably been made by individual firms, very little has been published regarding the results of such experiments. Only by coordinating theoretical calculations and experimental investigations is it possible to arrive at any data which may be regarded as approaching reality and thus be of value. By using such an approach to this complicated problem, the usual safety factor will no longer be a "factor of ignorance" in so far as pipe lines are concerned.

JOSEPH MARIN.[6] Considering the condition of static loading, the authors' Equation [5] includes the stresses due to bending, torsion, and the longitudinal and circumferential stresses due to pressure. It is of interest to study, in addition, the radial stress and to determine the influence of the various forces in producing failure. If the radial stress f_3 is included as shown in Fig. 8 of this

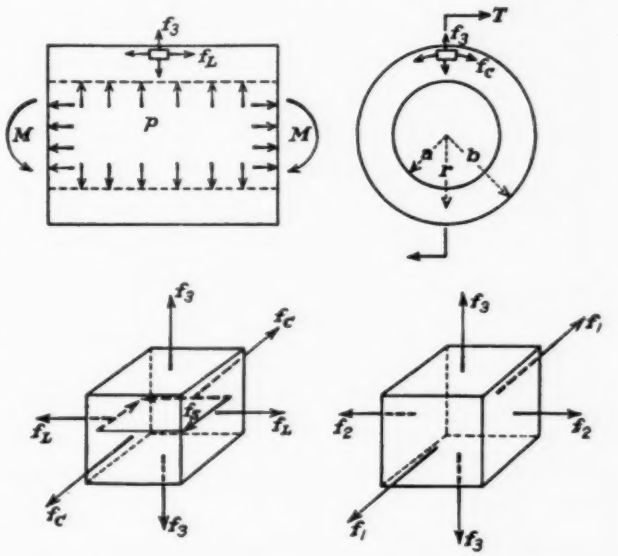

FIG. 8 THREE-DIMENSIONAL ASPECT OF STRESS PROBLEM WITH RADIAL STRESS INCLUDED IN ADDITION TO STRESSES DUE TO BENDING, TORSION, AND PRESSURE

discussion, the problem becomes a three-dimensional one and the distortion-energy theory of failure becomes

$$f_1^2 + f_2^2 + f_3^2 - f_1f_2 - f_2f_3 - f_1f_3 = f^2 \quad [11]$$

where f_1, f_2, and f_3 are the principal stresses.

Designating f_L, f_C, and f_S as the longitudinal stress, circumferential-pressure stress, and shear stress, respectively, the principal stresses f_1 and f_2 are

$$f_1 = \tfrac{1}{2}[f_L + f_C + \sqrt{(f_L - f_C)^2 + 4f_S^2}] \quad [13]$$

and

$$f_2 = \tfrac{1}{2}[f_L + f_C - \sqrt{(f_L - f_C)^2 + 4f_S^2}] \quad [14]$$

Placing values of f_1 and f_2 from Equations [13] and [14] in [12]

$$f_L^2 + f_C^2 - f_Lf_C + 3f_S^2 + f_3(f_3 - f_L - f_C) = f^2 \quad [15]$$

Referring to Fig. 8 the components of stress are

$$f_S = k_1Tr, \quad f_L = k_2p + 2k_1Mr, \quad f_C = k_2p\left(1 + \frac{b^2}{r^2}\right)$$

$$f_3 = k_2p\left(1 - \frac{b^2}{r^2}\right) \quad [16]$$

[6] Associate Professor of Civil Engineering, Armour Institute of Technology, Chicago, Ill. Mem. A.S.M.E.

where $k_1 = \dfrac{2}{\pi\,(b^4 - a^4)}$ and $k_2 = \left(\dfrac{a^2}{b^2 - a^2}\right)$ . . . . [17]

Substituting values of the stress components from Equation [16] in Equation [15]

$$3k_2^2p^2\frac{b^4}{a^4} + 4k_1^2M^2r^2 + 3k_1^2r^2T^2 = f^2 \text{ . . . . . [18]}$$

The left side of Equation [18] is proportional to the distortion energy for an element at a distance r from the center. The critical element at which failure occurs will be for the maximum value

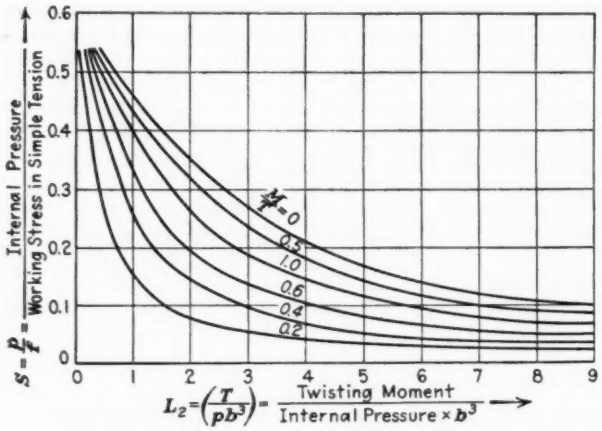

FIG. 9 VALUES OF LOAD RATIO S PLOTTED VERSUS LOAD RATIO L_2 FOR VARIOUS VALUES OF TWISTING MOMENT TO BENDING MOMENT AS A PARAMETER

of the distortion energy or for $r = a$. Then Equation [18] becomes

$$3k_2^2p^2\frac{b^4}{a^4} + 4k_1^2M^2b^2 + 3k_1^2b^2T^2 = f^2 \text{ . . . . . [19]}$$

Substituting values of k_1 and k_2 from Equation [17] in Equation [19]

$$\frac{3p^2}{(1-R^2)^2} + \frac{4(4M^2 + 3T^2)}{\pi^2b^6(1-R^4)^2} = f^2 \text{ . . . . . [20]}$$

where $R = \dfrac{a}{b}$.

Equation [20] gives a relation between the loads, dimensions, and the stress f in simple tension at failure. If the stress f is considered as the allowable stress, Equation [20] can be used for purposes of design. A design chart can be constructed by rewriting Equation [20] thus

$$\frac{3}{(1-R^2)^2} + L_2^2\frac{(4L_1^2 + 3)}{(1-R^4)^2} \times \frac{4}{\pi^2} = \frac{1}{S^2} \text{ . . . . . [21]}$$

where $L_2 = \dfrac{T}{pb^3}$, $L_1 = \dfrac{M}{T}$, and $S = \dfrac{p}{f}$

A plot of Equation [21] is shown in Fig. 9, in which values of the load ratio S are plotted versus the load ratio L_2 for various possible values of the twisting moment to the bending moment as a parameter. Fig. 9 is plotted for a value of $R = \dfrac{a}{b} = 0.25$. In this way the allowable loads can be determined for a given pipe or, by plotting Equation [21] for various values of R, the required size of piping can be selected.

ARTHUR MCCUTCHAN.[7] The authors of this paper have furnished a comprehensive analysis of stress problems involved in the design of pipe lines with a view to finding satisfactory bases for establishing allowable combined bending-plus-pressure stresses. Their lucid account of the factors involved should stimulate discussion of controversial issues and thus aid in reaching a consensus of opinion on how far a safety code such as the Code for Pressure Piping need go in setting limits on stresses other than girth stresses due to internal pressure.

The section on effect of "cold springing," or "prespringing" as the authors have termed it to distinguish from the similar effect resulting from "self-springing," is particularly valuable. Although those who have worked intimately with the subject of flexibility of piping fully recognize that a hot line will relieve itself of excessive bending stress through creep or yielding of the material, there appears to be a rather widespread misconception that creep tends to reduce rather than increase the initial cold spring usually provided in piping for high-temperature service.

The fact that an overstressed line at high temperature tends to relieve itself of any overburden of bending stress through creep or yielding of the component parts is responsible for the statement sometimes heard that: "The Lord takes care of flexibility experts." It is only when excessive bending moments result in leakage of bolted joints, or excessive thrusts or moments displace anchors or cause misalignment of equipment, that there is any untoward manifestation of lack of adequate flexibility. In recognition of the greater significance of stress related to high bending moments at bolted joints, the practice of the writer's company for the last 10 years has been to assign lower values of permissible stress at bolted joints than in curved pipe or straight pipe remote from joints.

In the case of creased bends, and corrugated bends and corrugated straight pipe, lower total combined pressure-plus-bending stresses also have been assigned, but for a different reason. The tests made by Lieutenant Robert Dennison (2), to which the authors refer, indicated rather high stress concentrations in such structures. Under cyclic stress, cracks eventually developed in the creases and corrugations at stresses corresponding to relatively small bending moments.

A study of the variable stress conditions existing in steam piping in central-station power plants, however, indicates that only in the case of a combination of a large constant bending stress and severe vibration of the line would it be possible to produce fatigue failure. Moreover, because of the self-unloading character of bending stress, arising from constraint of thermal elongation of a line, it appears doubtful if even this condition need be feared in practice.

For conditions encountered in power plants, the writer deduced the following stress-intensification factors from Lieutenant Dennison's tests (2) and Professor Moore's repeated pressure tests on boiler drums,[8] as applicable to creased bends and to corrugated pipe and bends:

Creased bends	2 to 2.5
Corrugated pipe and bends	2.5 to 3

These values for corrugated pipe and bends agree surprisingly well with the factor of 2.5 suggested by the authors for noncyclic loading. In the case of creased bends, the authors, in their effort to link such factors with flexibility factors, appear to have overlooked the fact that almost as great stress intensification was found in Lieutenant Dennison's tests of creased bends as in tests of corrugated bends.

[7] Engineering Division, The Detroit Edison Company, Detroit, Mich. Mem. A.S.M.E.

[8] "Tests of the Resistance to Repeated Pressure of Forged, Riveted, and Welded Boiler Shells," by H. F. Moore, Trans. A.S.M.E., vol. 53, 1931, paper FSP-53-6, pp. 55–60.

The satisfactory behavior of creased and corrugated pipe under actual conditions of use may be explained on the basis of the self-relieving characteristic of bending stress induced by constraint of thermal elongation. This unloading automatically reduces the bending stresses in the convolutions to those which the material will support at the operating temperature. Since the endurance limit holds up better than the yield strength and the creep strength as the temperature is raised, it is doubtful if a high-temperature line can support enough steady stress for the superposed vibratory stresses to cause fatigue failure.

Since the amount of the unloading will appear as an addition to the cold spring originally provided, rather severe stresses may exist in the convolutions of creased and corrugated pipe in the cold condition. These bending stresses emphasize the desirability of eliminating locked-up stresses by annealing such pieces after fabrication. The number of these major stress cycles, caused by change from a cold to a hot condition in a main steam line of a central station, ordinarily does not exceed a few hundred in the life of a plant. Consequently, failure under such conditions is related to a property of material termed by Professor H. F. Moore as "crackless plasticity."[9] Material used in fabricating creased and corrugated pipe usually is capable of considerable plastic deformation without developing cracks. It can be concluded therefore that the stress-intensification factors given by the authors, with the exception of those for creased bends, will insure proper application of such structures. The writer would suggest a factor of 2 for creased bends under noncyclic stresses and 4 for cyclic stresses.

In the writer's opinion, the maximum-shear theory (4) should be used in combining stresses resulting from effects of bending and pressure rather than the principal-stress theory advocated by the authors, since yielding, not eventual fracture, is the condition of so-called failure which can be anticipated in a structure loaded by constraint of linear expansion. The maximum-shear theory possesses the further advantage of extreme simplicity.

In the absence of torsion, the combination of bending and pressure stresses to obtain the tensile stress equivalent to the maximum-shear stress reduces to the following simple expressions:

1 For side of pipe in tension

$$Seq = S_b + S_l$$

2 For side of pipe in compression

$$Seq = S_b - S_l + S_t$$

in which

Seq = tensile stress equivalent to maximum shear stress
S_b = stress caused by bending moment, tension on one side of pipe, compression on the other
S_l = longitudinal stress due to internal pressure
S_t = transverse or hoop stress due to internal pressure.

Fine distinctions as to which theory to use in combining stresses are not justified, however, in analyzing structures in more than one plane, the flexural characteristics of which can hardly be determined within an assured accuracy of 10 per cent. Furthermore, commercial variations in pipe-wall thickness within the permissible limit of $12^1/_2$ per cent from nominal dimensions may affect the flexibility of the pipe line a corresponding amount. The writer would point out that the paper does not attempt to cover the method of computing expansion stresses, moments, and reactions, since there are a number of available methods which give comparable results, at least for simple structures. Some structures, however, are extremely difficult or impossible to compute by methods approaching rigorous accuracy, and square-corner approximations or other simplified assumptions often have to be resorted to. If too specific flexibility requirements are written into the code, the writer begs leave to ask who can determine whether they have been met in complicated structures? In the case of branch lines, three-ended structures, and the like, the most that can be determined is that certain stresses will not be exceeded.

The idea of establishing a permissible range of total combined stress to limit the stresses in both the hot and cold conditions has the advantage that the numerical value of such stresses can be made the same as the values of allowable stress given in the code for determining pipe-wall thickness and yet be high enough not to interfere with good design from a flexibility standpoint. The definitions of S_A and S_A' given in the paper seem inadequate, however, in that they fail to specify that these terms relate to bursting stress as distinguished from bending stress, or that the so-called allowable stress refers to total combined stress.

The proposed setup allows a conservative designer to ignore, if he so desires, the ameliorating effect of cold spring, whether actually present or not, but still permits him to use a total combined stress of not to exceed 75 per cent of the sum of the allowable bursting stresses at room and at operating temperatures. On the other hand, it allows more latitude in case of need or for those who want it. For instance, at 900 F using carbon-molybdenum pipe, the 75 per cent rule for no cold spring would allow a total combined stress of 15,750 lb per sq in., whereas the 100 per cent rule for 50 per cent cold spring would allow 21,000 lb per sq in.

It is possible that in lieu of these detailed stresses the simple requirement that a line should be designed so that it could be cold sprung 100 per cent of the computed linear expansion without developing stresses exceeding $^2/_3$, or some such fraction, of the minimum specified room-temperature yield strength of the pipe material would be a satisfactory code statement as far as any actual hazard is involved.

The writer's observation of the disturbing effect of bending moments on bolted-flanged joints is at variance with the reassuring conclusions reached by the authors which are to the effect that ASA standard flanges, at least where used with ring joints, can withstand any bending moments commonly encountered. Actual experience with 1000 F experimental flanged joints has indicated that even small bending moments can cause leakage of an otherwise satisfactory ring joint. Calculations also showed the desirability of using 1500-lb alloy-steel flanges on 865-lb per sq in. 910-F service, assuming a $^3/_8$-in-wide metal gasket, even where the bending moment was limited to that corresponding to a total combined stress of only 10,000 lb per sq in. Hence, it would seem desirable that the authors support their conclusions with adequate explanation of how they are arrived at.

Although there are a number of assumptions, regarding initial bolt loadings, necessary residual gasket compressions, and probable residual bending moments existing in steam lines after years of service, to which exception might be taken, the writer feels that a discussion of these points might tend to obscure the real purpose of this symposium, which, as he understands it, concerns how far a safety code need go in prescribing limits for total combined stress in piping systems, together with methods for combining such stresses.

P. E. PENDLETON.[10] The paper is valuable in that it points out the controlling design features for high-pressure and high-temperature pipe lines. Among these are relaxation stress, a proper theory of failure, and the importance of high localized

[9] "An Investigation of the Fatigue of Metals—Series of 1925," by H. F. Moore and T. M. Jasper, University of Illinois, Engineering Experiment Station, Bulletin No. 152, 1925.

[10] Lieutenant-Commander, U. S. N., Bureau of Engineering, Navy Department, Washington, D. C.

stresses in systems subject to repeated loading, as well as their lack of importance under conditions of static loading.

However, no quantitative data are presented in regard to relaxation stress, i.e., at what temperature does it become the controlling factor for a specific material and what are the values of this stress at various temperatures. Accurate data on this question are difficult to obtain, although several laboratories in the United States are actively engaged in this problem.

The importance of keeping the range of stress of a piping system midway between the positive and negative yield strengths is timely. In this connection, it would be interesting to see a development made of the influence of locked-in stresses of a welded-pipe system and their effect in extending the stress range between cold and hot conditions.

At present, the Bureau of Engineering of the Navy Department calculates total combined or equivalent stress by the Hencky-Mises maximum-shear strain-energy theory, specifying a maximum of 15,000 lb per sq in. for this stress. A 50 per cent cold pull-up is required on all main steam lines, but no credit is given for this in calculating the stress in the pipe line when hot. It is thus unlikely that many regions exist in which any localized stresses greatly exceed the yield point of the pipe material. Consequently, there will be but little self-springing in pipe lines designed in this manner. On the other hand, the 50 per cent prespringing will subject the piping to a maximum negative, or cold stress of 8500 lb per sq in. Since the combined working stress of 15,000 lb per sq in. is less than the relaxation stress, the former will control the upper limit of the stress range. This range will then be 23,500 lb per sq in. (giving no credit for reduction in hot stresses) for Navy main steam piping, which is carbon steel for temperatures up to 650 F, and carbon-molybdenum, for temperatures ranging from 650 to 850 F. However, if credit be given for 50 per cent cold pull-up, the stress range will be 16,000 lb per sq in., which compares with a 19,200-lb per sq in. combined-stress range for carbon steel at 650 F as given in the paper. It would be interesting to know what upper limits of combined stress were used in compiling the allowable stress ranges given in Table 2.

Attention drawn by the authors to the limitations of the various theories of failure when applied to piping design suggests that further development of this subject is desirable, especially in the plastic range.

The use of simplified formulas for the determination of thrust and bending moment for particular pipe systems suggests that much could be done in this connection to facilitate design calculations.

The writer wishes to endorse the suggestion often made that the various research problems involved in high-pressure-temperature piping design be allocated by a combination of interested groups to laboratories and technical organizations best-fitted for their solution, so that duplication of effort may be avoided.

In the preparation of this discussion, the writer is indebted to R. Michel, marine engineer, Bureau of Engineering, Navy Department, for his able assistance.

E. L. Robinson.[11] During the last 10 years new installations of high-temperature steam piping have definitely gone beyond the temperature range throughout which elasticity is preserved, until at the present time there are approximately 2,000,000 kw of steam turbines in operation at temperatures where plastic deformation under stress definitely takes place. Furthermore, most new installations are being made at temperatures above that at which elasticity may be expected to persist without plastic effects.

Ten years ago the determination of the elastic reactions and the corresponding stresses due to thermal expansion constituted one of the principal problems in connection with the design of high-temperature piping installations. Most modern installations are being designed for operation at temperatures at which relaxation causes a decrease in elastic stresses as time goes on, rapidly at first and then more slowly. On this account, industry is confronted with problems of design for which there is little substantial background. The authors have made a valuable contribution toward the solution of these problems. They are careful to distinguish between yielding and rupture and, for the most part, their conclusions are so well qualified as to make it difficult to disagree with them.

In a few respects it is possible that the writer can contribute some useful observations.

The authors favor more than 50 per cent prespringing, but it does not seem to the writer that they emphasize the benefits of the greater prespringing sufficiently. The attitude is taken that, since relaxation results in self-springing, the long-time conditions will be the same. However, as they point out, this requires a greater amount of permanent set or creep in order to effect the relaxation.

The results of high-temperature rupture tests conducted during the last 2 years raise a very real question as to whether or not it is wise to ask too much of readjustment by means of creep. Creep, in itself, is beneficial, but when it leads to a brittle break, it does not seem wise to base design upon the expectation that it will occur without any deterioration of the material.

The authors do not discuss the invalidation of elastic analysis by the occurrence of plastic deformation. It is, perhaps, unwelcome to those who have devoted much high-grade analytical work to the determination of elastic stresses in high-temperature piping to realize that the reactions fall off and the stress distribution alters. On the other hand, it might be pointed out that, if the practice of prespringing to the extent of 100 per cent of the thermal expansion should be generally adopted, the elastic analysis would have reality when the piping is cold and strong and when the stresses are not combined with pressure. While at high temperature when the strength is reduced, existing stresses will be due to pressure only and not due to the reactions brought into play by the prevention of thermal expansion. The writer believes that prespringing should certainly be sufficient to assure extremely low rates of creep from the beginning.

Equation [9] of the paper is quoted from Moore and Kommers (7) to represent the fatigue strength where the stresses are not completely reversed. The tests given in the reference were sponsored by the writer's company and were first reported in bulletin form.[12] Originally, in presenting this formula Professor Moore made a number of qualifying remarks. In particular the formula fails as the stress ratio in the denominator approaches unity because the tensile strength is almost never 3 times the endurance limit for complete reversal, and a maximum stress beyond the tensile strength should not be implied as satisfactory. Where test results are not available, the writer would prefer a modified Goodman diagram based upon $^1/_2$ the tensile strength for complete reversal. However, an actual diagram of test results for the conditions of application would be better.

The authors repeatedly refer to the "relaxation limit." As a matter of fact there is no true relaxation limit any more than there is a true creep limit. It all depends upon the time. Thus at high temperature within a few hours all high stresses decrease rapidly to a level at which further decrease is slow. This is what is accomplished during a stress-relief anneal. On the other hand, if the same process is continued for 1000 hr, the gradual reduction of stress proceeds still further, and the residual stress is progres-

[11] Turbine Engineering Department, General Electric Company, Schenectady, N. Y. Mem. A.S.M.E.

[12] "An Investigation of the Fatigue of Metals—Series of 1922," by H. F. Moore and T. M. Jasper, University of Illinois, Engineering Experiment Station, Bulletin No. 136, 1923.

sively lower after 10,000 hours and again after 100,000 hours.

The authors quote Bailey's conclusion that the relaxation limit for 100,000 hr corresponds to the stress causing 0.1 per cent creep in that period. The writer doubts the wisdom of such a generalization. It is much better to have a relaxation test than to try to determine bolt performance from a constant-stress test. Several simple methods of conducting relaxation tests, as reported by four different companies, were described in a report of a Subcommittee of the A.S.M.E.-A.S.T.M. Joint Research Committee on the Effect of Temperature on the Properties of Metals made in 1938.[13]

The writer's company has run hundreds of relaxation tests on all varieties of high-temperature steels and prefers such tests for the prediction of bolt performance and uses them instead of constant-stress tests for preliminary evaluations of material for high-temperature service. In many such tests, the residual stress at 10,000 hr corresponds closely to the constant stress causing 0.1 per cent per 100,000 hr, although in so many cases the residual stress is far below this level that it is unwise to take the correspondence for granted. Almost without exception, the residual stress for 100,000 hr is far below the stress corresponding to a creep rate of 0.1 per cent per 100,000 hr.

The authors refer to the "applied stress" for alloy-steel bolting. It is always difficult for the writer to visualize the applied stress in a bolt. It is easier to think of the bolt as having a measured extension when initially assembled, determined by the length of the bolt, the number of threads per inch, and the number of flats the nut is turned in tightening up. Technically, a "strain" is applied rather than a stress, and even this is not easily measured with soft gaskets. The authors suggest applying a stress to produce 1 per cent creep in 100,000 hr. The writer believes that an initial strain, corresponding to a considerably higher elastic stress, is desirable to assure tightness even though relaxation soon reduces it. Bolts may well be taken up 0.1 or 0.15 per cent. However, the effective stress remaining in the bolt to keep the joint tight after a period of time must be determined from the relaxation properties of the material. This will be far less than the elastic stress corresponding to the inital setup, although it is not quite independent of it. A bolt tightened 2 mils per in. initially will be measurably tighter after 10,000 hr than a similar bolt first tightened 1 mil per in.

N. O. Smith-Peterson.[14] The problems involved in such calculations as are carried out in this paper are not simple tension or bending-stress problems to which there can be only a right or a wrong answer. They are complicated and involve many assumptions as well as a choice of different formulas for their solution. In presenting the solutions of these problems in complete detail, with formulas, assumptions, and calculated results, it becomes possible for others to compare their methods with those of the authors. The writer has done so and has obtained results differing somewhat from those listed in Table 5, pertaining to flange stresses. The difference in amount is not nominal and is due to difference in choice of formulas and assumptions made. It is the stated aim of the authors in publishing this very thorough paper to develop just such difference in methods of calculation, and the writer is hereby presenting his methods as they apply to some of the problems.

The writer uses the same formula for flange stresses as the authors, namely, the Waters, Rossheim, Wesstrom, and Williams formula, presented to this society in 1937. The writer's reason for using this formula, among the many flange formulas in existence, is the fact that it is the only formula which permits calculating stresses in the three axial directions, viz., hub, radial, and tangential flange stresses. However, before being able to use these formulas, it is necessary to make assumptions concerning the end-force area, ring contact area (or gasket area), and residual-contact-pressure ratio.

The authors consider the end-force area to extend to the ring pitch diameter, the ring contact area to be equal to $^1/_4$ the annular-ring area, and the residual contact pressure to be $5^1/_2$ to 1.

The writer follows the A.S.M.E. Boiler Code regulation in considering the end-force area to extend to the outside diameter of the ring. The contact area is accurately calculated according to the sloping surfaces of the ring, and the residual contact pressure is taken to be 6 to 1.

This difference in calculations gives approximately 10 per cent higher flange stresses for a 24-in. 1500-lb flange than those listed by the authors in Table 5, items 14, 15, and 16.

These differences are largely in assumptions in that the same flange formulas are used. However, a formula difference also exists between the authors and the writer when it comes to calculating the transmission of pipe-line bending moments by a bolted flanged pipe joint.

The authors consider such bending moments to be transmitted directly to the flange bolts and, hence, use the section modulus of the bolt arrangement in the joint to obtain the total preloading bolt stress required for maintenance of joint tightness.

The writer believes that no bending-moment action can be transmitted to the flange bolts until the contact pressure on the ring has been completely absorbed (leak condition) and that, therefore, for a tight joint, where the existence of a residual contact pressure on the ring is required, the bending moment will affect directly the ring-contact pressure and not the bolt stress; hence, the ring section modulus is involved in obtaining the total preloading bolt stress.

In explanation of this latter theory, which does not take into account elastic effects, consider the universally accepted manner of calculating the required preloading of a ring in order to insure joint tightness when an end force is exerted upon it. The universally accepted way is to assume the end force, a tensile force, to be transmitted directly to the ring contact surfaces and there to reduce the existing contact pressure. The end force is not considered as being transmitted to the flange bolts and, therefore, does not cause any change in the bolt stress. Similarly, a bending moment, which on one side exerts a tensile force, should not be conceived of on that side as affecting the bolt stress, but should be conceived of as here reducing the contact pressure. On the other side, the compression side of the bending moment, the contact pressure is, of course, increased. Therefore, to calculate the amount of such decrease and increase in the contact pressure, the section modulus of the pressure area is required to be used and not the section modulus of the bolt arrangement. After calculating the contact-pressure changes due to a bending moment, the calculation of the required bolt stress is then undertaken.

The writer's method leads to an 18 per cent higher flange stress than those listed under items 17, 18, and 19 of Table 5, for a 24-in. 1500-lb flange.

These percentage differences in calculated stress results are not nominal, and it is to be noted further that the basic flange formulas used by the authors and the writer are the same. Were there any differences in the choice of these formulas, the percentage differences in calculated results would be greater yet. The situation, therefore, seems to call for the adoption, by code-making authorities, of flange formulas and calculating methods in general, as well as allowable stresses. The authors' paper makes this also evident throughout and is an excellent exposition of the whole pipe-line problem.

[13] "The Resistance to Relaxation of Materials at High Temperatures," by E. L. Robinson, Trans. A.S.M.E., August, 1939, pp. 543–550.

[14] Walworth Company, New York, N. Y.

Authors' Closure

The authors acknowledge their debt of gratitude to the many discussers who, by their interesting comments, have materially added to the value of this paper. Considering the relative novelty of the subject dealt with, it is gratifying to note fair agreement on the basic conclusions and, consequently, the closure can be limited to the clarification of certain points brought out in the discussions.

While the discussion of the theory of calculating a pipe line for flexibility has purposely been excluded from this paper, Mr. de Jonge's reminder that much is still to be learned on this subject is not untimely. However, the assumptions usually made are on the side of safety and the available methods of calculation, if applied by competent engineers, are entirely satisfactory for engineering use.

The main issue, that of allowable stresses for pipe-bend calculations, has received wide comment. Professor Marin has contributed a study of the triaxial state of stress and its implications. The Hencky-Mises theory is advocated as a stress criterion by Professor Hovgaard, Lieut-Com. Pendleton, and, in the verbal discussion, by Mr. Soderberg, whereas Mr. McCutchan favors the maximum-shear theory. While it is conceded that a matter of principle is involved, either failure criterion appears adequate considering the present undeveloped state of our knowledge. As pointed out by Mr. Robinson, the authors have avoided more than passing comment on the invalidation of the elastic analysis by the occurrence of plastic deformation. They felt justified in slighting this aspect by the fear of confusing the issue which is to define workable rules for evaluating the flexibility of piping. Again, the redistribution of stresses due to creep and the phenomenon of relaxation are in favor of the structure, and an elastic analysis gives the limits of stress through which the material goes in each cycle of change from the elastic to the semiplastic and ultimately, in extreme cases only, the fully plastic state.

On the other hand, the authors gladly comply with Mr. Robinson's request to lend added emphasis to the injunction to use prespringing in excess of 50 per cent. Appreciation of the benefits obtained from cutting a line short is growing steadily, and we would assume that this will soon be general practice. The authors have used the following rough rule as a guide in setting the desirable amount of prespring s:

$$\frac{S_A/E}{S_A/E + S'_A/E'} > s < \frac{2S_A/E}{2S_A/E + S'_A/E'}$$

In order to understand the significance of this formula, it should be remembered that S_A, the bursting stress specified in the codes, corresponds to 40 to 50 per cent of the yield point cold; and S'_A either corresponds to the same percentage of the hot yield point or to from 80 to 100 per cent of the stress producing 1 per cent creep in 100,000 hr, which can be considered the virtual relaxation limit (in the same sense as Lieut. Dennison defines the "virtual" endurance limit). E and E' are the cold- and hot-elasticity moduli, respectively. Since the allowable stress range for a prespring s in excess of 0.5 is $S_A + S'_A$, the lower limit of s in the formula gives a stress of S_A cold and S'_A hot, or a range between, roughly, one half the cold yield point and one half the hot yield point or, for elevated temperatures, the relaxation limit; this state of stress will also be produced in an unsprung bend (at temperatures involving creep) after a period of operation producing complete relaxation. The upper limit of s, which should be approached in particular for high-temperature applications, places the average stress midway between the yield point at room temperature and the virtual relaxation limit, thus reducing the operating stress. The formula gives presprings between 50 and close to 100 per cent, depending upon the material strengths at room and operating temperatures.

Mr. McCutchan favors reduced stresses at bolted joints. While the authors agree that bolted joints should receive special attention, their experience is that a reduction in allowable stress is not generally necessary with ring-type-gasket joints. Actually, the stress specified at the bolted joint would govern the entire piping design, since maximum moments usually occur at the connections to equipment where bolted joints are normally located. Mr. Smith-Peterson's comments on the detail calculations of the flanges have been found interesting, and the authors agree that it would have been more proper to base their investigations of the effect of bending moments on the ring section modulus in place of the section modulus of the bolting.

Properties and Performance of Plastic Bearing Materials

By L. M. TICHVINSKY,[1] EAST PITTSBURGH, PA.

Bearings made of plastic materials can be used successfully not only for the case of perfect fluid lubrication but also for that of semifluid lubrication. Certain additions, such as graphite, will sometimes permit the application of these materials under conditions of dry friction.

By virtue of good physical properties these bearings find a wide application. Heavy-duty plastic bearings are used in the steel-mill industry. Lubricated and cooled with water, they carry heavy loads at pressures of several thousand pounds per square inch. As guide bearings their performance ranges from small, high-speed spindles, to large ship-propeller shafts. Oil-, water-, and grease-lubricated plastic bearings are used extensively in industrial, marine, and farm machinery.

There are many differences in the behavior of plastic and metal bearing materials by virtue of which the performance is also different. This article intends to point out the most important physical properties, as well as some of the characteristic performances of plastic bearing materials.

THERE are many reasons for the increase in the use and application of various kinds of bearing materials bonded with synthetic resin. The industry in this country became interested in these materials mainly because of some qualities superior for certain applications to those found in bearing metals and alloys. An extensive development and application of plastic bearing materials abroad was and is due primarily to the lack of basic bearing metals.

This article describes the bearing materials bonded with synthetic resin. Rather complete data are given on the laminated materials, including physical properties as well as the results of various bearing performance tests. This information was gathered from various domestic and foreign technical and scientific publications, as well as from testing in the author's laboratory.

Types of Synthetic Resin-Bonded Bearing Materials

All bearing materials bonded with synthetic resin can be divided into three types in accordance with their internal structure.

1 The bearings of the first type are made from various plain or graphitic molding powders. Numerous kinds of bearings for light and medium load applications are made from these materials. Guide bushings for high-speed spindles, or gland materials for sealing purposes, are typical examples of the use of this material; these bearings perform under all types of friction, namely, dry, boundary, and fluid. The application of these materials is rather limited because, as they are very brittle and fragile, impacts of even small magnitude may cause failure. Those made of graphite powder have a rather high heat-transfer coefficient.

2 The second type comprises the most important and widely used bearings. Such bearing material is obtained by molding at high pressure and temperature sheets of woven textile fabric treated with an organic binder. Synthetic resin of the phenol-formaldehyde type is usually used in the manufacture of laminated bearing materials. The molding is done in hydraulic presses (pressure varies from 1200 up to 2200 psi) at temperatures ranging from 120 to 180 C (1).[2] Under the combined action of heat and pressure the resin softens or melts and undergoes a further chemical reaction, resulting in a material which no longer is fusible. By this action the filler (cuttings, laminations, and the like) is permanently bound. The desired thickness for the final product determines the duration of this operation. It may last from 10 minutes to 30 hours.

Laminated bearing material is strong and tough. Bearings made of such materials perform efficiently when lubricated with water in which case the latter serves as lubricant and as a cooling agent. Almost any liquid (except strong alkalies) can be used, and although it might be recommended sometimes to add a lubricant, e.g., tallow or suitable emulsion, to the water, these bearings do not require oil or grease (2).

3 Bearing material of the third type is based on an internal felt-like structure. It is obtained by impregnating a felt of fibrous fillers consisting of cellulose fluff, linters, and similar materials. The resin is generally precipitated from a thin aqueous solution (sodium hydroxide) on and in the felt-forming fibers.

These materials range in their physical properties between the brittle powder moldings and the extremely tough and strong laminated materials.

Properties of Synthetic Resin-Bonded Materials

Laminated materials are the most important in bearing applications as already mentioned, therefore most of the information pertaining to the physical properties will be given in connection with these materials.

(*A*) *Modulus of Elasticity.* The modulus of elasticity, or Young's modulus, gives the relationship between stress and strain in the elastic region. It defines the amount of strain under load and, therefore, enables one to determine the deflection.

In connection with the materials in question, for a long time the value of the modulus of elasticity was found to be equal to 1.0×10^6 psi (2). However, methods were devised through which the use of artificial silk, cotton, and many other fibers resulted in the increase of the value of the modulus of elasticity up to 1.8×10^6 psi (3).

Many of the synthetic bonded materials were developed in connection with their extensive use by the electrical industry. Through a change in the molding pressure alone it is possible to attain a considerable increase in the modulus of elasticity. This is clearly shown in Table 1 (4).

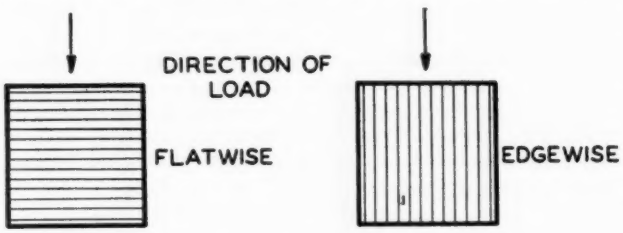
Organic textile	$(1.32 - 2.35) \times 10^6$
Organic filler	$(1.32 - 2.2) \times 10^6$

In the case of Micarta[3] tubing where the fabric during rolling is maintained in tension, the modulus of elasticity reaches a value of about 3.0×10^6 psi.



(*B*) *Compressive Strength.* For bearing application the compressive strength of these materials is important.

Compressive strength, as well as such properties as ultimate tensile strength and shear strength, can be increased by improved fabric filler as can be seen from Table 3 (3).

TABLE 3

Lb per sq in.	Ordinary fabric-filled phenol resin	Improved fabric filler
Compressive strength, psi	25,000	27,000
Ultimate tensile strength, psi	11,000	27,000
Shear strength, psi	4000–7000	6000–7000

[The compressive strength is usually given for laminated materials in two directions: right angle to laminae and parallel to laminae, as illustrated by the accompanying sketch.]

In Table 4 data on the compressive strength are given.

TABLE 4 COMPRESSIVE STRENGTH OF LAMINATED MATERIALS

Flatwise, psi	Edgewise, psi	According to
40–45,000	20–24,000	Eyssen (2)
45–50,000	30–35,000	Rochester (5)
30–45,000	.....	Smyth (6)

(*C*) *Heat Conductivity.* In this property all synthetic resin-bonded materials are inferior to white bearing metals. However, some improvements in this property have to be mentioned, especially those achieved during the last year. About a year ago one could say roughly that bearing plastic materials showed a heat-conductivity coefficient which is 100 times smaller than that of a tin-base white metal (0.845 w per sq in. per deg C per in. for babbitt). By reason of improvements made it can now be said that this ratio has decreased about one half.

The thermal conductivity of ordinary Micarta is taken as equal to 0.007 w per sq in. per deg C per in. Micarta for bearing application (I and II) has higher thermal conductivity as shown in Table 5.

TABLE 5

Bearing Micarta I, w per sq in. per deg C per in.	0.0099 –0.01
Bearing Micarta II, w per sq in. per deg C per in.	0.00925–0.01

Eyssen's (2) published data vary between 0.0045 and 0.0059 w per sq in. per deg C per in. for laminated products, and between 0.0077 and 0.0089 w per sq in. per deg C per in. for moldable materials based on felts of impregnated nonoriented fibers.

According to Richardson (7) the thermal conductivity of phenolic-plastic bearings is approximately 0.0072 w per sq in. per deg C per in.

Erk (8) gives a table of the thermal conductivity in a number of the "Kunstharz." In the phenol group there are some with thermal conductivity as high as 0.020, 0.021, and 0.023 w per sq in. per deg C per in.

In an endeavor to increase the thermal conductivity of Micarta and at the same time to improve friction qualities, a new method was developed for the manufacture of graphited Micarta. The thermal conductivity of this material was found to be equal to 0.015 w per sq in. per deg C per in. The heat conductivity of synthetic resin-bonded materials will never be of the same order as that for white bearing alloys. Certain developments in the methods of manufacture may still improve this property without impeding the others.

(*D*) *Other Properties.* The coefficient of expansion for the laminated product consisting of sheets of heavy square-woven duck bonded together by means of a synthetic resin of the phenol-formaldehyde type is 0.00002 per deg C per in. (6).

The specific gravity of the synthetic resin-bonded materials varies between 1.25–1.40. For general calculation it can be assumed that 1 cu in. weighs 0.05 lb. Oil absorption is negligible for practical purposes while water absorption was found to vary from 0.5–0.8 per cent when a test piece ($2 \times 2 \times 1/2$ in.) was submerged in water for 24 hr (2).

The Brinell hardness of synthetic resin-bonded materials was determined by Rochester (5) as 30–42, by Smyth (6) as 35–42.

Performance of Synthetic Resin-Bonded Bearings

The performance of all synthetic resin-bonded bearings is limited, as in the case of bearing metals and alloys, by the maximum allowable temperature of the bearing materials. The heat conductivity of the synthetic resin-bonded materials is lower than that of bearing metals. Therefore, such efficient cooling is required by which maximum amount of heat generated by friction can be removed by the circulating lubricant. An example of this is shown in Fig. 1. Such a bearing being lubricated and cooled with water performs at low speeds and medium loads. The sketch shows the arrangement of cooling and also the location of the high-pressure water inlet. This bearing is not operating in the boundary region at the starting and stopping periods because the high-pressure pump forces water into the bearing clearance.

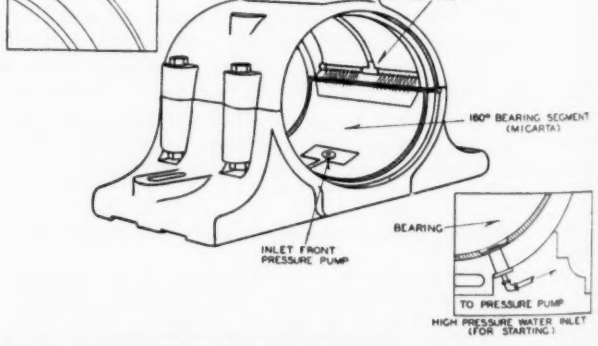


FIG. 1 TYPICAL WATER-LUBRICATED MICARTA BEARING FOR BALL AND ROD MILLS

[3] "Micarta" is a trade name for a plastic material. Other materials of the same general class are Textolite, Formica, etc.

TABLE 6 FINAL BEARING TEMPERATURE C AND COEFFICIENT OF FRICTION MEASURED AFTER 2-HR-20-MIN RUNS

(According to Heidebroek)

	0.0247	0.0267	0.0263	0.0278	0.0058	0.0060	0.0061	0.0062

The softening of the synthetic resin-bonded materials varies with type and grade of the bond. In this respect it is of interest to note some remarks by British authors pertaining to working temperatures of bearings. Smyth (6) indicated a safe working temperature of 100 C and an actual temperature of 150 C at which the material is unaffected. Rochester (5) recommends a maximum working temperature of 60–80 C. He mentions that the maximum allowable running temperature for short periods might reach 250 C. It is self-evident that high, localized temperatures might reach rather high values, not only in the region of dry or boundary friction, but even during perfect fluid lubrication (9). In Table 6 data are given for a series of tests (10) during which the final bearing temperature and the values of the coefficient of friction were measured as a function of peripheral velocity, clearance ratio, and pressures of 22 and 155 psi. The

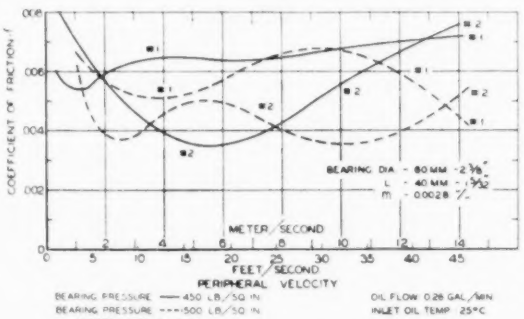

FIG. 2 COEFFICIENT OF FRICTION AS FUNCTION OF PERIPHERAL VELOCITY AT 450 AND 1500 PSI PRESSURE

bearing material was made of resin-impregnated cotton-cloth cuttings. A flow of light turbine oil varied between 0.238–0.715 gpm. The amount of circulating oil showed a tendency to increase with increasing clearance. Results of these tests indicate that the lower the bearing clearance ratio the higher is the running temperature, and the lower is the value of the coefficient of friction. For this reason it is advisable to provide the bearings with chamfered grooves, so that a large amount of lubricant may be admitted not only for lubricating purposes, but also for more efficient cooling. Another investigation was carried on during which the performance of various bearing materials was studied on a specially built test machine (11). The values of the coefficient of friction of two materials are plotted on Fig. 2 as a function of peripheral velocity for pressures of 450 and 1500 psi. The bearing bushings were $3^3/_8$ in. diam, $1^9/_{32}$ in. long, and were machined with a 0.0028 in. per in. clearance ratio. A light oil having 80 Saybolt sec at 100 F and 49 Saybolt sec at 150 F was fed into the bearing housing at 25 C and a rate of 0.26 gpm. The

TABLE 7

Material	Kind of resin	Resin, per cent	Structure	Molding time, min	Molding temp, C	Additional treatment

No. 2	Phenol	45	Cloth cuttings	20	165	8 hr at 125 C

two materials tested showed approximately the same performance, the values of the coefficient of friction being slightly higher for material No. 1 than for material No. 2. In Table 7 some of the characteristics of these materials are given.

The performance of wound bushings impregnated by cresol is given in Figs. 3 and 4. The variation of the coefficient of friction with bearing

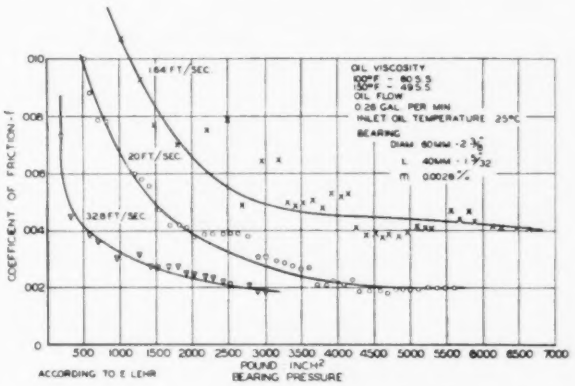

FIG. 3 VARIATION OF THE COEFFICIENT OF FRICTION UPON THE BEARING PRESSURE AND PERIPHERAL VELOCITY

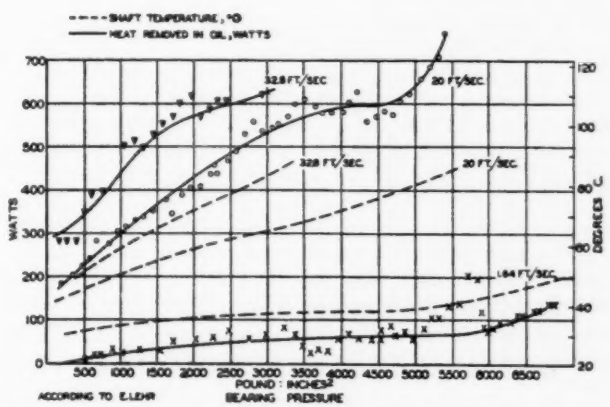

FIG. 4 VARIATION OF HEAT LOSSES AND SHAFT TEMPERATURE UPON THE BEARING PRESSURE AND PERIPHERAL VELOCITY

pressure and peripheral velocity is given in Fig. 3, while the variation of the heat losses and shaft temperature with pressure and velocity is given in Fig. 4.

These bearing tests were made at the same conditions as the tests of bearing materials given in Table 2. From Fig. 3 it is seen that the value of the coefficient of friction shows less variation at high loads at which it approaches some constant value. By diminishing the load, the values of the coefficient of friction rise rapidly. In the region of maximum pressures around 6000 psi the values of the friction coefficient lie between 0.002 and 0.005. More heat is being removed in the oil at higher peripheral velocities than at the lower, as can be seen in Fig. 4. It can also be noted that the slope of the shaft temperature is about the same as that of the heat losses. These shaft temperatures were recorded at steady-state conditions by means of a thermometer inserted in the journal hole specially drilled for this measurement.

All bearing surfaces must be well run in before optimum friction conditions are established. This is especially true for the case of bearings made of plastic material, where the running in

must be done carefully and skillfully. It is found (1) that the best scheme for running in plastic bearings consists in loading the bearing gradually at low speeds until full load is reached and then bringing the journal by steps to full speed. If the load be applied too quickly the excessive heat generated on the sliding surfaces might cause seizure. By frequent loading and unloading at various speeds the plastic bearings finally become insensitive to pressure increase as they become better fitted to the journal.

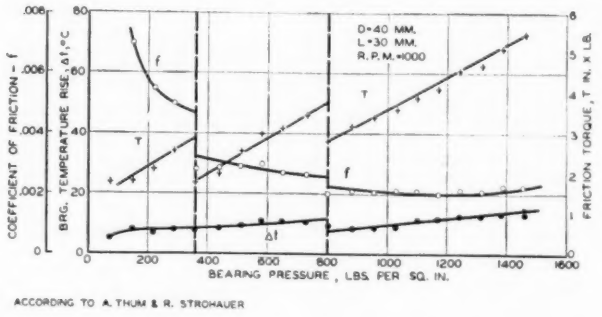

FIG. 5 RUNNING-IN PERFORMANCE OF A LAMINATED BEARING

The bearing can be considered well run in when the originally light-colored and finished areas disappear and form a light-colored, mirror-like, uniform surface. The bearing friction and temperature, which at the beginning were high, decrease considerably at the end of the running-in period. This period usually requires several days and can be substantially reduced by good machining of the sliding surfaces. Such running-in performance is very well represented graphically in Fig. 5. A bearing with textile laminae perpendicular to the axis, impregnated with cresol, was run in on a testing machine with forced-feed oil lubrication during 110 hr. The bearing pressure was increased in steps of 75 psi after steady-state conditions were reached. The friction torque and temperature increased gradually with the loading until at a pressure of 370 psi they rose suddenly and the journal speed dropped rapidly. After a few minutes, however, the torque and temperature readings decreased and their values slowly reached lower readings than previously recorded. By a further similar loading procedure the torque and temperature rose again as may be noticed in Fig. 5. At a pressure of 800 psi the torque and temperature reading went again off scale and the journal slowed down. After a few minutes the torque and temperature decreased again and rose slowly with increased load. The variation of the coefficient of friction may be seen also on the curve.

An article published recently on the performance of railway bearings (12) also points to the importance of running-in performance. This is done in connection with laminated textile material impregnated with cresol resin (65 per cent resin content). This running-in period is artificially accelerated by removing the upper layer of the bearing surface and polishing it by means of a special bushing having the same diameter as the bearing journal. As shown in Fig. 6, such bearing before the surface layer is removed performs with a value of the coefficient of friction which is in the boundary region. At a pressure of slightly over 400 psi the bearing seized. However, the same bearing after the upper bearing surface was removed and polished performed satisfactorily at much higher loads in the region of fluid film lubrication. These tests were carried on several bearings at peripheral velocities of 1.6 and 3.2 fps. Bearing temperatures are also plotted in Fig. 6. Optical measurements of bearing surface finish were made (13) on new and worn bearings; this, it is hoped, will help in further study and improvement of the performance of synthetic resin-bonded materials made for bearings. This is especially so since finish measurements of journal surfaces are now made (14, 15) and the performance of bearings can be elucidated also from this important point of view.

Fig. 7 indicates that the performance of a grease-lubricated Micarta bearing is approximately identical with that of an oil-lubricated babbitt bearing, both in the boundary region. These tests were made at various pressures and peripheral speeds while using a $2^1/_2$-in-diam bearing bushing 2 in. long. Fig. 8 shows the results when another type of Micarta bearing material lubricated with grease was tested at various loads and speeds. The friction properties of synthetic resin-bonded materials can be improved by various additions. The variation of the coef-

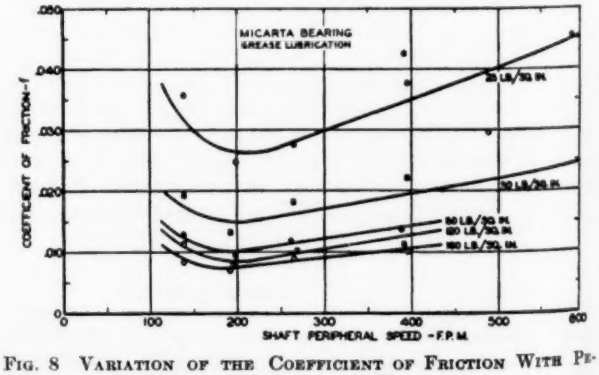

FIG. 8 VARIATION OF THE COEFFICIENT OF FRICTION WITH PERIPHERAL VELOCITY AND PRESSURE

ficient of friction depending upon such additions is shown in Fig. 9. These experiments were made on the machine previously described by the author (14). All bearings tested were run in for a few hours with a small amount of lubricant. Its supply was then shut off and the values of the coefficient of friction and of the temperature were recorded for different pressures. The standard Micarta, as can be seen, performs with a higher friction and temperature. Additions of mica and talc decrease both the friction and the temperature. A marked improvement is obtained when hard graphite is added to Micarta; the values of the coefficient of friction are low and so is the temperature, due to the improved heat conductivity as mentioned previously.

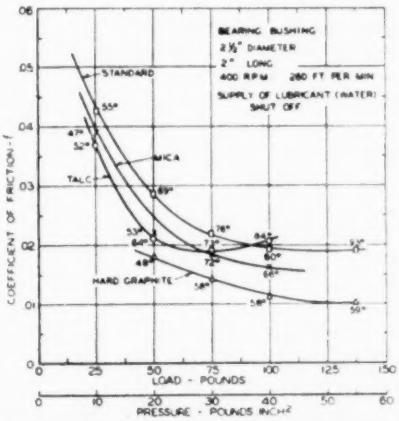

FIG. 9 INFLUENCE OF ADDITIONS TO SYNTHETIC-RESIN BEARING MATERIALS UPON THE VALUE OF THE COEFFICIENT OF FRICTION

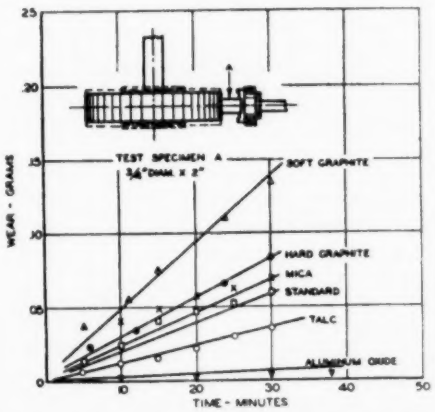

FIG. 10 INFLUENCE OF ADDITIONS UPON THE WEAR

The wear properties of the same materials were also investigated on the wear-testing machine previously described by the author (16). The principle of the machine is sketched in Fig. 10. The rotating test specimen A is pressed on the rotating and oscillating outside surface of a hard disk. A small jet of water is played upon the disk for removing the heat. The loss in weight of the specimen gives a comparative measure of wear. The addition of aluminum oxide greatly improves the wear qualities of Micarta. The rate of wear of the standard Micarta is approximately the same when hard graphite and mica are added to it.

The foregoing data and several performance examples, it is hoped, will assist a designer in his work when selecting and specifying synthetic resin-bonded bearings. Being made of a comparatively new material, the plastic bearings now find more and more application. The continuous development of the material itself and studies of its performance which are carried on by a combined force of chemists, physicists, and engineers will result undoubtedly in many more improvements and in wider application.

ACKNOWLEDGMENT

The writer thanks the Westinghouse Electric and Manufacturing Co. for permission to publish this paper. All the data of experiments performed by the author were made with the assistance of E. G. Fischer, of the Westinghouse Research Laboratories, and C. Jahing, graduate student.

Discussion

CARL CLAUS.[4] The author mentions that appreciation of plastic bearing materials is not caused by lack of basic bearing materials but by advantages in certain applications. These seem to be confined to installations where it is possible to carry off frictional heat by water or oil which act as coolants and lubricants. There is little objection to this method in rolling mills where operators have long been accustomed to these conditions.

The author states that bearings made from graphitic molding powders show a better heat conductivity, but that they are ex-

[4] Research Engineer, Bound Brook Oil-Less Bearing Company, Bound Brook, N. J.

tremely brittle. A familiar bearing used for several decades consists of a metal shell with graphite inserts. This combination of the conventional metallic-sleeve bearing with the plastic graphite dissipates the heat satisfactorily without a cooling liquid. The metallic structure gives proper support to the graphite. A well-known application is the trolley bushing of streetcars for which no better bushing has as yet been found. The constant jars of the trolley pole do not loosen a well-bonded plastic graphite in this and other applications.

Another bearing somewhat related to plastic bearings is the porous-metal bearing. It is manufactured by the cold pressing of metal powders. Instead of using a resinous binder it is sintered and obtains a strength and ductility not approached by the resin-bonded bearing. Its heat conductivity is excellent and its porosity is used for storing lubricant in its structure.

By using hard graphite in the author's tests with Micarta a "marked improvement" was found in reducing the coefficient of friction and the operating temperature. It would be interesting if the terms "hard graphite" and "soft graphite" were explained, as well as the effect of the different kinds of graphite. Fig. 10 of the paper shows more wear for soft graphite than it does for hard graphite.

The condition of the shaft before and after the test is also of interest. Graphite has a tendency to fill up depressions of the shaft surface and make it smoother. Unless a pure graphite is used it may also act as a polishing agent which will rub off high spots.

Aluminum oxide is reported to have improved the wear qualities of Micarta in a test shown in the testing machine, Fig. 10. This material is an abrasive which may have smoothed the contacting surfaces. It was apparently firmly imbedded in the molded test specimen and may have acted as a lapping compound, which wears down the shaft or disk rather than being worn down by them.

An interesting observation can occasionally be made on oil-impregnated wooden bearings which may wear down a steel shaft when abrasive dust embeds itself into the wood. As a result of such a condition the soft-wood bearing shows no wear but the shaft does.

In conducting the tests the author has found it necessary to run in the bearing surfaces carefully for hours. The designing engineer quite naturally wonders what may happen to a bearing which he specifies and which will assuredly not receive such tender care. Since two bearings are mostly used to support a shaft, the question of misalignment will also have to be considered. Misalignment can easily result in failure at the start when excessive pressure prevails over a small area.

The difficulty with testing machines for bearings seems to be that they do not duplicate operating conditions. Results obtained from them cannot be applied to cases which vary from those of the individual testing machine itself. In the ideal sleeve bearing the load is supposed to be carried by an oil film, and a wearing down of bearing material and shaft should be impossible without contact between them.

As a result of the limitations of the bearing testing machines, most engineers reluctantly turn to comparative tests of bearing materials in commercial applications such as electric motors, automobile engines and their accessories, etc.

Performance tests under operating conditions rather than accelerated breakdown tests give us the only reliable answers to our bearing problems. Even then results are greatly influenced by numerous conditions outside of the bearing material itself.

The hardness and finish of the shaft, the degree of misalignment, and particularly the lubricant between the shaft and the bearing are often of even greater importance than the bearing material itself.

H. A. Everett.[5] It is an axiom in research work that wherever possible the actual points for observed data be shown when curves are presented. The author has been meticulous in this respect in all of the illustrations in his paper except Fig. 2. Will he be kind enough to let us have the observed data points for that figure, as there seems to be a surprising and gregarious change in the coefficient of friction with increasing speed.

E. F. Heer.[6] Limited investigations have been conducted on the graphites used in bearings. While experience thus far has not been sufficiently comprehensive to arrive at definite conclusions, the fact is definitely indicated that for each class of bearing there probably is at least one type out of the several varieties of graphite which is superior to others.

Following the author's division of the subject we shall first discuss bearings made from various plain or graphitic molding powders. Since it is the purpose of the graphite to supply a lubrication factor, it is important to have a complete distribution of the graphite throughout the molding powder in the ratio desired in order to supply a constant coefficient of friction. At the same time, it is equally important to make sure that the structural strength of the bearing is not weakened. This immediately brings up the consideration of—What effect, if any, does the particle size of the graphite have on the performance of the bearing in service and does the particle size influence the internal strength of the bearing? Further consideration must also be given the question as to whether or not the particle size of the graphite influences the molding characteristics of the bearing. What effect does loading have on the finished product?

It is conceivable that the internal strength of a plastic will be affected by the relation of binder to inert material. If such is the case, the embrittlement mentioned by the author may be attributed to overloading with graphite or other inerts (by inerts is meant any nonplastic ingredient).

It would seem to be equally important to study the performance of bearings formed from resin in which dry flake graphite has been used as opposed to bearings formed from resins which have been treated with colloidal graphite in either an aqueous or organic carrier.

As mentioned, some experience along these lines has already been had, sufficient to indicate that there is a relation between the particle size of the molding powder and the particle size of the graphite to be used, if admixture of the graphite and resulting friction properties are to be constant.

A study of the particle size of the molding powder examined under a low-power microscope indicated that the small particles are rod-like crystals about 20 mu in diam and from 80 to 100 mu in length. These are held together in agglomerates with a binder making up particles which range in size up to $^1/_8$ in. diam. It is the writer's opinion that, with molding-powder particles of this nature, it is almost imperative to have the graphite particles of suitable size to maintain proportionate distribution of graphite to produce a homogeneous finished product. If large particles of dry powdered graphite surround the finer particles of molding powder, the proportion of graphite to molding powder will probably be greater than is desired and a weakness in structural strength would probably result. On the other hand, if the largest of the particles of molding powder are to bear their complement of graphite in the form of a coating, it becomes necessary to use a form of graphite other than a dry powder, for obviously it is most difficult to maintain the proper proportion of dry powdered graph-

[5] Head of Department of Mechanical Engineering, The Pennsylvania State College, School of Engineering, State College, Pa. Mem. A.S.M.E.

[6] Sales Research Department, Acheson Colloids Corporation, Port Huron, Mich.

ite adjacent to and in contact with these large particles of molding powder. Experience thus far has indicated that graphite, the range of particle size of which lies well below the ordinary fine-mesh powders, when dispersed in a suitable organic fluid, will give much better distribution of the graphite throughout the mass of molding powder and will enable the graphite to be attached to all resin particles regardless of size of the latter. The organic solvent can be disposed of by evaporation which leaves the molding powder in discrete particles not cemented together but at the same time properly coated with graphite.

With respect to the second and third types of bearings mentioned by the author, namely, the laminated type, we would again submit for consideration the selection of the graphite to be used for impregnating the textiles and the methods which should be adopted. A study should be made of the effect of overloading the textile fabrics with graphite as well as a study of impregnating the fabrics with a colloidal dispersion of graphite as compared with fabric which has been treated with powdered graphite. These studies, of course, would not be complete without a further study concerning the variations produced by treating the fabrics with aqueous and organic liquid dispersions of graphite.

Much that has been said with respect to molding powders of course applies to impregnating fabrics, inasmuch as particle size is of prime importance; also distribution of the graphite throughout the fabric to supply properties which will be constant. In dealing with fabrics, as is the case with molding powders, the wetting properties of the graphite dispersions are also of great importance. Some experience has already been had in connection with fabrics. It has been found that dispersions of graphite in aqueous as well as organic liquid dispersions are quite useful. Furthermore, a selection of particle size is important because there must be the proper relation between the particle size and the fibers used in the fabric, also the coarseness of the mesh of the woven fabric. The limited experience thus far indicates that, among the methods which can be used to impregnate the textiles with graphite, the one which appears to hold greatest promise is the immersion of the fabric in a dispersion of graphite in water or suitable organic solvent. The content can be closely controlled by using colloidal dispersions of graphite in these fluids for submerging the fabric for a given length of time. The graphite content together with the time involved in keeping the fabric submerged contributes to a homogeneous result and the proportion of graphite to the fabric can thereby be controlled and, of course, varied according to requirements.

From the paper it may be concluded that the initial run-in period is a predominating factor in the life of the bearing. If that is the case, it is apparent that a study should be made of the behavior of such bearings where water is used as the lubricant. Such study should determine the effect or what can be accomplished by introducing an aqueous lubricant, consisting of a colloidal graphite dispersed in water, into a circulating system for delivery to the bearing during this run-in period. This technique, in the opinion of the writer, should be valuable particularly in locations where the water used to lubricate the bearing is very high in mineral content.

In conclusion the writer should like to emphasize by repeating that experience thus far definitely points to the desirability of using graphite of fine particle size dispersed in suitable fluid carriers in order to produce homogeneous distribution of graphite throughout the bearings, thereby giving the bearings constant friction properties.

W. Trinks.[7] The writer has often wondered why composition bearings are called "plastics," when they are as hard and brittle as a piece of coal. Even less success has attended the determination of the origin of the word "Micarta." It seems to indicate that the bearing material contains, or at some time did contain, mica. Can the author supply any information on these questions?

A great deal of information is given in the paper on strength of Micarta in different directions. This brings to mind the question: Why is Micarta made in layers? The writer is familiar with at least one material in which the shredded cotton fibers are mixed with the uncured phenolformaldehyde and the mass cured as a solid block. If the block of composition is not sufficiently strong, a steel framework is placed in the raw composition and is cooked with it. This design has been successful not only for bearings but also for slippers of universal joints in rolling mills. These slippers act, in a way, like bearings.

Author's Closure

Regarding Mr. Claus's remarks, it was indicated in the paper that it is necessary to differentiate between plastic materials of the first and the other two types. The materials of the first type are made from various plain or graphitic molding powders, while the second and third types are obtained by molding laminated textiles and felt fillers. By virtue of their different internal structures, finished products made according to the three types mentioned have different physical properties, as shown in the paper. Material of type one might be brittle, but laminated bearings are very strong and tough. They are not brittle, and have high bond strength.

Hard and soft graphite Micarta simply designates the way in which graphite is put into the material. In the case of hard Micarta, the graphite is put on the cloth before the resin is applied, while in the case of soft graphite the graphite is put into the resin.

Mr. Heer's discussion is interesting since it indicates a few fine points pertaining to the properties of graphite. The amount of 325-mesh lubricating graphite powder used was evenly distributed in the cloth in such a quantity as not to decrease the bond strength.

Professor Everett correctly indicated the surprising change in the coefficient of friction at increasing speed as shown in Fig. 2 of the paper, taken without alterations from Mr. Lehr's paper.

As far as the writer was able to find a correct answer to Professor Trinks's question, the name "Micarta" (a trade name, used for laminated products only) derives its name from mica, which has a laminar structure and high dielectric strength, and which was originally added in a small quantity to Micarta.

Neoprene as a Spring Material

By FELIX L. YERZLEY,[1] WILMINGTON, DEL.

In this paper the mechanical properties of neoprene which are important for vibration isolation and damping are evaluated and compared with the analogous properties of rubber. Static and dynamic moduli and damping action are specifically treated.

ADVANCES in engineering design proceed from the development of new materials, from increasing knowledge of available materials, and from the exercise of imagination in the creation of new applications. It must be evident that every increase in the variety of available materials diminishes the number of restrictions on mechanical invention. It must also be true that, as the variety of physical characteristics available in different materials increases, fewer compromises are necessary with imperfectly suited materials. Neoprene has taken its place at the side of rubber as an elastic material for springs. As an addition to the variety of materials available to engineers it has already increased the variety of structures that can be made from them.

The Field for Neoprene Springs

There can be no question of the superiority of metallic springs over those made of the rubber-like materials (1),[2] including rubber for certain applications, and there can be no doubt of the superiority of rubber-like materials in other cases. One needs only to survey the present applications of rubber-like materials in automobiles to verify the latter statement. Many improvements in riding comfort and performance became possible only as the availability and characteristics of rubber were appreciated. Further affirming evidence of the unique advantages of rubber may readily be found in the literature (2, 3) and in the prevailing trend toward further uses of rubber.

Analysis of spring applications reveals at least five outstanding reasons for the use of rubber springs. These are:

1 To reduce noise. The function of rubber in this respect is to avoid transmission of audiofrequencies through metallic supports (4, 5). It is interesting to note, however, that other steps must sometimes be taken simultaneously to eliminate sounds which are air-borne.

2 To impart flexibility. In addition to the technically more interesting applications, involving periodic vibrations which are subject to more or less precise mathematical treatment, there are numerous applications arising from the need for a mild cushioning effect, for example, as supplied by the numerous rubber pads and cushions used in automobile bodies (6). These provide the automobile structure with a necessary degree of over-all flexibility and elastic yield in an economical and simple way.

3 To reduce production cost. The trend in modern machine production is toward lighter construction and higher speeds. In general, this means also that precision in manufacture must be increased, usually at an increase in the cost of machining operations. Rubber in compression will conform readily to irregular surfaces and can, in some cases, be employed to eliminate a machining operation as well as maintenance expense. This is illustrated in Fig. 1. A self-aligning bearing is made by replacing a lubricated ball-and-socket construction with a less expensive assembly involving a rubber-like material. A spherically formed band of neoprene between the bearing and the block not only provides the necessary self-aligning feature, but does so with an appreciable saving in cost.

4 To reduce maintenance costs. Rubber springs frequently eliminate guides and other points of metal-to-metal contact, and thereby reduce maintenance costs (7).

5 To obtain definite damping action. When damping action is required with metallic springs, auxiliary frictional equipment is usually required. Leaf springs provide damping, but the extent of the damping action varies with the lubrication between the leaves and is not subject to practical control. The damping action of a rubber compound is definite and reasonably constant and is obtained without mechanical wear and without need of attention.

The foregoing considerations apply generally, but in varying degrees, to all of the rubber-like materials. In addition, the following distinctive advantages of neoprene over rubber are characteristic:

1 Relative immunity from deterioration in petroleum products. All petroleum solvents cause disintegration of rubber. Although

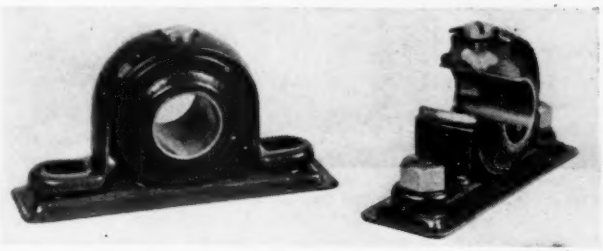

Fig. 1 A Self-Aligning Bearing Constructed With Neoprene Cushion

the rate of deterioration is dependent upon the nature of the petroleum product, the end results are similar. Penetration into the rubber first causes softening and swelling, followed by gradual loss of strength and eventual failure. Neoprene differs from natural rubber, first, by showing much greater resistance to the penetration of petroleum products and, second, by retaining its original physical properties to a much greater extent (8, 9).

2 Greater chemical stability at high temperatures. Rubber and neoprene, which are organic materials, cannot be exposed to the moderately high temperatures at which metallic springs frequently operate without undergoing chemical changes. The changes of rubber and neoprene on continued exposure to high temperatures are quite different. Continuous exposure to elevated temperatures of the best modern heat-resisting rubber compositions, which have low sulphur content, tends to cause reversion. Reverted rubber compositions are characterized by loss of resilience, elastic modulus, and tensile strength. Neoprene compositions do not revert at high temperatures, but gradually become harder with increased modulus and with relatively slow

loss of tensile strength. The residual plastic effect, drift, of the vulcanizate is decreased by continued heating, and the modulus increases rather than decreases.

3 Resistance to the action of sunlight and ozone. Sunlight and ozone are grouped together because formation of ozone at the surface of rubber in sunlight is considered the prime cause of the surface deterioration which occurs (10). In many industrial situations, the presence of ozone precludes the use of rubber. Neoprene, on the other hand, is used extensively as a jacketing material for high-voltage cables, where ozone is generated by corona discharge. It is also used in direct sunlight, where rubber does not possess the necessary degree of permanence.

4 Greater damping action. The hysteresis loss and hence the damping action of both rubber and neoprene may be varied considerably by compounding. In general, however, hysteresis loss, with stocks that are also practical in other respects, is greater for neoprene than for rubber. The thermal conductivity of neoprene is also higher than that of rubber and permits more rapid dissipation of heat.

The foregoing statements relate to the preliminary selection of a spring material. It is equally important to have definite knowledge of the various moduli of elasticity in order to determine the size and shape of the required spring. For that reason the balance of the paper will deal almost exclusively with the elastic properties of neoprene.

Elastic Properties of Neoprene

The author has recently described a compact mechanical oscillograph (11), Fig. 2, particularly for the evaluation of rubber-

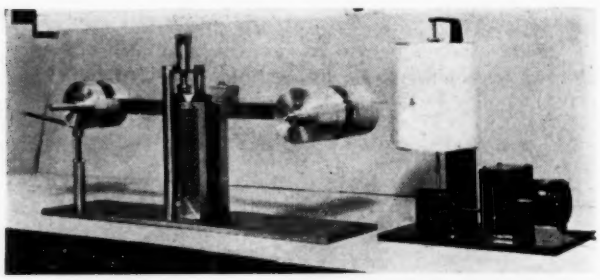

Fig. 2 The Oscillograph: Oscillating Bar and Loading Platform Are Mounted on Knife-Edges
(Machine is shown in static equilibrium position with test piece under compression.)

like materials in compression, both statically and dynamically. This apparatus has been used for the tests reported herein. Small cylindrical test pieces nominally $^3/_4$ in. diam $\times$ $^1/_2$ in. high are used. For static-load-compression relationships, deflections under various dead loads up to 280 lb per sq in. are recorded. For dynamic characteristics, the bar is allowed to oscillate at its natural frequency of vibration under the combined action of gravity and the elastic force of the test piece. The dynamic modulus is then calculated from the frequency and the inertia of the bar by means of the equation, $K = 210\,If^2$. Test frequencies are usually of the order of 2 to 5 cycles per sec. Data are recorded autographically. A typical oscillogram from this series of tests is shown in Fig. 3.

It is well known that rubber and neoprene do not show the same stiffness on the first cycle of loading and unloading as they do on successive cycles. Each of the test pieces was subjected to several conditioning cycles of loading and unloading under an average load of 280 lb per sq in. Static-load-compression data were then obtained, followed by further conditioning and a dynamic test under the average load corresponding to approximately 30 per cent compression. Data obtained in this way were plotted as shown for a rubber and a neoprene compound in Fig. 4. It will be observed, as Haushalter (12) has said, that the curves are approximately straight up to 20 per cent compression but that for greater deformations there is pronounced curvature. The slopes of the dotted lines, shown in Fig. 4, represent the dynamic moduli and were calculated from the dynamic tests under average loads of 120 and 100 lb per sq in. for the neoprene and rubber compounds, respectively. The crosses shown on the dotted lines indicate the points of equilibrium reached at the end of the dynamic test. The difference between the slopes of these lines and the tangents to the static load-compression curve illustrates the difference between the dynamic and static moduli.

It will be noted in Fig. 4, that the general shape of the curves for rubber and neoprene is the same. The neoprene loop is slightly wider, however, indicating greater hysteresis loss or damping action. The increase in modulus of neoprene in the dynamic test is greater than that of rubber. These differences are characteristic of the two materials today. Subsequent chemical developments may change this comparison.

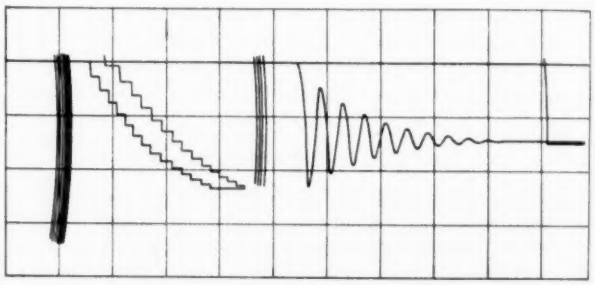

Fig. 3 Typical Oscillogram

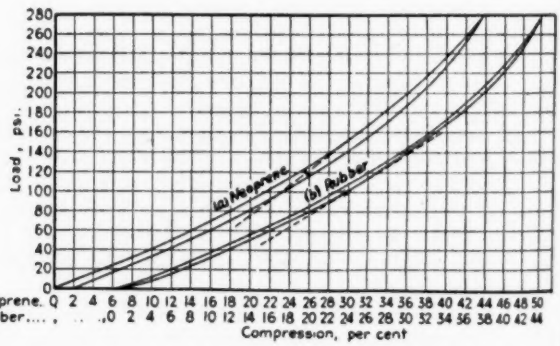

Fig. 4 Static Hysteresis Loops and Dynamic Moduli of Neoprene Test Cylinder and Rubber Test Cylinder in Compression

For the purposes of this paper, it is considered satisfactory to apply the term "compression modulus" to the slope at any point of the load-compression curve. It will be noted, however, that the values of the static modulus are obtained as slopes on the loading branch of the hysteresis loop. Although this is an arbitrary procedure, it appears to be common practice. For certain problems, the slope at points of the unloading curve might be more important. In other cases, an over-all average for successive cycles of loading and unloading is a more important value. Indeed the dynamic modulus reported in this paper is such a value.

During the last few years, correlations have been developed between the elastic moduli of rubber and values of the Shore durometer type A hardness. These correlations, though only approximate, provide a convenient way of determining the elastic moduli near zero load without resort to more extensive and some-

times expensive tests.[3] Conversely it provides the convenient method of specifying moduli by stating the hardness desired, particularly for springs in small quantities. The author intends in the following discussion to establish a similar relationship for neoprene with the hope, however, that some evaluation more precise than hardness data may win preference in the future.

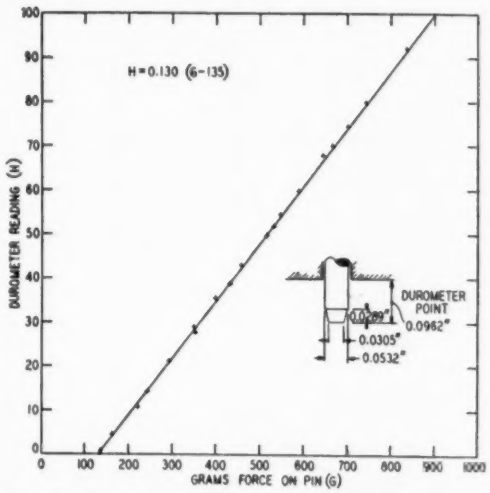

FIG. 5 CALIBRATION OF DUROMETER USED IN TESTS

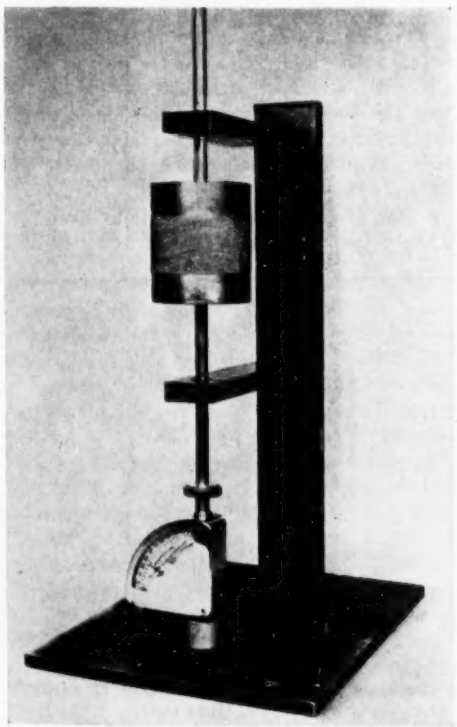

FIG. 6 SPECIAL DUROMETER STAND

There are three apparent reasons for unavoidable errors in correlations between durometer hardness and moduli. In the first place, the calibration of the durometer has not been adequately standardized by the manufacturer. As a consequence, different instruments will lead to different evaluations. In the second place, rubber technologists will readily agree that, unless operators are schooled with extreme care, different operators will obtain quite different durometer readings on the same compound and with the same durometer. In the third place, one cannot expect the same correlation between shear modulus and durometer readings for all types of rubber compositions. In appreciation of the fine work that has been done in establishing this correlation, expressed by Haushalter (12) and others, this criticism is offered only as constructive caution.

To remove doubt regarding the calibration of the durometer employed in this work, durometer readings were correlated with force in grams on the pin. These data are given in Fig. 5. The dimensions of the pin are also shown. Other dimensions are assumed to be standard. To eliminate the personal element as far as possible a stand, Fig. 6, was built. The instrument and the sliding rod together weigh 2 lb which then becomes the total actuating force (13).

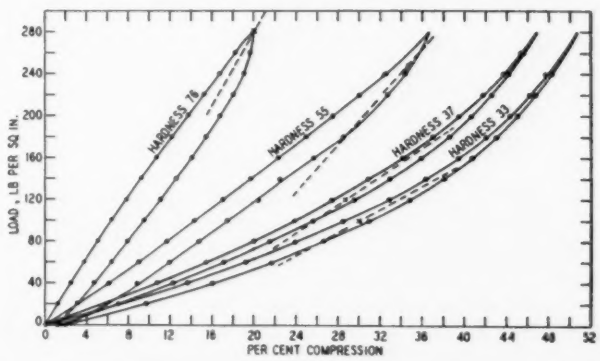

FIG. 7 LOAD-COMPRESSION DATA FOR GROUP OF NEOPRENE TYPE-G VULCANIZATES

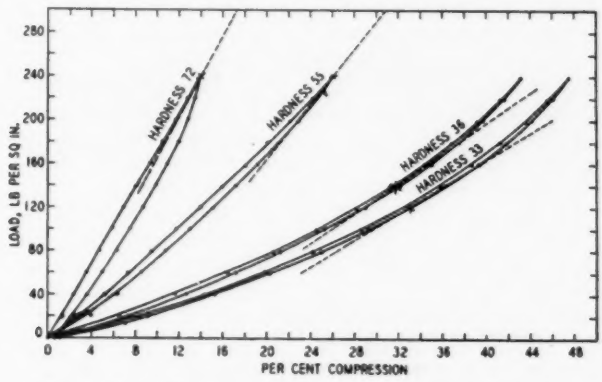

FIG. 8 LOAD-COMPRESSION DATA FOR GROUP OF RUBBER VULCANIZATES

In Fig. 7 are shown load-compression data of a group of neoprene type G compounds having different hardness numbers and, in Fig. 8, a similar group of rubber compounds. It is not feasible to present extensive data in curve form; condensation for the purposes of this paper as well as for practical use is required.

Data for neoprene and rubber compounds in compression are given in Table 1. It will be noted in the table that the static modulus at zero load is in most cases considerably lower than the static modulus under the load used for the dynamic test. As stated previously, the compression curve for rubber, up to 20 per cent, is practically a straight line. This is convenient, since

[3] The oscillograph is intended to provide a direct and inexpensive test for compression moduli and will soon be adapted to direct tests in shear.

it may be used in many cases to simplify calculations appreciably. It is true, however, that as a general rule the tangent to the load-compression curve at zero deformation is lower than the tangent at 20 per cent compression. This trend continues and, at 30 per cent compression, a still greater slope exists. The values given in Table 1 for the compression modulus at zero load are the closest values that could be obtained graphically, disregarding any irregular curvatures that were shown by the data for small deformations. In some cases, they correspond to the constant slope of the curve up to 10 per cent compression and, in other cases, they correspond more closely to the particular slope at 10 per cent compression. It will be recognized that errors in obtaining a load-deformation curve for rubber may readily occur at zero because of the difficulty sometimes experienced in determining the zero deformation. This is particularly true of soft stocks which may undergo appreciable deformations with very light loads and it is also true for compositions which have excessive creep or pronounced damping characteristics.

The dynamic tests reported were conducted at 30 per cent average compression, which in terms of usual practice is somewhat abnormal. Various tests conducted by the author have indicated that the relation between static and dynamic moduli is practically independent of the load up to 30 per cent compression. It is also independent of the frequency obtainable by this technique as indicated by the uniformity of the ratio obtained at two frequencies for compounds 302N-40, -41, and -42 in Table 1.

It has frequently been claimed that rubber is considerably stiffer dynamically than it is in static loading. Circulation has even been given to the statement that the dynamic modulus of rubber is 2 or 3 times greater than the static modulus. As the result of his recent work, Kosten (14) has concluded that the ratio of the dynamic modulus to the static modulus lies, as a rule, between 1 and 2 and that the ratio is independent of frequency. The present work, employing a different technique of measurement and a somewhat different frequency range, confirms these conclusions drawn by Kosten. Naunton and Waring (15) on the other hand, have found in tests up to 60,000 cycles per min that the increase in modulus is proportional to frequency. They confirm the finding, however, that the ratio of dynamic to static modulus is between 1 and 2.

The ratio of the dynamic modulus to the static modulus in Table 1 is given in the eighth column and it will be seen that these are in the range 1.04 to 1.75. In the next to the last column, the resilience in per cent, or in other words the elastic efficiency of the compound, is given. These data were calculated from the dynamic records by obtaining the ratio of successive heights of rebound on the oscillograph. If resilience is plotted against the ratio of dynamic modulus to static modulus, as in Fig. 9, it will be noted that there is an increase in the ratio as the resilience of the compounds decreases. It should also be kept in mind, however, that the compounds given in this paper are of a commercial grade and that many complicated factors involved in the state of cure and physical composition have been introduced other than the obvious change in resilience.

Assuming that, under operating conditions likely to be encountered, the dynamic modulus can be as much as 2 times

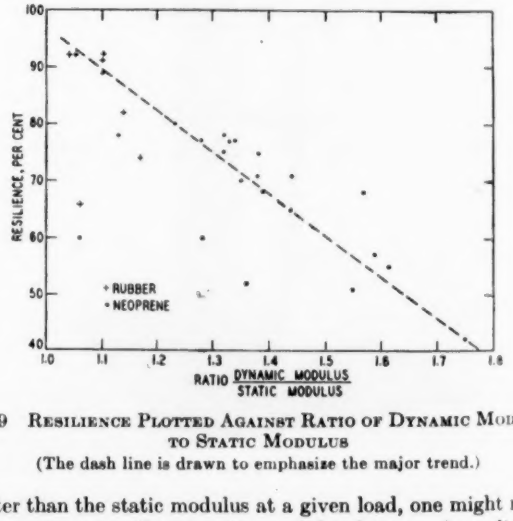

FIG. 9 RESILIENCE PLOTTED AGAINST RATIO OF DYNAMIC MODULUS TO STATIC MODULUS
(The dash line is drawn to emphasize the major trend.)

greater than the static modulus at a given load, one might naturally inquire as to the importance of the change. According to the usual theories of vibration, the frequency at resonance is given by the equation, f = constant $\sqrt{\text{spring constant}}$. In other words, a doubling of the modulus of rubber or neoprene will cause a 41 per cent increase in resonant frequency. This is not a negligible factor, but as this work and that of Kosten (14) indicate, a doubling of the modulus is not apt to occur. The actual change in

resonant frequency will be moderate and in most cases negligible. This is especially true, in view of the usual design practice of allowing a factor of 3 or 4, if possible, between the natural frequency of the supports and the probable frequency of impressed forces.

In his useful summary of the theory of vibration, Rosenzweig (16) has presented a discussion of the importance of damping at resonance. When critical speeds are encountered, some damping action or restraining force is absolutely essential. The data in the next to the last column of Table 1 give values for the resilience of the compounds. For the neoprene compounds selected, resilience ranges from 42 to 80 per cent and the corresponding energy absorption would consequently range from 58 to 20 per cent. The values for rubber are different, ranging from 66 to 92 per cent for resilience and from 34 to 8 per cent for energy absorption in a given cycle of loading and unloading. The art of compounding has not yet progressed to the point where resilience can be varied independently from all other properties, but there are ways of varying the resilience in a limited range for a given modulus.

In Fig. 10 durometer hardness is plotted against compression modulus at zero load as taken from Table 1. Other data of this same form have been published by Haushalter and are shown by the dotted line. This illustration confirms the relationship found by Haushalter (12) between compression modulus and durometer hardness as closely as one might expect. It will be noted, however, that there are points which do not lie on the curve.

Haushalter (12) and Kosten (14) both have emphasized the importance of the ratio between the height of a cylindrical test piece and its diameter. Haushalter has indicated that, if the ratio is approximately 1:1, the compression modulus is 6.5 times the shear modulus. In the present case, the ratio of the height to the diameter is 0.67. Consequently, it is of interest to determine how nearly the test pieces $^1/_2$ in. high and $^3/_4$ in. diam approach the characteristics of test pieces fulfilling the ratio requirement. Fig. 11 shows the changes caused in the load-compression curve by changes in the height of the cylinder from 0.135 in. to 0.995 in., i.e., by varying the ratio from 0.18 to 1.33. It can be seen that the difference in compression between the 0.502-in. and 0.995-in. cylinders is considerably less than 10 per cent of the percentage of compression at all loads.

In Fig. 12, the diameter of the cylinder is varied from 0.433 in. to 0.950 in., i.e., varying the ratio from 1.15 to 0.53. The discrepancy between the curves for the 0.742-in. and 0.433-in. cylinders is less than 10 per cent of the percentage of compression. If the ratio of 6.5 : 1 is valid for rubber, one might reasonably expect approximately the same ratio to apply for neoprene. Smith, on the other hand, has found the theoretically derived ratio of 3 : 1 (17) between compression modulus and shear modulus to be useful. Although the discrepancy between 6.5 and 3 appears offhand to be disturbingly large, further investigation will probably unify the methods of treatment and contribute better understanding. The measurements in shear so far made by the author have been limited and inadequate to establish a clear relationship between the shear and compression moduli. It is known from several comparisons, however, that the shear modulus of neoprene can be varied over the same range as that of rubber; for example, for practical purposes from 50 to 350 lb per sq in.

Whenever damping action is important, due to the unavoidable occurrence of critical speeds, it will be recognized that mountings will be called upon to absorb substantial quantities of energy. The direct result of this absorption of energy will be an increase in the temperature of the mounting. The specific heat of uncompounded and unvulcanized neoprene is 0.52 cal per g and its thermal conductivity 0.00046 cal per sec per cu cm per deg C. Vulcanization seems to have little, if any, effect on the thermal properties of neoprene, although loading ingredients will alter thermal values of vulcanizates in amounts proportional to the volume content and properties of the added ingredients. Since the specific gravity of neoprene compounds is relatively low, being as a rule between 1 and 2, the thermal capacity of neoprene on the volume basis is low. The temperature rise on absorption of energy is, therefore, rapid. In comparison with rubber, however, the thermal conductivity is about 30 per cent higher. Neoprene is, therefore, a better damping material than rubber from the standpoint of its damping action, its chemical stability when

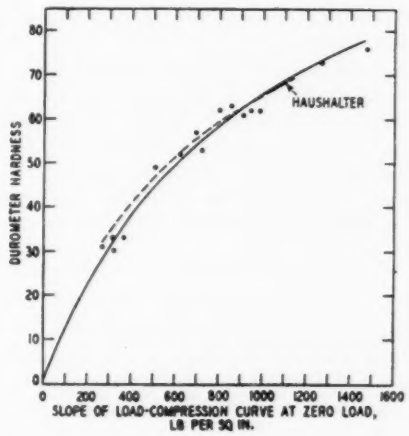

FIG. 10 DUROMETER A HARDNESS PLOTTED AGAINST SLOPE OF LOAD-COMPRESSION CURVE AT ZERO LOAD
(The average obtained by Haushalter for similar data is shown by the dash line.)

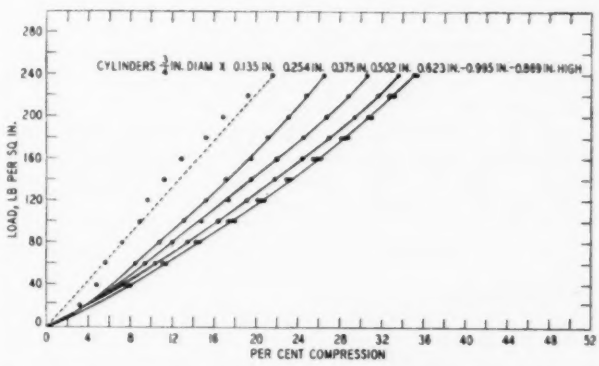

FIG. 11 EFFECT ON LOAD-COMPRESSION CURVE OF TEST CYLINDERS ¾ IN. DIAM, CAUSED BY VARYING HEIGHT

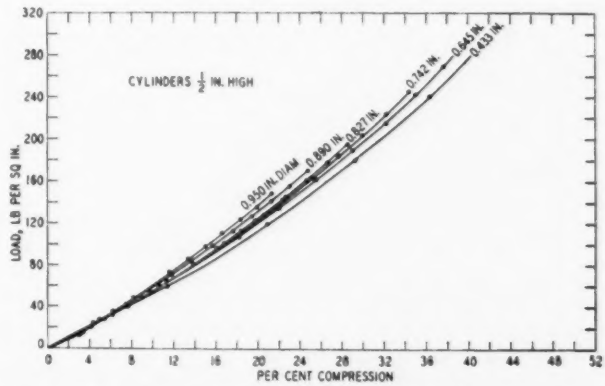

FIG. 12 EFFECT ON LOAD-COMPRESSION CURVE OF TEST CYLINDERS ½ IN. HIGH, CAUSED BY VARYING DIAMETER

heated, and its higher thermal conductivity, permitting more rapid dissipation of heat.

It has been shown that the elastic characteristics of neoprene in which design engineers are interested are similar to those of rubber. Greater damping action and a somewhat higher value for the ratio of dynamic to static moduli are, however, characteristic. The similarity permits the design and application of neoprene springs by the same methods developed for rubber by many investigators (2, 3, 7, 12, 16, 17).

Electrical Properties of Neoprene

Although not related to the main subject of this paper, brief mention of the electrical properties of neoprene is warranted by the occasional demand for combined electrical and mechanical service. The values given in Table 2 are roughly representative of neoprene compounds which contain no fillers and only enough added ingredients to insure proper vulcanization.

TABLE 2 ELECTRICAL PROPERTIES OF NEOPRENE AT 28 C

D-c resistivity	1×10^{12} ohm-cm
Dielectric constant at 1000 cycles per sec	7.5
Power factor at 1000 cycles per sec	3.0 per cent
Dielectric strength, rms at 60 cycles per sec	800 v per mil

Individual compositions will, of course, have different electrical properties. The d-c resistivity, the dielectric constant, and the power factor can be improved somewhat over the figures given in Table 2 by compounding. Compositions containing high proportions of carbon black have lower values of d-c resistivity and dielectric strength than those given in Table 2, and higher values of the dielectric constant and power factor.

Adhesion of Neoprene to Metal

Neoprene compounds can be adhered firmly to brass and brass-plated metals by vulcanization in direct contact with the brass surface. Other commercial methods employ cements to obtain equally strong adhesion. Bond strengths above 1300 lb per sq in. in tension have been obtained under the most favorable conditions.

Performance

Under normal operating conditions, the permanence of neoprene mountings is of a high order. They are not damaged by millions of cycles of loading and unloading and they resist deterioration from oils, chemicals, heat, sunlight, and oxidation. Abnormal conditions may be encountered, however, if mountings are installed or operated incorrectly so that excessive temperature rise occurs in the neoprene as the result of overstressing or excessive frequency of operation. Although no general statement will apply to all conditions, a temperature of 65 C is a reasonable maximum. If operation at higher temperatures is unavoidable, a commensurate reduction should be made in the unit load on the mounting to compensate for loss in spring strength resulting from the abnormal temperature condition.

The functional purpose of neoprene mountings is to isolate and dampen vibrations. The structural requirement is that the mounting shall safely support a given load. If the mounting is operated continuously at excessively elevated temperatures, it is inevitable that the modulus of the composition will gradually increase. The effect of this change will be to alter the characteristics of the mounting, as a vibration isolator, without impairing the ability of the mounting to carry the required load. Hence, although the functional purpose of the mounting may be impaired, the structural safety of the installation ordinarily remains unchanged.

At low temperatures, neoprene temporarily acquires an abnormal hardness. The rate of hardening depends primarily upon the temperature. Preliminary tests, at a temperature of 40 F, have indicated that the modulus of neoprene type-E compositions may increase by a factor of 2 or 3 over a period of 5 days. Furthermore, the change will not occur if the mounting is in normal operation, since the mechanical working of the compound will prevent freezing. If a neoprene mounting has been stiffened by freezing, tests have proved that the mounting will recover its original characteristics quickly upon resumption of operation. It is believed that the rate of freezing increases slightly as the temperature decreases to a value of about 20 F, and that below this temperature the rate of freezing decreases. A study of these points is in progress and more information will be available in the future.

Discussion

B. S. Cain.[4] It would be helpful if the author could furnish some of the characteristics of neoprene at low temperatures. In particular, is material available for use where some flexibility is required over a wide range of temperatures, including a sub-zero range?

Stuart H. Hahn.[5] This is another excellent presentation of reasons why neoprene can be used for the construction of rubber

[4] Assistant Engineer, Locomotive Division, Transportation Engineering Department, General Electric Company, Erie, Pa. Mem. A.S.M.E.

[5] Physical Research Laboratory, The B. F. Goodrich Company, Akron, Ohio. Mem. A.S.M.E.

springs. This material, as well as several other modern synthetic rubber-like materials, has certain desirable properties for this service.

The value of the oil resistance and good aging properties of neoprene is well known and appreciated by rubber technologists. However, the admitted tendency of the material to harden continuously upon exposure to elevated temperatures must be balanced against its age resistance at elevated temperatures when spring service is to be considered.

Many designers of rubber springs will disagree with the author's thesis that damping characteristics greater than those of normal rubber compounds are desirable, particularly since high damping usually is accompanied by increased creep. It is, unfortunately, true that low creep is rarely, if ever, a characteristic of compounds of rubber and other rubber-like substances which have low resilience (high damping). Available information on the creep-resilience relationship for neoprene is even less complete than that for rubber compounds. It is hoped that the author will soon be able to fill the need for such information.

The addition to the literature of data on the dynamic modulus of neoprene and other compounds is welcome. It is unfortunate that the author has not been able to extend his investigations above a frequency of about 4 cycles per sec, which is below the ordinary range of resonance frequencies for the more common rubber-spring designs. The modulus effective in determining the actual working transmissibility of such springs is the modulus at the impressed or forcing frequency, which is usually from 2.5 to 10 times the resonance frequency.

It is interesting to note that the data points, in the author's Fig. 9 which shows the resilience versus dynamic/static-modulus ratio for neoprene and rubber compounds, appear to be grouped distinctly into two categories which seem to distinguish the two materials. Although the rubber data are too limited to be conclusive, a curve giving a good fit to the available points would appear to intercept the 40 per cent resilience axis at a value much lower than the intercept for the line shown, which fits the neoprene data rather well.

One most important property of rubber-like materials for spring service is the safe and economical stress to which they may be subjected in service. The working stresses for compressive use are nearly always dictated by creep considerations so that deflections are ordinarily limited to values of about 20 per cent or less. Failures due to actual fracture or cracking of the rubber are quite rare in such service. The determination of working stress for service in shear is not nearly so simple. Some applications which have proved practical in service have made use of deformations somewhat more than the thickness of the rubber (shear strain $>$ 100 per cent thickness) and static or mean dynamic stresses in the region of 100 lb per sq in. are known to be practical in certain limited classes of use, especially where compressive strain perpendicular to shear adhesion areas is imposed. However, in no case does the actual breaking shear stress in continuous service approach the breaking stress as determined by short-time loading tests. It is important to the designer, who contemplates the use of a material such as neoprene in spring service, to know what safe working loads may be applied to the material if service over a given period at approximately known temperatures is to be rendered without failure. The effect of temperature increase in reducing the strength of neoprene and rubber cannot be ignored.

The author's experience with poor standardization of the durometer (type A) agrees with that of many others. His description of the calibration of his instrument adds to the value of his hardness-versus-modulus curves, even though there are theoretical objections to the method of calibration which he used. It also emphasizes the precautions which must be taken to avoid or compensate for the well-known shortcomings of the instrument. Tests and theoretical studies by another member of this laboratory have indicated very clearly that the most reliable results may be obtained only when the durometer is held in such a way that the lightest possible pressure is obtained between the rubber surface and the foot or disk surrounding the indenter point.

The author seems to be guilty of overemphasis in saying that the slightly higher thermal conductivity of neoprene compounds is sufficiently great to constitute an appreciable advantage of this synthetic over natural rubber. The thermal conductivities of neoprene and rubber compounds suitable for spring service are all so low that any appreciable energy absorption produces sizable temperature rises in both classes of materials. The conductivity of the softer rubber-spring stocks is about 0.95 Btu/(hr) (sq ft) (F/in.) or roughly $^1/_{300}$ that of steel.

An estimate of the temperature which might be produced in mountings made of a neoprene compound and used under conditions of moderately severe vibration has been made for the following hypothetical case:

Machine weight, 2000 lb
Shear stress on mountings, 40 lb per sq in.
Static deflection of mountings, 1 in.
Resilience of neoprene compound used in mountings, 60 per cent
Magnitude of simple harmonic disturbing force, $\pm$20 lb
Frequency of disturbing force, resonant (approximately 190 cycles per min)

For this particular case, the mean rate of temperature rise works out to something like 3 F per min and, since the mountings would necessarily have a thickness of 1 in. or more, the maximum temperature in each mounting would probably attain a value of about 200 F after starting at 80 F and running for about 1 hr, if failure of the material did not occur before that, through the combination of the weakening effects of temperature and the gradually increasing amplitude which would result as the damping coefficient decreased with increasing temperature. Hence, intentional operation at resonant frequency would be impractical, since the comparatively higher conductivity of neoprene stocks is still too low to permit their extensive use as shock absorbers.

In some cases there has been a real need for a cool-running rubber or synthetic compound for use in services where occasional or even rather frequent shocks or dynamic-stress cycles are encountered. However, the solution of the problem in most cases, and probably in every case, has been the use of a compound which possesses relatively high resilience with ordinary values of thermal conductivity, rather than low resilience accompanied by the maximum possible conductivity. It should be emphasized that thermal conductivities of all rubber-like materials are so low that they are unable to dissipate very much energy continuously except in the case of relatively small pieces.

F. L. Haushalter.[6] The writer expected to learn from this paper how high neoprene might be stressed as compared with rubber, without experiencing trouble from creep or drift. If neoprene springs are used to support a machine, what would be a reasonable estimate as to how much lower the machine would be setting in a year's time? Also, what would be the modulus or rate of the spring in a year and, possibly, in 3 or 10 years hence? If the springs are to be used in an atmosphere of elevated temperature, data on creep would be essential before choosing the stress at which the spring will function. Values of dynamic modulus versus static modulus for this material are useful enough, but what are these moduli after creep has taken place at elevated temperatures? We know that for rubber the values are appreci-

[6] Development Engineer, The B. F. Goodrich Company, Akron, Ohio.

ably higher, and it is reasonable to suppose that for neoprene the values would be still higher because it is the writer's experience that neoprene compounds have greater creep than equivalent rubber compounds.

The more work the writer does with springs made from rubber, or rubber-like materials, the more he is convinced that damping is an unwanted characteristic in the material. About the only place one would require a spring to operate at resonance would be to counteract and neutralize the vibration of a body or member, the critical period of which was at that same frequency. Such applications are rare. About the only instance of this kind which the writer can recall occurred several years ago. In this case, the front wheels of an automobile developed a critical period causing bad wheel shimmy at a certain operating speed when traveling on cobblestone pavement. This vibration, which was in the horizontal plane, was neutralized by attaching a mass on the end of a spring, which in turn was fastened to the tie rod. The spring was designed to give the suspended mass the same resonant frequency as the wheels in the horizontal plane.

In the vast majority of cases, it would certainly be ridiculous to want to isolate a vibrating body with springs and then have the springs function at their point of resonance. If we wish to do any damping in passing through critical speeds, it can be done much more cheaply by using hydraulic shock absorbers. If we do not operate springs in the resonant range, which Hull pointed out should not be less than a frequency ratio of 1.4, damping is a distinct disadvantage, for the energy consumed in damping increases the transmissibility through the mounting.

Furthermore, the more damping there is in the material, the more creep will take place in the spring. The author has a good opportunity to disprove this statement, but if Isaac Newton was right, it is very probable that, as compounds made from neoprene G are developed, which take on less and less creep, we shall find that the hysteresis loss, or damping effect, will diminish accordingly.

As for the argument on durometer and hardness, which seems to be an endless one, as unscientific as this instrument appears to be, the writer dislikes the thought of condemning it to the scrap heap, for when properly used it certainly can pick out small differences in hardnesses of stocks in a comparative way. For the detection of these small changes in hardness, the writer would not use the author's method, but would depend upon the human hand. The writer was once confronted with the task of making a rubber spring slightly stiffer than a previous spring, which meant an increase of about $^1/_2$ point in hardness on the durometer. After using the Olsen hardness tester and the Pusey & Jones plastometer with conflicting results, the only way discovered for accomplishing this was to lay on a table disks of the possible compounds of the same thickness, and go from one to another with the durometer in hand. The stock was selected in this way and, when the spring was made up, the shear-modulus value was found to be exactly that required. It is truly a difficult matter to standardize durometers, but there is no reason why we cannot calibrate one against the other. Undoubtedly, one who works constantly on the compounding of rubber and rubber-like materials soon acquires facility in the use of his own durometer.

J. F. Downie Smith.[7] The material given in this paper will, in the writer's opinion, be welcomed by designers who are interested in the application of rubber and rubber-like materials in industry. It is hoped that more information of this type on other rubber-like materials will be made available in the near future. At present the mechanical engineer feels rather at a loss when he is trying to determine the proper material to use for a specific application.

A short time ago the author gave the writer two samples of neoprene and one of rubber each bonded to metal plates in the form shown in Fig. 13 of this discussion. In order to make a cursory examination of each sample to see if it would be applicable in springs as used in experimental work, each sample was loaded and unloaded quickly a few times. Then a loading curve was taken in $7^1/_2$ min with the unloading curve taken in about the same time. A second set of curves was then made with loading and unloading periods 6 times as great. The results are shown in Fig. 13.

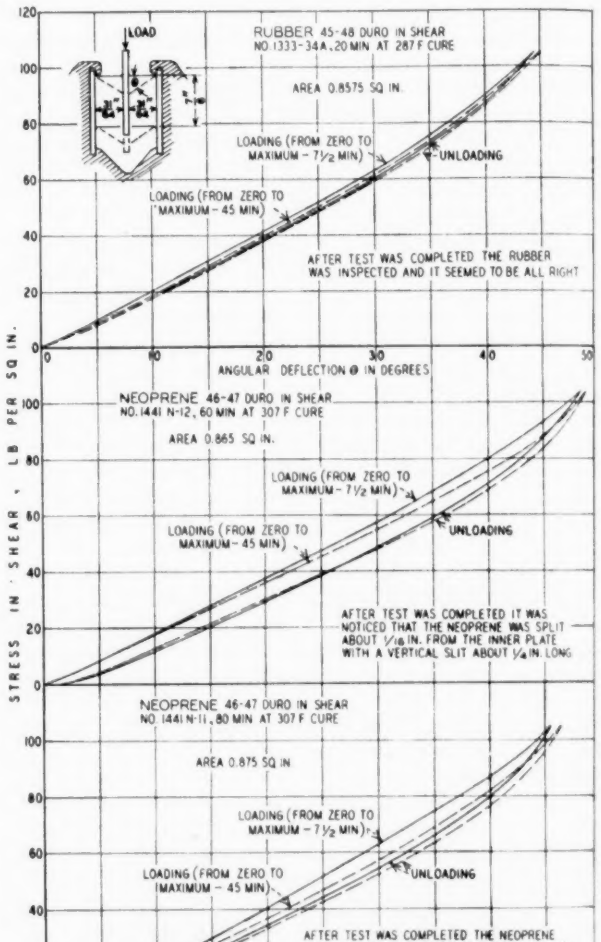

Fig. 13 Loading and Unloading Curves of Neoprene and Rubber Samples Bonded to Metal Plates

One of the neoprene samples, No. 1441 N-12, after the tests were completed, was found to be split, and could no longer be recommended as a spring. The other neoprene sample and the rubber one were apparently satisfactory.

It may be observed that one of the neoprene samples gave a much greater variation between quick and slow loading than did the rubber. At two shear stresses the percentage variations between the two loading curves are as follows:

[7] Executive Engineer of Research, Edward G. Budd Manufacturing Company, Philadelphia, Pa. Mem. A.S.M.E.

		At 40 lb per sq in.	At 60 lb per sq in.
1	For rubber No. 1333-34A	4.4	2.6
2	For neoprene No. 1441 N-12	4.5	4.8
3	For neoprene No. 1441 N-11	9.9	8.9

The writer would like to ask the author if such results would always be expected from typical rubber and neoprene springs, or if these samples are unusual in some way. If results of this type are expected, would he consider them detrimental to the use of neoprene as a spring?

An additional point of concern is that none of the curves comes anywhere near the theoretical shear loading curve which might be expected from previously published data on rubber. This theoretical curve is based on the calibration of definite Shore durometers against known moduli of elasticity in shear for rubber. Now all three of the curves shown in Fig. 13 check one another reasonably well, and one of the samples is of rubber and two are of neoprene so that the change from natural rubber to a synthetic rubber-like material is not the answer. One thought which arises is: "Does the size of the sample have an influence on the rough relationship of durometer hardness and modulus of elasticity in shear?" These particular samples are much smaller than those ordinarily used by the writer, and it occurred to him that this may explain the discrepancy to some extent.

Author's Closure

In this paper, an attempt was made to summarize such portions of the present knowledge of neoprene as might contribute to the design of springs. It is a paper on a spring material, however, and not a detailed paper on springs or on vibration in engineering. The author attempted to cite adequate references, without giving a complete bibliography, on these topics as collateral reading for anyone sufficiently interested. The fact is appreciated by the author that the present knowledge of neoprene has limitations. In some respects, additional research and further years of experience will permit a more definite account in the future than is possible today.

Mr. Cain has asked a question particularly pertinent to outdoor service. A specific answer would require definition of the expression "some flexibility." At — 40 F neoprene compositions of a high-grade mechanical type properly cured approximate the stiffness of hard leather but they are not brittle after exposure for as long a period as 14 days. If this condition is considered to fall within the intended meaning of the question, neoprene is flexible at all low temperatures down to — 40 F for any length of exposure. The change of modulus under these conditions would, of course, drastically alter the characteristics of a neoprene spring and would be against its application in some cases. Stiffness acquired by exposure to low temperatures can be overcome by heating from external sources, or by mechanical working.

A detailed discussion of each of the points raised by Mr. Hahn and, in some cases, again by Mr. Haushalter would be inordinately long and involved. There seems to be peculiar disagreement in the literature and among engineers as to what properties in rubber are desirable for some types of service. Every individual taking part in such technical controversies as this has some real basis for his views but, when the situation is viewed broadly, the arguments in good faith seem to arise from deductions based upon distinctly different types of service. The author has culled from the literature the outstanding reasons given for the use of rubber as a spring material under particular conditions. These reasons are, therefore, advantages possessed by rubber springs over metallic springs and are listed as such in the introduction to the paper. The same literature has pointed out further properties to be desired. Such properties, when possessed by neoprene, thus become advantages of neoprene over natural rubber for particular conditions which have been adequately defined in the early part of the paper. It seems trite to point out that, where these conditions do not exist for either rubber or neoprene, other selections would be made and that the selection of neoprene or rubber would sometimes be based upon one or two outstanding characteristics, in spite of attendant disadvantages.

The relatively high damping rate obtainable with neoprene is an advantage when relatively rapid damping is desirable. In other cases a high rate of damping would be a distinct handicap. The author does not believe that any engineer could specify the properties of an ideal spring system without including in the specification a desirable range of damping rates. Although Rosenzweig (16) has discussed the advantage of damping at critical frequencies, the bulk of his paper is devoted to proof that, outside of the critical range, damping is undesirable in the isolation of vibration. Numerous other references could also be given which cover the same point. The author has merely attempted to show that neoprene increases the range of damping rates available with rubber-like materials beyond the limits feasible with rubber. It is the job of designers to determine how much damping is required in a given case.

Mr. Haushalter's statement that spring systems are not designed to operate at resonance, apparently, is made without considering the present importance of dynamic balancers. The example of front-wheel shimmy on automobiles has been supplanted in industrial importance by a host of harmonic balancers in other applications. Those used on lightweight crankshafts to reduce torsional vibration are particularly interesting. Combinations of frictional and dynamic absorption offer the possibility of effective refinements in design.

Various authorities have suggested the desirability of damping action by rubber springs. Among them Haushalter, in a recent discussion,[8] expressed himself as follows: "It would be very desirable to have a rubber spring with a high damping coefficient but, with a compound giving this, the drift greatly increases. A combination of high damping and low drift in a rubber stock is yet to be found. The two conditions, apparently, are diametrically opposed. Work is still going on, however, and there are some possibilities in this direction with synthetic rubber."

In his experience with neoprene, the author has noted frequent exceptions to the statement that there is a general correspondence between creep and resilience. In a current series of tests, for example, two neoprene compounds, cured for the same length of time and having the same compression moduli, have 78 and 76 per cent resilience, respectively. However, in a shear-drift test, the former compound shows roughly twice the drift rate indicated by the second. This is not an isolated case, but is a repetition of a rather frequent occurrence. If the correlation were strictly true for rubber, as it certainly is not for neoprene, long and expensive tests of creep could be dispensed with in favor of fast and relatively inexpensive tests of resilience. Unfortunately, this is not the case.

Very properly, Mr. Hahn has pointed out that the thermal conductivity of rubber and of neoprene is relatively low. Many mechanical designs of rubber parts have failed because excessive heat was developed in operation. Other things being equal, any increase in thermal conductivity will assist the dissipation of energy, but a 30 per cent increase can only offer help to a minor extent. The relative values of thermal conductivity are quite incidental and, if the author is guilty of overemphasis, the point is well taken.

The use of neoprene commercially as a spring material is a relatively recent development and it is not possible, at the present

[8] "Rubber Cushioning Devices," by C. F. Hirshfeld and E. H. Piron; discussion by F. L. Haushalter, Trans. A.S.M.E., vol. 60, 1938, p. 204.

time, to predict what will happen to a spring in 3 to 10 years. Yet, it is believed to be true that the best rubber compositions have lower drift than the best neoprene compositions. However, the author knows that it is possible to produce neoprene compositions which compare very favorably with some of the rubber compositions commercially used. Unfortunately, tests which are now in progress at the du Pont rubber laboratories have not yet progressed to the point where detailed presentation is permissible.

With reference to the discussion by Dr. Smith, the author considers creep to be a type of dimensional instability and any type of instability in a structural material is undesirable. It is indicated by the tests that neoprene will creep more under dead load during the first hour than a comparable high-quality rubber under similar conditions. Since the neoprene samples under discussion are the best obtainable at the present time from the creep standpoint, it is apparent that neoprene will creep more during the first hour than rubber. The fact that a defective sample appeared to be better than an undamaged specimen is somewhat surprising and is probably an indication that a more reliable comparison between the compositions might be obtained from a more extended test. It has been the author's experience that the maximum discrepancy in rate of creep between properly vulcanized neoprene and rubber compositions occurs during the first 24 hours.

Inasmuch as the discrepancy in theory mentioned by Dr. Smith concerns a correlation of shear modulus with durometer hardness, it does not seem to be a matter of the greatest importance. If we remember that the correlation between elastic moduli and durometer readings is at best an approximation, occasional departures should not be too disturbing. On the other hand, data in the author's personal files indicate that the published values of shear modulus referred to by Dr. Smith are about 30 per cent low and this observation is confirmed by Dr. Smith in this case. It should be more disturbing if the size of the samples has a large effect upon the value of the shear modulus, since this would vastly complicate the design of shear springs by requiring a shape or size factor. The author's experience has been more extensive with small samples than with large ones, but there is inclination to doubt that the size of shear mountings has any great influence upon the modulus of a spring composition, provided each specimen is uniformly cured throughout its entire volume.

It is quite apparent that the introduction of rubber springs to industry, particularly to the automotive industry, preceded the development of an adequate literature and engineering background for general purposes. Even today, data on rubber are extremely meager and without a satisfactory network of correlating theory. It is to be hoped that information on rubber and similar materials will develop more rapidly in the future and that the present mystery surrounding the mechanical properties of these materials will soon no longer exist.

Automatic Integrating Pressure-Traverse Recorder for Study of Flow Phenomena in Steam-Turbine Nozzles and Buckets

By H. KRAFT[1] AND T. M. BERRY,[2] SCHENECTADY, N. Y.

The high efficiency of modern steam turbines can be safely predicted only when the flow phenomena in all passages of the turbine are well understood. The General Electric Company maintains an air-test laboratory where these passages are studied over a wide range of conditions. The principal test is a series of impact-pressure traverses in an air stream simulating flowing steam. The test is a "contour-map survey" of emerging energy, formerly requiring thousands of observations. Recently an instrument has been built which automatically traverses the passage, calculates the corresponding flow and energy quantities, integrates them against the traversed path, and records the integrals in an easily readable manner. The high speed of the instrument increases greatly the range of possible tests. Its inherent accuracy of 0.1 per cent surpasses the best previous performance. The instrument, using mechanical devices for measuring, calculating, and integrating, has all moving parts controlled by electric and photoelectric means.

THE automatic integrating pressure-traverse recorder is an instrument employed by the turbine-engineering department of the authors' company. The air-test laboratory of this department uses it for the following purposes:

The rapid recording of impact-tube pressure traverses run over turbine passages.

The simultaneous evaluation of these readings into flow and energy quantities.

The concurrent integration of these quantities against the impact-tube travel.

Purpose of Turbine Tests

The desirability of a high efficiency in a large steam turbine hardly need be emphasized. A loss of 1 per cent from an output of 50,000 kw represents, in addition to a 1 per cent increase in fuel rate, a loss of 500 kw installed capacity, which is rather an appreciable amount of power. It is necessary, therefore, to be in a position that will allow reliable judgment on all factors contributing to the efficiency of the turbine. As in all similar fields of human endeavor, continuous effort directed toward progress is the only means to assure higher efficiency or, if ever diminishing returns should someday make this impossible, to maintain what has been won.

Published knowledge of the many phenomena, which influence the efficiency of a steam turbine, is very limited. Many years of intensive work, many times too voluminous for publication, have built up a body of information which forms the basis of present-day design. It is imperative to add continuously to this information. Failure to do so would soon lead to questionable extrapolations into unexplored fields. Most surely it would arrest the trend toward ever better efficiencies.

The largest single part of the losses occurring in a steam turbine is caused by phenomena of fluid flow. The behavior of a compressible, viscous fluid, such as steam, is a function of a large number of variables. Every single problem that arises will bring these variables into play in one of a practically infinite number of combinations. No solution so far has been found that would permit attacking the problems by way of theoretical deduction.

On the other hand, it is evident that over-all results, obtained from tests on complete turbines, cannot give much detailed information.

To gain additional design information, the only practical method that is available is to collect a large amount of empirical results from tests on turbine elements, single and in various combinations. If proper consideration is given to unavoidable differences between test conditions and turbine installation, there is every reason to believe that satisfactory results can be obtained.

Of late, the method of model testing has received much attention from engineers. Briefly, it consists of the simulation of the conditions of the actual machine by a convenient model set up in such a manner that a definite comparison with the actual machine is possible. The model may be full-scale or may be merely geometrically similar. Materials and flowing media may differ from machine conditions and so may velocities and forces. Definite rules regarding the similarity of model conditions are available for various applications, e.g., Reynolds', Froude's, Mach's numbers, etc. Probably the model tests owe much of their popularity to the good results obtained from the aircraft engineers' wind-tunnel and hydraulic-laboratory work.

The turbine-engineering department of the General Electric Company has been using this type of model testing continuously during the last 19 years. In 1924, H. L. Wirt presented a paper[3] before the Society, describing this method of testing.

It is a high tribute to the engineers, who instituted and developed this fact-finding method, that this type of test in its essentials is still the same today as it was 19 years ago. Its advantages were so apparent that considerable thought and money have been spent to develop it to still greater usefulness.

Herewith is a short description of the test: Compressed air is passed through the actual turbine element or a scale model of it. Knowing the temperature, the total energy of the entering air is easily ascertained by means of a single impact tube. The test aims at obtaining a complete detailed picture of the flow energy leaving the element. The ratio of the energy integrated over the passage at its exit to the entering energy will furnish its efficiency. The details of the energy "picture" will help toward the explanation and cure of unsatisfactory behavior.

The principal advantages of such a test are:

1 The details of the energy distribution are visible.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[3] "An Experimental Investigation of Nozzle Efficiency," by H. L. Wirt, Trans. A.S.M.E., vol. 46, 1924, pp. 981–1003.

2 In the case of nozzles and buckets a few single passages can be tested as representative of the whole ring. No additional end conditions need be introduced, as must be done in the case of reaction and impulse tests.

3 The use of air instead of steam facilitates the test very considerably:

(*a*) Free atmosphere provides a known constant pressure in a practically infinite space into which to exhaust and in which the observer can live without special precautions.

(*b*) The temperature is constant enough to eliminate special measurements, at least as long as efficiency ratios close to 1 are obtained. Nor is there any possible condensation to be taken care of.

(*c*) The air temperature is low enough to permit the use of wood as the principal model material. This is important, as the building of models as well as all changes and modifications can be done much faster and cheaper with wood than if metal is used.

Several important characteristics of the test require special consideration:

1 The similarity rules of model testing must be obeyed. When applying air-test results to steam conditions complications can arise. Both steam and air are compressible fluids with low viscosity. So long as the viscosity is neglected, all the forces occurring in the flow of a compressible medium are due to mass actions. The forces acting on every particle of flow are all caused by the mass of the particle, as expressed by its density and its accelerations or decelerations. This includes, of course, all centrifugal actions due to the curvature of the streamlines. The static-pressure forces do not need to be considered. They are in equilibrium with the inertia forces and thus equal and opposed to them. If one set is known, the others are. It can be shown that the mutual relationship of all inertia forces in a flowing medium remains unchanged as long as, at a chosen geometrical position in the flow, the velocity always bears the same relationship to the sound velocity of the medium. Expressed in the terminology of the physicist, this amounts to maintaining a constant Mach number. This condition is easily fulfilled in a model test.

At high efficiencies, however, the viscosity forces enter the picture as the preponderant causes of the flow losses. In this case it is obvious that the ratio of these forces to the inertia forces also must be the same in the test as in the machine, if all forces in the flow are to retain their proper geometrical relationship. The ratio between mass and viscosity forces is expressed by the well-known Reynolds number. It is this Reynolds number which, once the flowing medium is chosen, coordinates one certain velocity to a chosen model scale or vice-versa, i.e., the size of the model passage must be such that the forces, due to speed changes, maintain a proper magnitude with relation to the viscosity forces as given by the medium. Usually it is impossible to find in another flowing medium a condition where simultaneously the same Mach and Reynolds numbers prevail as in the original. This difficulty usually can be taken care of when the behavior of the flow in question is known, both as a function of Mach's as well as of Reynolds' number. This is entirely possible, but calls for a certain expenditure of testing and engineering effort.

2 Means must be provided for recording and integrating rapidly a large number of test readings. For example, the upper curve of Fig. 8, had it been obtained by manual testing methods, would have required the taking, recording, calculating, and integrating of a minimum of 11,000 test readings. This makes the test cumbersome and slow. The more that becomes known about turbine nozzles the more it is apparent that the situation is aggravated by the fact that a systematic, statistical approach seems to be the only reliable method of controlling closely their efficiency. The numerous determining variables are so closely interwoven and related to the geometry of the nozzle as a whole that only a very large number of tests will yield a satisfactory solution.

It is well known how thousands of wind-tunnel tests on various shapes of airplane-wing profiles had to be made before the present knowledge of wing behavior was available. The turbine nozzle presents a much more complicated problem than the single wing, since the close pitching of the partitions, their position on a circle, and the compressibility of the medium introduce additional variables.

Here then, was a definite need for mass production of nozzle tests. The engineers' approach to such a problem was chosen, to wit, the employment of a labor-saving machine.

The conception of such a machine was dormant in many engineering minds. When the need for more and better test results became more and more pressing, the idea began to take form and grew into the instrument that is the subject of this paper.

Design Features of Instrument

The experiences mentioned in the foregoing paragraph crystallized into the following specifications for the instrument:

1 The instrument has to record the pressure difference, measured with impact tubes between the entrance and the exit sides of a row of nozzle or bucket passages. The impact tube at the entrance can remain stationary, as it reads a point value of an equally distributed entrance energy. Since each test naturally is run with the entrance energy remaining constant for one set of readings, this impact tube reads a constant pressure.

The exit impact tube is the traversing impact tube. Low impact pressure at the exit is an indication of the deficiencies of energy that are due to the losses in the nozzle. Set at the angle of the nozzle, the tube is moved over the nozzle exit at a constant clearance, usually equal to the axial nozzle-to-bucket clearance in the turbine. The traverse should include at least three single nozzle passages. The difference between the two pressures should be recorded at a suitable scale.

One set of readings should consist of a number of traverses suitably spaced to give a complete "contour map" of the emerging jet.

2 From the impact readings, the flow and the energy contained in the measured point of the jet should continuously be calculated. The calculation should be made according to the well-known formulas for compressible fluids. ($\gamma = 1.4$ for air.)

It was realized that for most velocities and for most purposes, the simple formulas for incompressible flow would have been sufficient. However, aside from some additional calculation work to be made for the design of the instrument, no additional complication resulted from the application of the accurate flow formulas. With the initial pressure and temperature kept constant, both quantities are functions of a single variable, the pressure difference, and each can be represented by a cam in the instrument.

3 The instrument has to integrate mass flow and energy against the path of the impact-tube travel. This will result in line integrals, i.e., the summed up mass flow and velocity energy along the path of a traverse. The theoretical 100 per cent energy can be found by multiplying the mass flow by the correct factor.

4 The instrument should record the integrals along the impact-pressure curve in such a manner that the integral along any portion of the traverse can be found by taking differences. Thus, it is always possible to evaluate any single section of the readings, wherever special phenomena may warrant it.

5 The instrument should perform these operations with an

accuracy of plus or minus 0.1 per cent of full scale reading or better. A 1 per cent error in the efficiency of a turbine must be considered a rather large figure. It was thought that 0.1 of that amount would constitute the smallest component part that might be of interest. Of course, the result must be so recorded that it is easily possible to read the results to such accuracy.

6 The specified accuracy must be attainable throughout a range of nozzle velocities from 800 to 1200 ft per sec. This covers a large number of turbine-diaphragm conditions. With lower-velocity nozzles, somewhat less accurate results will be expected from an instrument designed for the high velocity range.

7 A high working speed of the instrument is, of course, of great importance. An instrument as complicated as this represents a sizable investment which must be justified at least partially by a saving in labor. Increased accuracy and the possibility of making tests that otherwise never would have been undertaken will compensate for any difference along this line. The speed required of the instrument is such that one normal nozzle opening can be traversed in 1 minute. This represents a speed superiority over the hand-traversing method of between 7 and 10 to 1, exclusive of the simultaneous evaluation.

8 Such speed necessitates one additional specification. The instrument that is expected to use such working speed economically must possess unusual sturdiness. It was foreseen that it would be in practically continuous operation throughout the year. The turbine air test is run on a three-shift basis and the setting-up time of the test, during which the instrument is idle, is comparatively short.

The foregoing specifications were met fully, while in several points the expectations were considerably exceeded.

Description of Instrument

The instrument, as it was built, consists of four main-component sections, i.e., the traversing system, differential-pressure-measuring system, integrating system, and the recording system. Fig. 1 is a diagrammatic representation showing how this device functions.

The traversing system consists of a motor-driven worm A, driving a section of a large gear B, to which is attached the exploring impact tube C. This tube is moved in the arc of a circle across the nozzle opening D. The speed of the motor E, driving this gear, is controlled by means of thyratron tubes (not shown in Fig. 1). The speed-control circuit provides for both hand and automatic control of the traversing speed to give proper integration and recording.

The differential-pressure-measuring system consists of a photoelectric-controlled balancing circuit F, which operates a thyratron-controlled motor G that applies a force, through a steel spring H to a flexible bellows I. This flexible bellows divides a cylindrical compartment into two sections. The initial impact pressure is applied to one section and the impact pressure at the nozzle discharge is applied to the other section. The deflection of the bellows, due to the pressure difference, turns a mirror J and deflects a beam of light which falls on two phototubes. The deflection of the beam causes a change in the division of the light between the two phototubes. This unbalance operates the thyratron motor so that the tension on the spring attached to the bellows increases or decreases to restore the bellows to its normal position. Since the application of force to the bellows by the spring requires an elongation of the spring, which is directly proportional to the applied force, the number of turns of the motor that extends the spring is directly proportional to the total unbalanced force and, hence, proportional to the difference in force per unit area on the two sides of the bellows.

The integrating system consists of two turntables K, turned by a Selsyn receiver L, which is driven by the Selsyn transmitter M. This transmitter, in turn, is driven mechanically from the traversing motor E. Upon the turntables roll two integrating wheels N which are free to turn on their axes, and which may also be moved axially along radii of the turntables.

These integrating wheels are moved radially on the turntables by means of two large cams O, which are positioned by the motor G, balancing the pressure cell.

Since the angular displacements of the turntables are proportional to the angular displacement of the impact tube and, since the integrating wheels are positioned by cams that are cut to represent the proper functions of the differential pressure, the amount the integrating wheels turn is in proportion to the product of the displacement of the impact tube along the arc of the nozzles and the functions of the differential pressure.

In each of the integrating wheels are four holes through which is passed a beam of light. As the integrating wheels turn, light beams are intercepted four times for each revolution. The light beams thus intercepted fall on two phototubes P, which cause electrical impulses to operate counting and recording mechanisms.

The recording system consists of a chart-drive mechanism Q, which moves a paper chart R in proportion to the number of turns of the turntables and, therefore, in proportion to the motion of the impact tube. Recording simultaneously on this chart are three pens S, T, and U, which record the differential pressure and the two integral functions. The differential pressure is re-

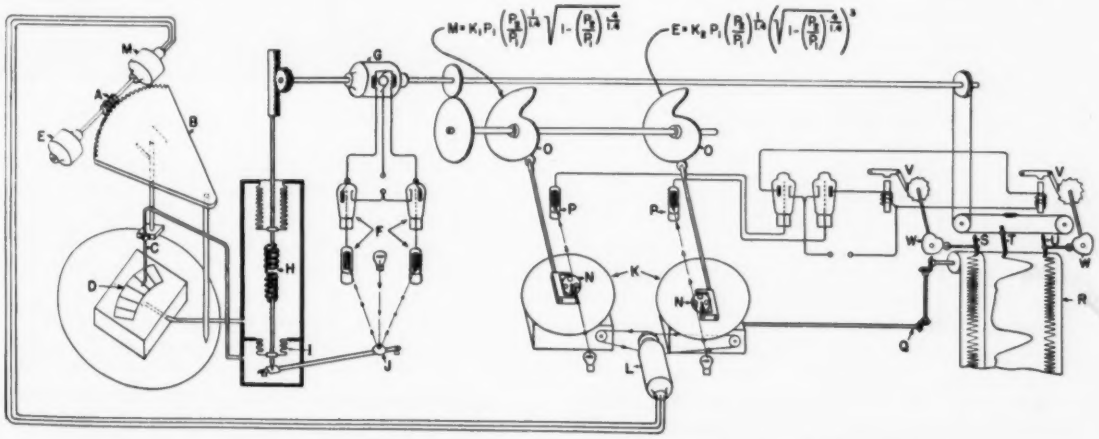

Fig. 1 Diagrammatic Representation of Automatic Integrating Pressure-Traverse Recorder

corded in the center of the chart and the integrals along the two sides. The pen *T*, recording the pressure, is moved by the motor *G*, which drives the pressure-balancing system.

The electrical impulses caused by the rotation of the integrating wheels are used to actuate ratchet-and-pawl mechanisms *V*. Turning with the ratchets are two cardioid cams *W*, which act through their followers to move pens *S* and *U*, in steps, back and forth along the sides of the charts. Fifty electrical impulses are required to turn the ratchets and cams one revolution. By counting the impulses recorded on the sides of the chart, 50 for each cycle, the integrals between any two points on the chart are quickly obtained.

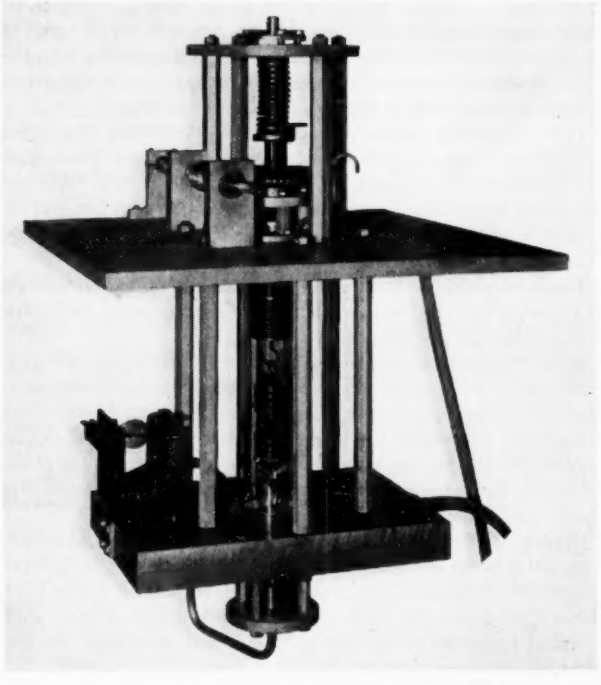

FIG. 2 PRESSURE CELL AND OPTICAL SYSTEM OF RECORDER

Since it was required that the over-all accuracy of the pressure system, integrator, and recorder be within limits of plus or minus 0.1 per cent, special care had to be taken in the mechanical and electrical details for the design and construction of this instrument to make this possible.

In the pressure cell, attention was given to the linearity and permanency of calibration of the steel springs used to balance the differential pressure of the diaphragm. A double helical spring was used, the two halves coiled in opposite directions to eliminate the effect of twisting as the spring extended and contracted.

The volume of air in the low-pressure compartment of the pressure cell was minimized by almost completely filling this compartment with oil. This was done to reduce the time required for the pressure in this compartment to reach its ultimate value when extremely small impact tubes were used. In some cases a modified hypodermic needle is used as an exploring impact tube. It can readily be seen that a large volume of air in this compartment would slow down the response of the pressure cell considerably.

To detect any deflection of the flexible bellows away from its normal position, a pivoted armature is mounted so that a sharp point, attached to the bellows, bears on this armature in such a way that any motion of the bellows causes the armature to rotate on its pivots. Attached to the armature is a small mirror that turns with it and deflects the light beam. The image of the small coiled filament of a lamp falls on a divided mirror, after being reflected from the mirror on the armature. This divided mirror splits the light beam, causing the two parts of it to fall on two phototubes. These phototubes are electrically connected in a bridge circuit. Any change in the division of light falling upon them causes a change in the balance of the bridge circuit. A split-field series motor operated by means of thyratrons in response to the voltage unbalance in the bridge circuit tends to restore the balance of the bridge as previously explained.

The over-all sensitivity of the bellows, optical system, and the electrical circuit is such that the thyratron motor responds to a differential pressure of less than 0.0075 in. of mercury.

Fig. 2 illustrates the pressure cell and optical system.

A differential pressure of 30 in. of mercury causes the two large cams to turn 350 deg. The cams were calculated from the formulas for mass flow and energy of flowing air.

A total of 350 points was calculated for each cam and the cams were cut to an accuracy of plus or minus 0.0002 in.

The integrating wheels were made of tool steel and chromium-plated to prevent corrosion and to give a hard long-wearing surface. Jewel bearings were used for the integrating wheels, in order to minimize friction which might cause slippage between the integrating wheels and the turntables. Plate glass was used for the surface of the turntables, giving a hard smooth surface for the integrating wheels to roll on.

Fig. 3 shows the mechanical arrangement of the parts which constitute the integrating system.

In the recording system, two gear shifts are provided. One shift lever changes the ratio of chart speed to turntable speed, giving three speed ratios.

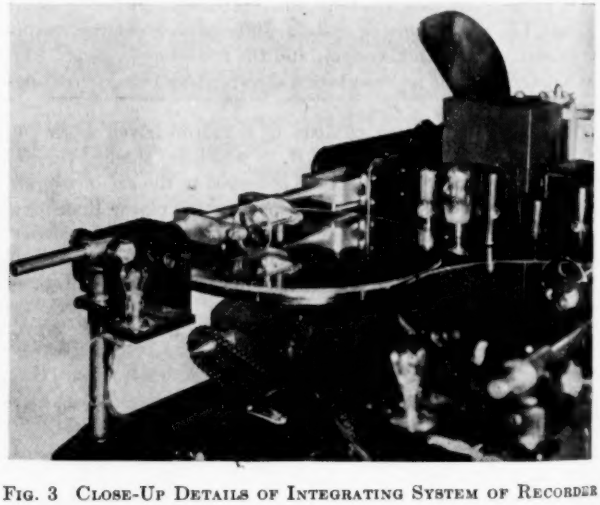

FIG. 3 CLOSE-UP DETAILS OF INTEGRATING SYSTEM OF RECORDER

The other gear-shift lever allows for magnification of the pressure record when low differential pressures are to be recorded. Three ratios are also provided in this gear shift.

A hand crank is used to adjust the calculating cams to the proper position for integration. The position of the cams is indicated by two dials at all times.

Below the recorder compartment are the manual speed-control knob for the traversing motor and two switches. One switch reverses the traversing motor and, at the same time, changes the connections to the Selsyn receiver, driving the turntables so that the turntables and recording chart run in the same direction for both directions of travel of the impact tube.

The other switch changes the speed control from manual to

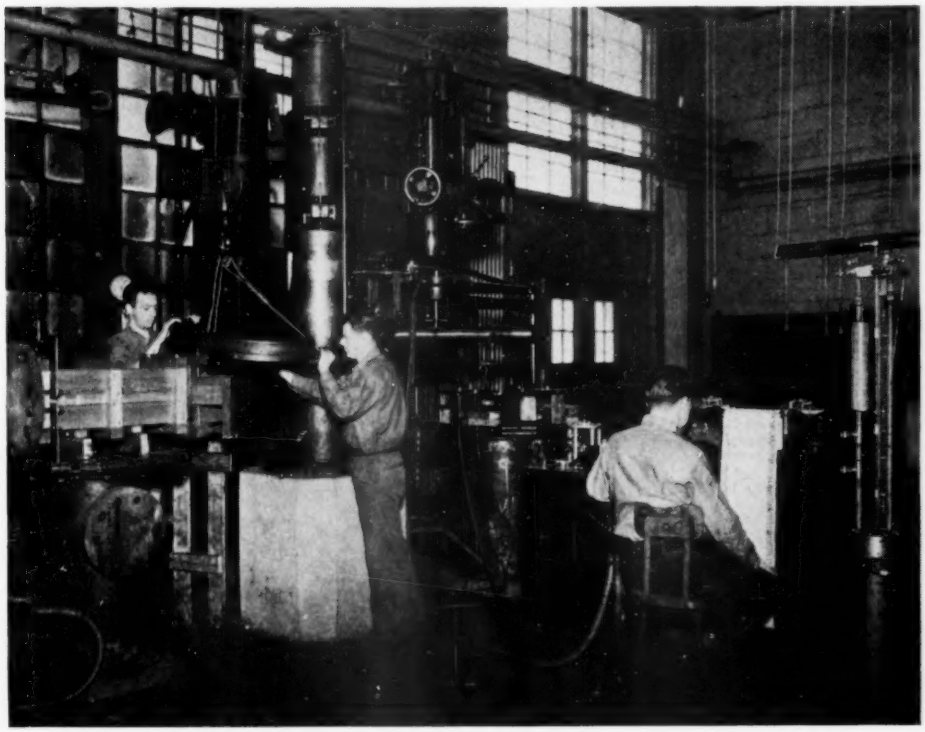

FIG. 4 INTERIOR OF THE AIR-TEST LABORATORY WITH THE RECORDER IN SERVICE

automatic. When the switch is in the automatic position the traversing-motor speed-control circuit is connected to the pressure-cell control circuit so that the speed of the traversing motor is dependent upon the balance of the pressure cell. When the differential pressure is changing rapidly, the traversing motor runs more slowly than when it is constant.

In order that the accuracy of this instrument might be maintained, it was built as sturdily as possible, and a number of safety features were incorporated so that no damage would result from the application of abnormal pressures to the pressure cell. An overdrive mechanism operates when the pressure-recording pen reaches its limit of motion. The pen stays at its maximum or minimum on the chart until the differential pressure returns to a value which again brings the pressure-recording pen on scale.

The large cams are prevented from turning too far by a similar overdrive mechanism which stops them at their limit of motion without damaging the instrument.

A second Selsyn receiver is arranged so that it, instead of the pressure cell, may drive the integrating cams and pressure pen. This Selsyn turns in synchronism with the Selsyn receiver that drives the turntables and is used in checking the accuracy of the integrator and recorder. This accuracy check gives the integration of an equivalent differential pressure which varies uniformly from 0 to 30 in. of mercury in 1600 turns of the traversing motor. This integral has been accurately calculated. The comparison of this theoretical value with the recorded value gives an absolute check of the integrator.

The accuracy of the pressure-measuring system and the integrating system are checked daily. It has been found that the over-all accuracy of the instrument stays well within the required 0.1 per cent.

Fig. 4 shows the instrument in actual use. It was designed by the general engineering laboratory of the General Electric Company in close cooperation with the turbine-engineering department. It was built entirely by the former.

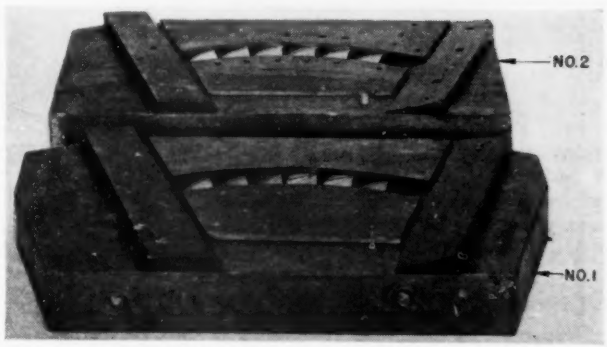

FIG. 5 COMPARISON OF MODELS OF TWO NOZZLES USED FOR TEST

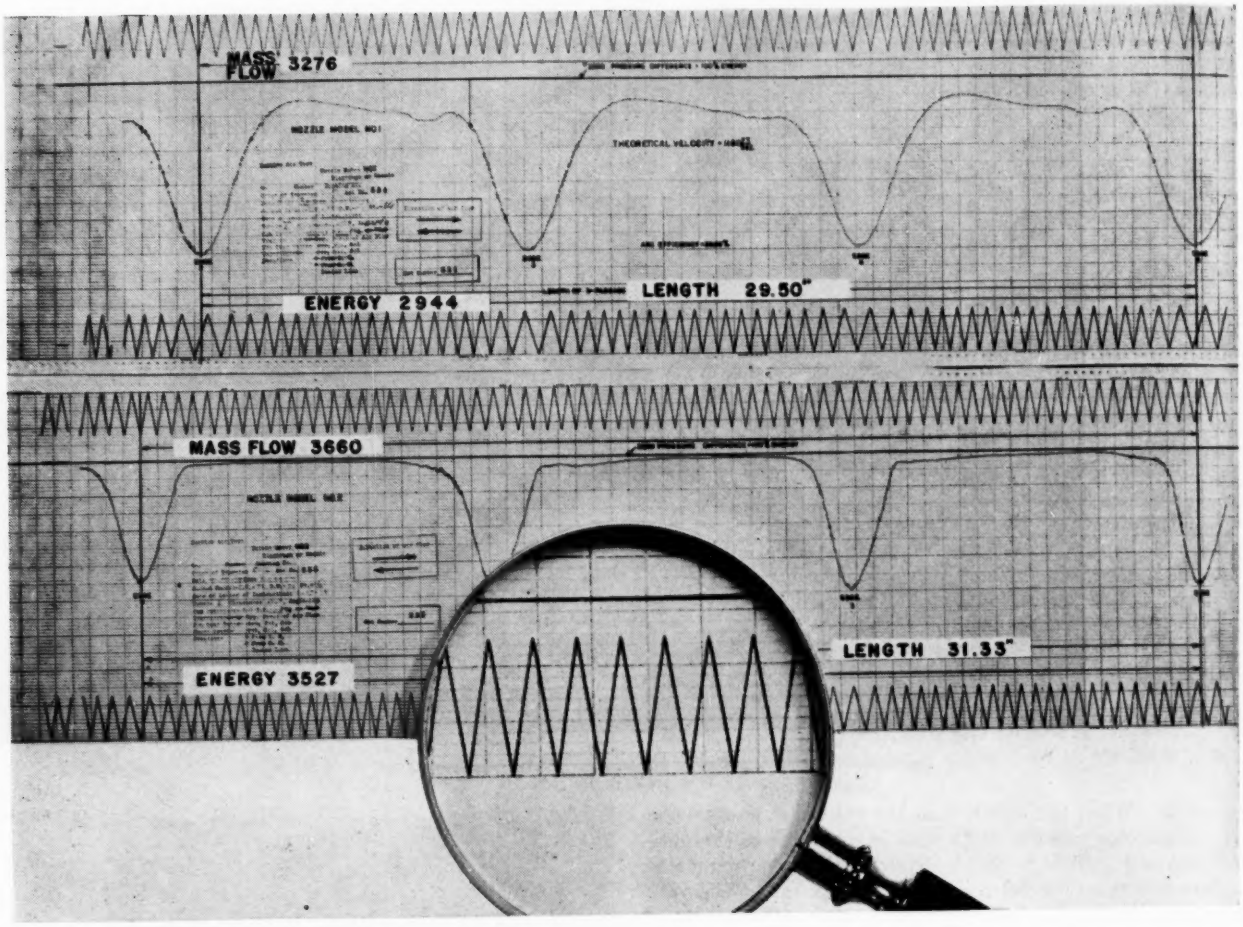
APPLICATION OF INSTRUMENT

The problem to be solved, herewith, to demonstrate the use of the recorder was the design of a nozzle partition for a given set of geometrical conditions with the additional specification of a high strength of the trailing edge against a high steam-pressure difference. Two nozzle models were made having partitions of different design, Fig. 5. The dimensions of the annulus, the exit angle, and the depth of the diaphragm are identical in both cases—so is, of course, the workmanship. The only difference is the contour of the actual passage and that of the partitions, a difference that will easily escape the eye of the nonspecialist. Fig. 8 shows, as the final result, the efficiency of both nozzles plotted against the theoretical air velocity. As can easily be seen, one is superior to the other by a very comfortable margin. A difference of the same order of magnitude would be expected from the nozzle partitions were they put in a turbine. The two curves also show the accuracy that can be obtained with this test, all of the actual test points, which in no way have been corrected, forming a good curve. Deviations from this curve are less than



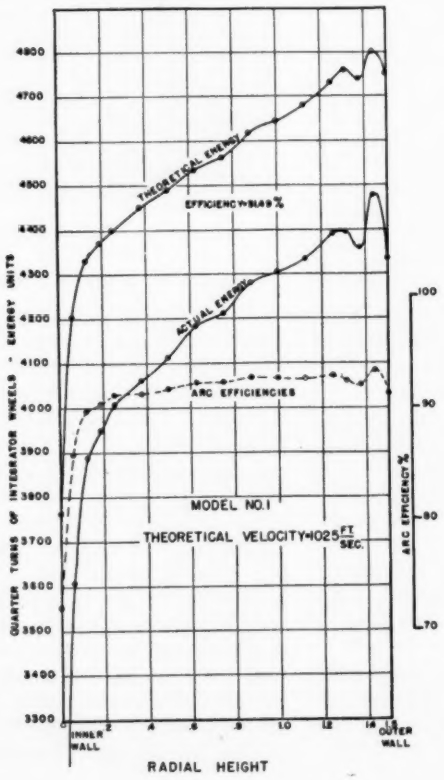


FIG. 6 (ABOVE) INSTRUMENT RECORDS SHOWING COMPARISON OF TWO MODELS

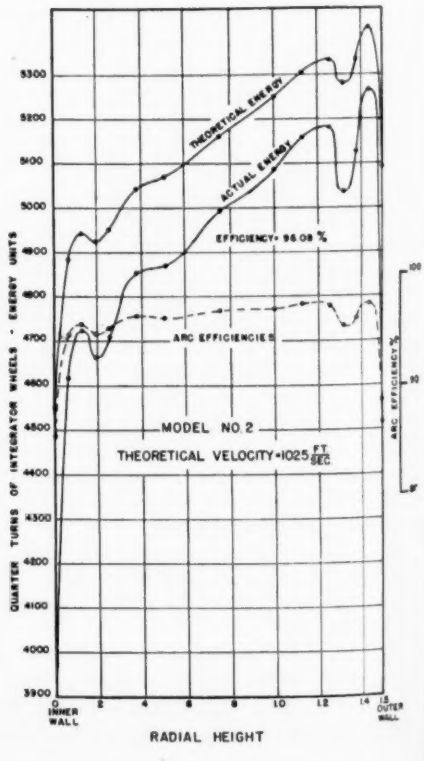

FIG. 7 (RIGHT) ENERGY AND FLOW INTEGRALS PLOTTED AGAINST RADIAL HEIGHT OF THE NOZZLE

0.1 per cent not of full scale reading of the instrument, but of any reading at the tested velocity. It must be remembered that this result is obtained, not from the instrument alone, but that the final cross integration in the radial direction has been made by the manual cross plotting of the line integrals, drawing the curve and planimetering two areas.

Figs. 6, 7, and 8 show the stages of this calculation. Fig. 6 shows one original record per nozzle as obtained from the instrument. It is one of 15 traverses over three nozzle passages at one velocity. For each constant velocity (constant initial pressure) 15 such traverses were made. The more efficient nozzle was tested at 9, the other nozzle at 6 velocities. The curve in the middle of the paper is the curve of impact pressure. The friction and wake loss, caused by the partitions, can readily be seen. The stepped zigzag lines along the two margins give the continuous integration of mass flow and energy. The number of small steps between any two points of the traverse is proportional to the in-

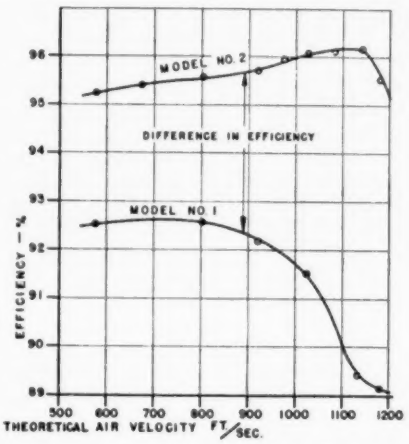

FIG. 8 COMPARISON OF THE TWO NOZZLES SHOWING OVER-ALL EFFICIENCY

tegrated mass flow and energy. Each step represents a $^1/_4$ revolution of a planimeter wheel, which serves as the unit of the integrated energy values. The integral curves are folded over after each 25 steps to allow for a scale large enough so that 0.1 per cent can conveniently be read. The figures shown on the curves are the mass-flow and energy integrals, counted up for the three openings, and also the total length of periphery covered by the flow from the three passages.

In Fig. 7, these energy and flow integrals are shown plotted against radial height of the nozzle. The scale of the ordinate is given in energy units, i.e., quarter turns of the integrator wheels. Since efficiency ratios only are of interest in this test, a conversion into customary energy values is considered unnecessary. The ratio between the areas under the theoretical and actual energy curves is the efficiency. The dotted curve gives the arc efficiencies, i.e., the efficiency of each individual traverse as taken along the traversed arc. It shows the location and size of the deficiencies given by mass flow and energy. For each constant theoretical air velocity one such curve sheet is made. The final result appears in Fig. 8, as previously indicated.

These curves explain, at least to an engineer, better than words the advantages accruing from such a test and also, of course, of the instrument that permits the large-scale application of the test.

No sooner was the instrument built than its advantages were used to the utmost. Many problems that formerly would never have been attacked in an experimental way are now handled in a matter-of-course manner. One very important application of the instrument is the checking of finished nozzle diaphragms before they go into the turbine. It is often desirable to make sure that no variations of design or of finish have reduced the expected efficiency. Automatically such variations are submitted to the instrument and its judgments obeyed.

It hardly need be emphasized that the cooperation of this new member of the turbine-engineering department of the General Electric Company has been greatly welcomed and at present enjoys complete confidence.

Discussion

WINSTON R. NEW.[4] We are indebted to the authors principally for their concurrent emphasis of the general need for recognition of the great number of variables upon which steam-turbine stage efficiency depends. With a background of well over 5 years of successful experience in the use of completely mechanized exploratory traverse equipment, we are gratified at their second statement in the section, "Design Features of Instruments," as well as other statements by independent experts, which so thoroughly justify the type of flow research now a fundamental part of turbine engineering by the writer's company. We join them in paying tribute to the engineers who instituted and partially developed search-tube studies, not 19 years ago, as has been stated, but well over 30 years ago, principally in Europe but also at many places in this country.

Turbine engineers have been quick to realize that a strict adherence to the recognized criteria of dynamic similarity surrounds model testing with difficulties almost as insuperable as those which prevent more exhaustive experiments on full-size, steam-driven stages. Coupled with this, there seems to have been a general failure on the part of many investigators to recognize the important part of the turbine-flow problem from the viewpoint of the designer, or to realize what appears to this writer to be the main strength of air tests. Too much emphasis has been given to fragmentary results established by tests at a few combinations of conditions for which most criteria of dynamic similarity could easily be satisfied. On the other hand, too little emphasis has been accorded to the systematic prosecution of a comprehensive program embracing both the nature and magnitude of the energy losses in representative turbine elements, and their mode of dependence upon key variables involved. Samples of the kind of comparative information needed, selected from a file of thousands of tests, constitute part of a current Westinghouse communication to the profession. When such results are available, improvement in design follows, independent of whether or not the general level of laboratory measurements is optimistic or can be applied without modification to the prototype.

Attempts to magnify an energy loss of 1 per cent to make it sound more impressive bespeaks an inadequate grasp of the magnitude of destructive effects encountered in a general treatment of fluid-flow problems. Further experience in the application of their method will reveal to the authors the wisdom of avoiding needless restriction of search-tube exploration only to the comparatively efficient assemblies. With the multiplicity of variables upon which stage efficiency depends one cannot go far from the old established paths in many directions without encountering the more significant losses. To cite but a single case; excessive pitch of blades with large turning angle almost invariably results in a loss of fluid contact from the passage wall (called "stalling flow" in aeronautics) with complete collapse of performance and not merely a decline of a few per cent in efficiency.

The instrument described by the authors is ingenious but com-

[4] Research Engineer, Westinghouse Electric & Manufacturing Co., Philadelphia, Pa.

plicated by the adherence to photoelectrically controlled mechanical means for both recording and integrating. We have preferred a combination of direct mechanical and electrical means employing the magnetic-strain gage as the sensitive element. A brief exposition of major differences between the two methods and equipment seems appropriate in this discussion.

The cell shown in Fig. 9 of this discussion for converting pressure differentials into small displacements, in content not unlike the one described in the paper, has been used successfully in the South Philadelphia flow laboratory for over 7 years. At this point, however, the similarity ceases, for the displacement in this pressure cell is communicated directly to a magnetic keeper supported at small clearances from the pole faces of two U-cores. High-frequency excitation at constant voltage is furnished by a small inductor alternator to primary windings connected in series on the U-cores. Secondary windings, connected phase-opposed, produce a small voltage linearly proportional to the

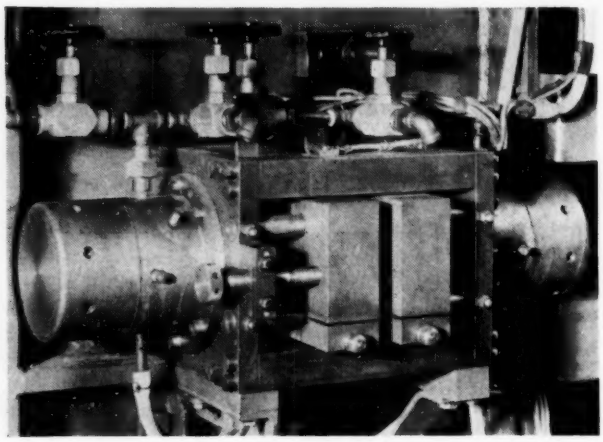

FIG. 9 PRESSURE-DISPLACEMENT CELL

differential pressure on the cell, due to variation in coil reactance with motion of the iron keeper. This voltage is applied to a suitable, high-speed recording voltmeter and to the current coil of a high-precision induction watt-hour meter. The potential coil of the watt-hour meter is fed from the constant voltage of the alternator. The search tube and recorder chart are driven through gears, permitting a selection from among several speeds, by small synchronous motors.

Traverse records from the voltmeter are identical to those produced by the center pen of the instrument described by the joint authors. The watt-hour-meter speeds corresponding to zero and 100 per cent efficiency are known constants which can be readily checked by subjecting the pressure cell to the required maximum and minimum pressure differentials. Integration of a traverse simultaneously with its recording consists merely of counting the watt-hour-meter revolutions for the time of transit of the search tube over an integral number of blade pitches and a small amount of simple arithmetic.

The sensitivity of this system is about the same as the figure of 0.0075 in. of mercury given in the paper. Calibrations systematically repeated over a period of many months likewise exhibit remarkable consistency. Two of the complete assemblies, herein briefly described, and shown in Fig. 10 are still in almost daily operation.

It is recognized, of course, that our integration proceeds from a motion proportional to a pressure difference instead of a combination of odd powers of pressure ratios. A small, experimentally determined, additive compressibility correction to efficiency

(Tubes located in the substantially loss-free core of an air jet from a reaction-blade grid.)

given as Fig. 8 in a paper[5] by the writer insures that the simplicity of this method involves no sacrifice in accuracy.

The use of segmental packs, as indicated by the authors, instead of rectangular grids with blade edges parallel from base to tip is an unjustified complication. It does not insure closer simu-

[5] "An Investigation of Energy Losses in Steam-Turbine Elements by Impact-Traverse Static Test With Air at Subacoustic Velocities," by Winston R. New, published on page 489 of this issue of the Transactions.

lation of turbine-operating conditions except possibly for the single case of Curtis stage nozzles with a nondirectional stream at the inlet. Furthermore, it always obscures the comparison sought between two or more models by introducing changes in several features of the geometry at the same time. Thus any attempt to specify a dimensionless pitch or gaged opening for the nozzles used as an example in the authors' paper immediately requires designation of the radial position at which the measurements are to be made. This criticism is based upon use of the instrument as a research tool and does not apply for purely comparative work on alternative assemblies of temporary commercial significance.

In concluding these comments attention should be called to an important matter relative to the use of impact tubes at supersonic velocities which seems to have escaped consideration by the authors. Quoting from the section "Design Features of the Instrument:" "The specified accuracy must be attainable throughout a range of nozzle velocities from 800 to 1200 ft per sec." Assuming that the compressed air expands from a room temperature of say 70 F, local acoustic velocity is reached in the stream at 1031 ft per sec for zero energy loss. With reheating of the jet due to losses, the acoustic velocity at any point will be somewhat higher, but by comparatively little, say 1050 ft per sec. The upper limit of test velocities mentioned is, therefore, quite certain to be substantially in excess of the local acoustic velocity. When this supersonic-velocity stream encounters the muzzle of the impact tube, a compression shock occurs. This process involves an abrupt deceleration to a subsonic velocity with increase in entropy. The subsequent isentropic compression to zero velocity at the impact tube fails to restore the initial-state point of the fluid even if there were absolutely no energy losses along that particular filament through the passage. Thus losses attributable solely to the measuring method might be wrongly charged to the assembly on test.

Some idea of the magnitude of losses due to compression shock at the impact tube may be obtained from Fig. 11 of this discussion. Impact tubes with differently shaped leading edges, but each fashioned from a hypodermic needle with 0.025-in. bore and 0.013-in. wall thickness, were properly oriented in the substantially loss-free core of a jet from a blade grid exhausting to the atmosphere. The measured reservoir pressure ahead of the grid was gradually increased and at each step the difference between reservoir pressure and impact pressure was observed for each impact tube. The critical pressure ratio for air is about 0.5283 and the pressure ratio corresponding to a jet velocity of 1200 ft per sec is in the neighborhood of 0.4 with expansion from room temperatures. Of interest are the conclusions:

1 Losses in the central core (remote from blade surfaces) of a subsonic-velocity jet are negligible.

2 The shape of the leading edge of the impact tube is not critical for subsonic-velocity exploration.

3 Shock loss at the impact tube can amount to several per cent of the initial pressure for pressure ratios in the order of 0.4. The importance of not overlooking this where accurate loss measurements are essential seems to require no further comment.

4 The shape of the leading edge of the search tube materially affects measurements at supersonic velocities.

Much thought has recently been given to the matter of search-tube exploration at highly supersonic velocities. Further consideration of this, however, lies beyond the scope of the present discussion.

J. I. YELLOTT.[6] The results, shown by the authors in Fig. 8, indicate the great value of the type of equipment which is so well described in their paper. Without endeavoring to predict analytically the exact performance with steam in an actual turbine, it is undoubtedly true that "what is better with air will be better with steam."

The extremely ingenious devices whereby variations in impact pressure are transformed into efficiency variations deserve particular note. The writer has had the opportunity of seeing this equipment in operation and he has been particularly impressed with the ease and rapidity with which accurate data can be secured.

It would be valuable for the authors to comment briefly on the materials from which the models are made. The relatively low cost of these models is a valuable feature, and the ease and rapidity with which changes can be made is another factor to which attention should be called.

G. B. WARREN.[7] Both of these papers[8] are valuable contributions to the literature dealing with the details of the steam-turbine art. The authors are to be commended for attempting to apply to the steam-turbine problem much of the recent knowledge with respect to fluid flow, most of which has been worked out in connection with aerodynamic research relating to airplanes.

As higher and higher efficiencies are obtained with the turbine elements and as a wider range of conditions of pressure, temperature, vacuum, etc., are encountered, the relationships expressed as Reynolds' number, Mach's number, etc., begin to have greater importance.

On the other hand, it might be worth while to review some of the history relating to the development of this research tool as it has been worked out by the writer's company, through the period when rapid gains were being made on the less efficient turbine elements with this and other tools in their cruder first forms.

Following the rapid development of the turbine through the World War period of 1915 to 1919, it became apparent to those in charge of the General Electric Company turbine work that means would have to be sought to obtain more accurate information as to what was occurring inside the turbine-blading elements.

Two research tools were set up in 1920 to remedy this situation. The first was an 8-stage 2500-kw test turbine. In this machine, a large number of nozzle-and-bucket combinations were tested during the next few years, with steam under actual conditions of operation.

In parallel with this, a second tool was set up in the form of a nozzle-reaction testing machine in which actual nozzle elements could be tested over a wide range of steam conditions. Some of the results of the testing on this second tool were set forth in a paper[9] presented by J. H. Keenan, then of the General Electric Company, turbine engineering department, now professor of mechanical engineering at the Massachusetts Institute of Technology, and the writer. A comprehensive research program, covering scores of nozzle designs, both expanding and nonexpanding and at a range of velocities from 500 ft per sec to 4000 ft per sec was studied.

Early in this program, it became apparent that both of these tools gave over-all answers and did not permit an analysis of the

[8] This discussion applies jointly to the present paper and the paper "An Investigation of Energy Losses in Steam-Turbine Elements by Impact-Traverse Static Test With Air at Subacoustic Velocities," by Winston R. New, which appears on page 489 of this issue of the Transactions.

[9] "A Machine for Testing Steam-Turbine Nozzles by the Reaction Method," by J. H. Keenan and G. B. Warren, Trans. A.S.M.E., vol. 48, 1926, pp. 33–64.

places in the various elements in which losses were occurring.

In order to meet this situation late in 1920 and early in 1921, W. E. Blowney of the turbine engineering department of the General Electric Company started out to build wood models of single-nozzle passageways, picking out certain nozzle passageways in some turbines which did not appear properly designed, particularly those in which a change of diameter occurred between successive wheels. These models were blown with air on a simple test stand and the jet was traversed in a crude way with an impact tube.

It immediately became evident that there was often a "hole" in the discharge of the nozzle, that is, a spot over a considerable portion of the nozzle height in which the velocity was much lower than normal. It could be felt by traversing the nozzle jet with one's finger.

The next step was to make the jet visible, and an attempt was made to introduce a water spray in the air. This showed up certain irregularities in the flow although, because of the inertia of the water, a false picture of the true direction of the jet was obtained.

Next, low-temperature steam was tried mixed with the air and the jets were photographed, with some additional gain in results.

The next step Blowney tried was to put paint dots on the inside of the nozzle passageway. The air was turned on while the paint was wet, and the dots were, of course, streaked out in the direction of the air in the boundary layer at each particular location.

Although crude, all of these methods gave results which were immediately turned into improvements in construction and which resulted in some gains when applied to the 8-stage test turbine described.

H. L. Wirt was then given charge of this development; under his direction it advanced with great strides during the ensuing years. Later the work was continued under the direction of others.

The next development was, of course, the testing of multi-nozzle passageways with much more refined impact tubes and the expansion of Blowney's "paint-dot" practice into a means of getting a "flow cast" of the nozzle, showing the flow in the boundary layers which, to the experienced eye, permits a close approximation to the total flow in the nozzle to be derived. Much of this work was described in a paper[10] written by H. L. Wirt.

This tool was then added to the two previously described, and many points of great inefficiency were discovered in the turbines as then designed which were rather quickly and definitely cleaned up.

The writer has in mind three particular changes in construction, two of which each method of testing showed to give substantially comparable gains. The third modification in construction was not susceptible of analysis on the reaction nozzle-testing machine, but was discovered in connection with the air test, and widely applied to the test turbine and actual turbines in service with resulting improvements in over-all performance.

The nozzle-reaction test was discontinued in 1928, but the "air test" has remained as an ever-expanding tool for the turbine designers, and has continued to give gains in over-all turbine performance year by year. It has been expanded so as to cover not only turbine nozzles and buckets, but the flow through valves, inlet-steam chests, exhaust "hoods," crossover connections, piping connections, and all parts of a turbine where fluid flow with low loss is an important factor.

[10] "An Experimental Investigation of Nozzle Efficiency," by H. L. Wirt, Trans. A.S.M.E., vol. 46, 1924, pp. 981–1003.

Authors' Closure

As Mr. New states, there are some earlier publications on the art of flow testing as applied to steam turbines. They are all mentioned in Professor Stodola's book and are thus readily accessible. Therefore, it does not seem necessary to elaborate further on this matter.

The phenomenon of jet separation or stalling flow, as Mr. New calls it, was correctly explained by L. Prandtl in 1904. It truly is most destructive. Fortunately, this phenomenon is under our control. Except for related phenomena occurring at supersonic conditions, there is little reason to be apprehensive on this account. It appears the part of wisdom to devote the greatest effort toward the improvement of nozzles and buckets already known to be good.

Mr. New has suggested that the testing of nozzles grouped around a circle is an unjustified complication. We cannot agree with this attitude. However, he does admit its value for comparative assemblies of commercial significance. We fully agree with this opinion. In fact, we consider successful commercial application to be our one guiding principle. Therefore, our research must adapt itself to the additional space variable, uncomfortable as that complication may be.

The correction of impact-tube readings under supersonic conditions has been given careful consideration. No fear from wrong readings appears justified down to pressure ratios as low as 0.5. The velocities mentioned in the paper are based on an initial temperature of 185 F, which corresponds to a minimum over-all pressure ratio of 0.5. Thus, the highest velocity corresponds to expansion from double atmospheric pressure.

The instrument described by Mr. New furnishes, as results, velocity coefficients, assuming air to be an incompressible fluid. A compressibility correction is then introduced. Such a correction is based on a particular assumed average form of loss curve.

There can be no argument about the value and practicability of using assumptions and simplifications in connection with engineering problems. They always are present in great number and their existence and limitations must always be borne in mind.

In view of this situation, the authors felt inclined not to introduce, by a measuring method, additional deviations from true conditions which in turn involve additional watchfulness and corrections. This point of view has been held by the research engineers of the General Electric turbine air test since its inception, 19 years ago.

It appeared to be possible to build, without too great an effort, an instrument which is free from all limiting assumptions and correction factors. This course was so attractive that the General Electric Company designed and built its instrument based on this reasoning. It furnishes accurate efficiency directly from the measurements and without any limitations and qualifications.

Mr. New's instrument uses electrical measurements only. The use of purely electrical measuring equipment was, of course, considered during the design of our apparatus. However, its accuracy at the desired speed of operation was not accepted as satisfactory. Hence, the vastly more accurate and speedier photoelectric control of mechanical measuring equipment was chosen.

In the paper the authors mention that wood is used as model material. Following Professor Yellott's suggestion, this fact is herewith emphasized. Where standard partitions are tested, steel nozzle partitions are inserted in the wood. Novel and special partitions are carved from hard wood. Thus, there is great freedom in building new models and such saving in time that the speed of the instrument can be used to best advantage.

No further comment appears necessary on Mr. Warren's vivid description of the early history of the General Electric air tests.

An Investigation of Energy Losses in Steam-Turbine Elements by Impact-Traverse Static Test With Air at Subacoustic Velocities

By WINSTON R. NEW,[1] PHILADELPHIA, PA.

Efficiency of any turbine stage depends upon many variables. Blade pitch, orientation, height, and velocity ratio among purely geometrical quantities, and effects attributable to compressibility and viscosity of the medium all deserve special consideration. Investigation of energy losses as functions of the key variables is accomplished statically on various forms of equipment among which the impact-traverse tester is considered an important type. The necessary and sufficient conditions to be satisfied by the static test, in order that it represent fully dynamic conditions are (*a*) the flow relative to the given static element must be at all points the same in magnitude and direction as it would be if the element were in uniform rotation relative to the flow in a turbine; (*b*) output of the element measured statically must differ from power only by the linear-velocity term eliminated by the static test. The apparatus, procedure, and results attained in meeting these test requirements are explained by the author.

Nomenclature

The following nomenclature is used in this paper:

Symbol	Definition	Unit
	Geometrical Quantities (Refer to Fig. 1)	
α	Efflux angle. Angle which leaving velocity relative to blades makes with exit plane of row	deg
β	Entrance angle. Angle which approach velocity relative to blades makes with inlet plane of row	deg
h	Blade height	in.
l	Blade chord	in.
n	Number of pitches (passages) in test pack	1
o	Minimum opening between blades	in.
r	Mean radius of bladed annulus	ft
s	Blade pitch	in.
u	Peripheral blade velocity at radius r	ft per sec
w	Blade or groove width measured in direction of turbine axis	in.
Δw	Small distance beyond exit edge of blade measured in direction of w	in.
x	Coordinate of position of exploring tube measured in direction of s	in.
y	Coordinate of position of exploring tube measured in direction of h	in.
θ	Angular displacement	1
	General Quantities	
A	Minimum area of a passage	sq ft
c_p	Constant-pressure specific heat of air	Btu per lb per deg F
c_v	Constant-volume specific heat of air	Btu per lb per deg F
g	Acceleration of gravity	ft per sec per sec
ΔH	Enthalpy change at constant entropy	Btu per lb
J	Mechanical equivalent of heat	ft-lb per Btu
k	Exponent of isentropic expansion, c_p/c_v for an ideal gas to which air is assumed to conform	1
K	Constant of proportionality	
N	Useful power output of a stage	Btu per sec
Q	Aggregate energy loss in a stage	Btu per sec
t	Time	sec
W	Actual rate of flow	lb per sec
W_t	Theoretical rate of flow with purely isentropic changes of state	lb per sec
	Pressures, Densities, and Temperatures (Refer to Fig. 3)	
P_t, γ_t, T_t	Initial absolute air pressure, density, and absolute temperature in reservoir	lb per sq ft; lb per cu ft; deg F
P_s, γ_s	Absolute static pressure and air density at any point $(x, y, \Delta w)$ in a plane beyond and parallel to plane of exit edge of blades and distant Δw therefrom	lb per sq ft; lb per cu ft
P, γ	Absolute impact pressure (static plus dynamic) and air density at any point $(x, y, \Delta w)$ in a plane beyond and parallel to plane of exit edges of blades and distant Δw therefrom	lb per sq ft; lb per cu ft
P_1, γ_1, T_1	Barometric pressure, resulting air density, and absolute temperature at any point $(x, y, \Delta w)$ reached by actual expansion from conditions (P_t, T_t) in reservoir to environment	lb per sq ft; lb per cu ft; deg F
γ_1', T_1'	Air density and absolute temperature resulting from isentropic expansion from conditions (P_t, T_t) to pressure P_1	lb per cu ft; deg F
	Velocities and Forces (Refer to Fig. 3)	
C_t, F_t	Velocity and net force on blade pack resulting from isentropic expansion from conditions (P_t, T_t) in reservoir to atmospheric pressure P_1	ft per sec; lb

[1] Research Engineer, Westinghouse Electric & Manufacturing Company.

Contributed by the Power Division and presented at the Annual Meeting, Philadelphia, Pa., December 4–8, 1939, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

C.....Actual velocity at any point (x, y, Δw) in plane beyond and parallel to plane of exit edges of blades and distant Δw therefrom. ft per sec

F.....Integral of elementary forces dF on blade pack resulting from elementary flows $d(W/g)$ at velocities C..... lb

F_1.....Net force on blade pack resulting from an actual flow W/g from conditions (P_t, T_t) in reservoir to atmospheric pressure P_1... lb

C_1.....Fictitious mean velocity for blade pack defined as quotient of actual net force and mass-flow rate, F_1g/W..... ft per sec

a.....Acoustic velocity in air at temperature resulting from isentropic expansion from conditions (P_t, T_t) to atmospheric pressure P_1..... ft per sec

Dimensionless Ratios

η.....Stage efficiency. Quotient of useful energy output and available energy

v.....Velocity ratio u/c_1

σ.....Aggregate energy loss in per cent of available energy

δ.....Energy loss along any particular filament from reservoir to measuring point in per cent of available energy

ξ.....Value of δ when effect of compressibility of fluid may be neglected

ω.....Efficiency of narrow slice dy of passage of height h, neglecting compressibility of fluid

ω_c.....Value of ω corrected for compressibility of fluid

ω_p.....Profile efficiency. Special value of ω_c characteristic of an infinitely long blade

Ω.....Efficiency of a blade passage from impact-traverse tests when evaluated, neglecting effect of compressibility of fluid

Ω_c.....Value of Ω corrected for effect of compressibility of fluid

φ^2.....Square of momentum coefficient for a blade passage defined as $(C_1/C_t)^2$

ϵ.....Exponent employed in formulating velocity distributions in blade passages

χ.....Compressibility factor

Introduction

Recent technical literature appertaining to problems of steam-turbine design contains many articles on the use of air in the study of turbine elements normally steam-driven. By "turbine elements" are meant, collectively, stationary or moving passages accommodating a flowing elastic fluid with enthalpy changes, functioning as generators or absorbers of momentum or both. Air rather than steam is used as a test medium because of practical considerations, such as economy, simplicity in design and operation of the equipment, less danger to observers who work with instruments directly in an exposed high-velocity jet, more precise measurements on a more homogeneous medium, easier control of test conditions, and the applicability of perfect gas laws to simplify analysis.

Similarity Requirements

Adequacy of air tests as a means of indicating performance coefficients for steam-driven apparatus required extensive justification. Some of the articles (1, 2),[1] referred to in the preceding paragraph, deal with the general theory of mechanical similarity applicable to this phase of model testing. It has been shown that, for dynamic similarity of flow of two elastic fluids with no free surfaces, four criteria of similarity must, in general, be satisfied, namely, geometrical similarity, and equality in Mach's, Reynolds', and atomic numbers. Fulfillment of these conditions insures equality in all dimensionless coefficients of which efficiency is one, appertaining to the two flows.

Variables Affecting Passage Efficiency

The turbine designer usually wants to know how passage efficiency depends upon blade shape, pitch, orientation, height, and velocity ratio at which the stage must operate. For any series of blades of different sizes but geometrically similar in cross section, it is possible to define three simple dimensionless ratios which, together with one angle, completely specify geometrical similarity. This is made clear by Fig. 1. If chord dimension l is chosen as a reference length, it is only necessary to know l_1, l_2, l_3, ... etc., to designate a blade of the chosen series, since the blade sections are geometrically similar. Then ratio s/l defines blade spacing or pitch measured circumferentially; ratio o/s defines blade orientation within the row; ratio h/l defines blade height; and angle β defines the velocity field in which the blades work. These parameters are called pitch/chord ratio, gaging, aspect ratio, and entrance angle, respectively, and collectively fix the geometry of the test passage. Efflux angle α

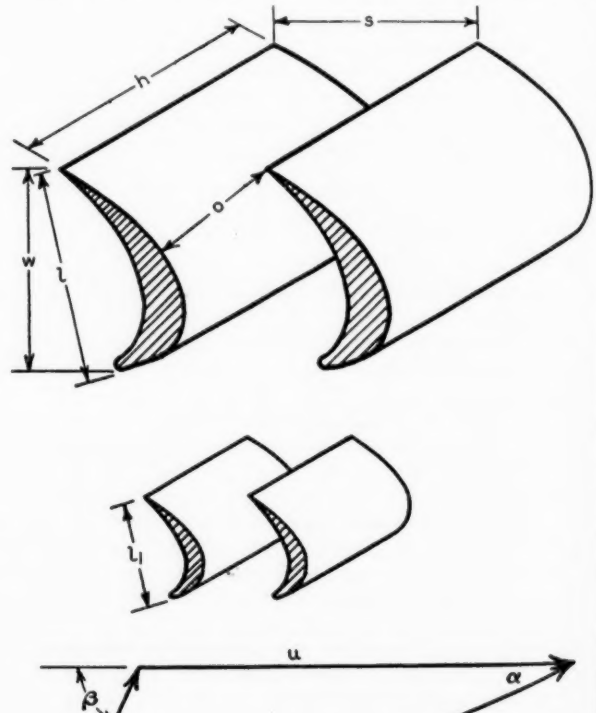

Fig. 1 Geometrically Similar Blade Passages and Conventional Velocity Triangle

$$\frac{u}{C_1} = \cos\alpha - \frac{\sin\alpha}{\tan\beta}$$

[1] Numbers in parentheses refer to the Bibliography at the end of the paper.

cannot be chosen at will. This angle, like the energy losses, is a consequence of the particular flow established. It is a measurable but not predictable quantity.

From the velocity triangle in Fig. 1, the actual velocity ratio of wheel speed to fluid speed is determined by the efflux and entrance angles. With a given pitch and gaging, it has been generally observed that the efflux angle is substantially constant for wide variations in any of the other independent variables. Hence, it is sometimes convenient to use velocity ratio interchangeably with the angles from which it may be calculated. Little generality is lost thereby provided the thought does not grow that α is absolutely invariant and, therefore, that changes in velocity ratio reflect changes in β only.

Experience has verified that the inequality in atomic numbers of air and steam is of no material consequence below acoustic velocity. Reynolds' number and Mach's number are the remaining parameters affecting a determination of energy losses. These ratios, arising from considerations unrelated to the geometry of the passage, indicate the relative magnitudes of forces affecting

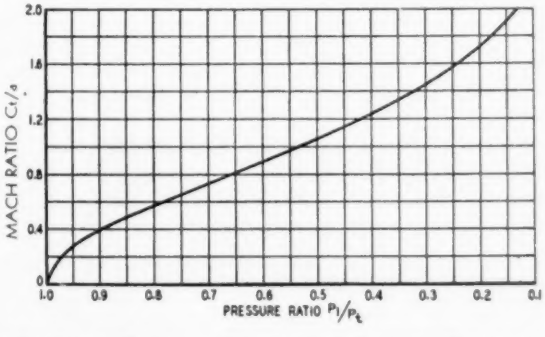

FIG. 2 MACH'S RATIO AS A FUNCTION OF PRESSURE RATIO FOR AIR

$$C_t/a = \sqrt{5\left[(P_t/_1P)^{(k-1)/k} - 1\right]} \quad k = 1.4$$

motion of a submerged fluid particle along a streamline and can be written directly from the terms of the Navier-Stokes equation.

In studies of flow through steam-turbine nozzle and blade passages, the range of velocities and viscosities encountered would theoretically permit of neglecting neither the influences of compressibility nor fluid shear. Prior to 1937, we had in our laboratory no facilities for the independent control of both Mach's and Reynolds' numbers over wide ranges.[3] We are, therefore, not yet in a position to discuss results of any experiments intended to separate these influences, but it has been found possible to obtain a comprehensive picture by considering their combined effect.

The Mach number for a constant value of c_p/c_v is a function of pressure ratio (3). The curve in Fig. 2 shows the Mach number as a function of pressure ratio for air. In our experiments, pressure ratio was obtained directly and, in view of the fact that it was then only necessary to read Fig. 2 to get the Mach number, reference will be made to this single variable. Efficiency measurements presented are characteristic of a certain Reynolds number as well as the particular Mach number. Along with the four parameters mentioned, is the dual parameter herein called Mach's number. These five ratios are key variables affecting efficiency of any blade assembly.

[3] Equipment recently installed provides for variation of back pressure on the test pack, thereby permitting independent control of velocity and kinematic viscosity and, hence, of Mach's and Reynolds' numbers. The new equipment bears the same relation to that described herein as the variable-density wind tunnel does to the atmospheric-pressure wind tunnel.

The variables retained are quantities which change in designing turbines of all sizes for a variety of steam conditions, employing blade sections of a chosen shape. Results which follow may therefore be expected to be of direct interest to turbine builders.

Since efficiency of any stage depends upon no fewer than five variables, there is need for some way other than the conventional economy test for providing information. This fact has greatly stimulated activity in fluid-mechanics laboratories maintained by a number of steam-turbine manufacturers. Investigation of energy losses as functions of the key variables is accomplished statically on various forms of equipment among which the impact-traverse tester herein considered is an important type.

TURBINE TESTS VERSUS STATIC TESTS

The power of any engine may be expressed as the product of torque and angular velocity

$$N = \frac{Fr\theta}{tJ} \quad \text{[1]}$$

If with a flow W lb per sec, an elementary turbine delivers power N Btu per sec at a constant angular velocity, θ/t turbine efficiency, defined as the quotient (energy output) ÷ (energy input), becomes

$$\eta = (N/W)/\Delta H \quad \text{[2]}$$

The value of η could be determined if some type of dynamometer were provided for the measurement of N, the flow rate W were measured by suitable means, and the energy, made available per pound of fluid by isentropic expansion from the initial-state point P_t, T_t to the final pressure P_s, were calculated. If only the energy losses arising from friction in the flow of fluid through closed passages are of interest, the elementary turbine may be further idealized by imposing the restrictions that there shall be no leaving loss or mechanical losses of any kind. Under these conditions the value of η would become the passage efficiency.

Flow, relative to the passages in an ideal elementary turbine, is unaffected by the uniform angular velocity. Theoretically, it would be possible to determine the basic performance of these elements with the wheel held stationary, if means of evaluating output could be substituted for the dynamometer. This is the idea underlying all static testing. The necessary and sufficient conditions to be satisfied by the static test, in order that it fully represent dynamic conditions, may be summarized as follows: (*a*) The flow relative to the given static element must be at all points the same in magnitude and direction as it would be if the element were in uniform rotation relative to the flow in a turbine. (*b*) Output of the element measured statically must differ from power only by the linear-velocity term eliminated by the static test. To comply with these requirements rigidly would be as impossible as to satisfy completely all the demands of dynamic similarity already mentioned. Some degree of arbitrariness must be introduced, and extensive satisfactory experience with the static test must remain the final proof of the adequacy of any procedure adopted.

From the definition of power represented by Equation [1], a comparison of elements statically or definition of their efficiency requires a comparison of forces. The ratio of force actually exerted on the blades per unit of mass flow per second to the corresponding quantity, assuming isentropic energy release, has been selected as a basic index of performance and named velocity coefficient. It is to be interpreted as a measure of the perfection of a passage as a machine for doing work. Velocity coefficient is commonly designed by φ. The extent to which the impact-traverse tests satisfy requirement (*a*) set forth in the preceding paragraph will become apparent from the description following.

Practical limitations have largely shaped the technique. The extent of conformity with requirement (ω) is less obvious and this is, therefore, made the subject of analysis in a separate section.

Impact-Traverse Tests—Description of Apparatus

An impact tube, oriented in the direction of a fluid flow at any point and suitably connected to a U-tube manometer or other differential pressure gage, is an instrument capable of indicating accumulated energy losses to that point from some chosen datum, provided that a satisfactory assumption regarding compression at the muzzle of the impact tube may be made. Having restricted the investigation to subacoustic air velocities, thereby eliminating the possibility of compression shock at the tube muzzle, and with a tube small in proportion to the dimensions of the passage to be studied aligned with the flow so as to receive the impact normally, it is fairly certain that the assumption of isentropic compression is satisfactory.

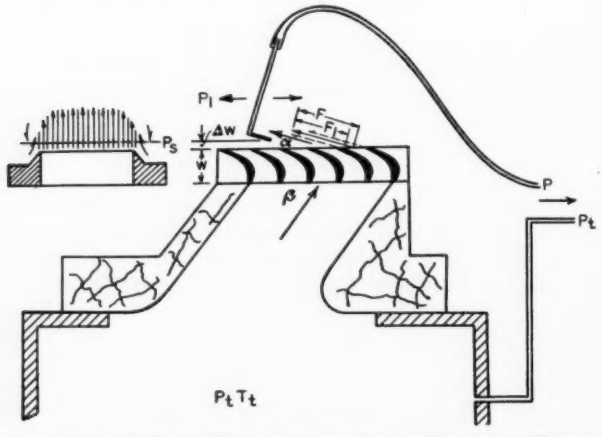

Fig. 3 Blade Pack Mounted for Impact-Traverse Testing

Referring to Figs. 3 and 4, a systematic measurement of total pressure, at many points along a line normal to the blade edges and in a plane distant Δw therefrom, will be called an impact traverse. Precaution against unnecessary disturbance of the flow finally led to an impact tube improvised from a hypodermic needle with 0.025 in. bore and 0.013 in. wall thickness set into a nicely streamlined rod and communicating with the tap through a hole drilled lengthwise through the rod. Smaller needles have been tried with some success, but generally they lack the rigidity required to stand without vibrating in a jet with velocities at times approaching acoustic value.

The impact tube was supported in the jet by a traversing mechanism built on the side of the reservoir from which the blade pack was supplied with air. The reservoir was sufficiently large that approach velocity could be neglected and the air considered flowing from rest at a pressure P_t and absolute temperature T_t. The position of the impact tube in space was controlled by three lead screws which permitted measurement of coordinates (x, y, Δw) from a chosen datum on the pack accurate to 0.001 in. Orientation of the tube on the traverse arm was controlled by two small worms and sectors which permitted rotation of the tube about two axes at right angles. These motions were locked when the apparatus was set for traversing. The tube was aligned with the flow by sighting on a fine silk thread attached to a thin steel rod which the operator held in the jet. The efflux angle α which the jet makes with the exit plane of the blades may be measured to within $\pm 1/2$ deg by aligning the edges of a bevel protractor with the pack and the thread. The search tube is insensitive to changes in velocity direction greater than the limit of accuracy in setting, hence, the accuracy of the total pressure measurements is unimpaired by the rather crude alignment technique.

Blade packs were made in the form of rectangular grids by soldering or doweling the foils to side bars and adding appropriate end pieces to enclose fully the passages. Special jigs and tools have been developed to secure sufficient accuracy in the location of foils. Success in attempts to allocate causes of small differences in efficiency to the many variables involved depends upon precise workmanship in the building of test packs. Flow to the blade packs from the reservoir was through wood approach passages of rectangular cross section with well-rounded entrance.

Energy losses in approach passages can be reduced by good design but can never be eliminated. These losses are not distributed but are localized at the walls. If a grid of several passages be used, and only the interior passages explored, the results will be almost entirely free from inlet losses over extremely wide ranges of the variables. Since only energy losses in the blades are of interest, the possibility afforded by the traverse-type test of selecting for study only those passages unaffected by inlet losses is a great advantage.

Studies of the influence of aspect ratio, gaging, and pitch/chord ratio require alteration of the blade pack for each test point. Variation in the velocity ratio can be accomplished statically by changing the entrance angle β, which is just the angle of the approach passage. The influence of Mach's number or pressure ratio is determined by tests with variation in the tank pressure P_t.

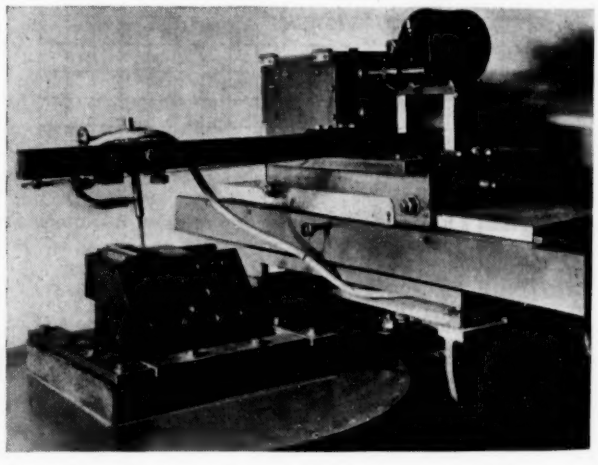

Fig. 4 Blade Pack and Traversing Mechanism Mounted on Air Reservoir

In any axial-flow turbine, the blades are radially disposed and not parallel as in the test packs. Except for the few large low-pressure stages of condensing turbines where blades of nonuniform cross section from base to tip are used, the ratio of blade height to mean diameter of the stage is small (less than 0.2 and usually nearer 0.1) and the flow may, without serious error, be considered two-dimensional.[4] Only cases with a blade of uniform cross section throughout its length are considered here. The work of such blading per pound of steam flow is normally calculated on the basis of velocities at the mean diameter of the row. The impact test should be considered as simulating a stage in which the blading is disposed on the mean diameter as in the test pack, and in which there is a minimum of variation in pitch and gaging from base to tip of the blade.

To measure only energy losses occurring in the element, the impact-tube muzzle should move in the plane of the exit edges of

[4] A three-dimensional flow is considered in calculations for long low-pressure blades.

the blades for which $\Delta w = 0$. This is simply saying that, in measuring friction losses per pound of fluid flowing through a given element, the traverse should exclude the entrainment-velocity field beyond the passage ends or that only those filaments should be included which would move through the element at theoretical velocity if there were no friction. With a finite-size impact tube, it is impossible to traverse in the plane for which $\Delta w = 0$, so we keep Δw a minimum. With the apparatus here described, practical limits of Δw are 5 to 15 per cent of the blade width depending upon the blade size. All that is necessary then is to connect a sensitive differential pressure gage across the search tube and reservoir in Fig. 3 and, with the initial pressure P_t held constant, to measure and to plot as a function of simultaneous values of the position coordinates (x, y), the pressure difference $(P_t - P)$. The datum or zero point of the coordinate system is arbitrary.

If only a few blade packs were to be thus explored, a differential manometer would serve very well as an energy-loss indicator and values of x and y could be measured in terms of the number of turns of the lead screws controlling the motion of the search tube. The labor involved in mapping out the dependence of energy losses upon a number of variables by these primitive means is prohibitive. The success of the undertaking rests entirely upon the adaptation of electrical means of recording and integrating the variation in impact pressure in the traverse plane at no appreciable sacrifice in the new order of precision in efficiencies made possible by direct-loss measurements.

To obtain an accurate continuous measurement of the pressure difference $(P_t - P)$, as the impact tube was driven across several pitches of the blade pack, we used the magnetic-strain gage (5). Developed as an instrument for precise measurement of small displacements, it was only necessary to construct a mechanism to move the keeper of the gage linearly proportional to pressure difference, and to provide suitable meters for recording and integrating the resulting voltage variations. The chart of the recording voltmeter and the impact tube were driven by synchronous motors operated from the same power supply. During the passage of the impact tube over n pitches of the pack, indicated by n cycles on the recorder chart and timed by stop watch, the integrating meter totaled a number of revolutions proportional to n P_s. The constant speeds of the integrator proportional to P_t and P_1 were established by test. To understand how energy-loss measurements can be evaluated so as to yield by summation a coefficient for the whole passage only negligibly different from φ^2 and to see how our instruments reduce the calculation to simple arithmetic, it is necessary to proceed with an analysis of the static test.

Keeping Δw a minimum and traversing only the projected area $h \times s$, it will be assumed that entrainment components are effectively eliminated and that the entire translational flow through the blade pack is included. Another section is reserved for comment on the validity of these assumptions following the analysis.

Analysis of the Static Test

Referring to Fig. 3, the jet as a whole has no rotational-velocity component and, in the plane of the exit edges of the blades for which $\Delta w = 0$, velocity c at angle α and static pressure P_s exist at any point. If dA represents an element of area normal to velocity C, application of the second law of motion leads to

$$\int_0^A \frac{\gamma_s}{g} C^2 dA + \int_0^A (P_s - P_1) dA = F_1 \dots\dots [3]$$

Here F_1 is the net force experienced by the blade pack as a result of a flow W lb per sec from initial conditions (P_t, T_t) to the atmosphere P_1. It will be observed immediately that F_1 differs from the change in momentum by a term composed of a static-pressure difference acting on a projected area A.

The function of any turbine element is to derive a force from a change in the momentum of the motive fluid. Strictly interpreted, therefore, any static test makes possible a determination of efficiency of an element only if means are provided for measuring force F_1, pressure P_s, and area A in Equation [3].

The force F_1 could be measured with fair accuracy in a number of ways that have been frequently described in the literature of static testing. Great precautions are necessary to avoid extraneous forces arising from entrainment of the atmosphere. For the plane for which $\Delta w = 0$, the area A is just the minimum area of the passages. Measurement of the static pressure P_s in such small regions of high velocity, as those encountered behind blade grids, offers difficulties[5] but is possible if we are not too concerned with errors due to turbulence. Fortunately, a very accurate integration of the static pressure in the survey plane is not needed to satisfy the accuracy ordinarily sought in the energy-loss measurements.

The velocity coefficient φ may now be more nicely defined as the ratio of mean momentum per unit mass flow to ideal momentum per unit ideal mass flow and expressed analytically by Equation [4], if ΔF_t represents the second term of the left-hand member of Equation [3], and F_t represents the net force on the blades with isentropic change of state.

$$\varphi = \frac{g(F_1 - \Delta F_t)}{W} \div \frac{g(F_t - \Delta F_t)}{W_t} \dots\dots [4]$$

Equation [4] may be recast in series form and factored as

$$\varphi = \left(\frac{F_1}{W} \div \frac{F_t}{W_t}\right)\left(1 + \frac{\Delta F_t}{F_t} - \frac{\Delta F_t}{F_1} + \frac{\Delta F_t^2}{F_t^2} - \frac{\Delta F_t^2}{F_1 F_t} + \frac{\Delta F_t^3}{F_t^3} - \frac{\Delta F_t^3}{F_1 F_t^2} + \dots\right) \dots [5]$$

The first factor does not involve the static pressure P_s. Using only three terms of the second factor, it is a matter of arithmetic to show that, with a value of the first factor as low as 0.9 and $\Delta F_t/F_t$ as high as 0.05, the first factor can differ from φ by little more than 1 per cent. A value of ΔF_t equal to 5 per cent of the total theoretical force on the blade pack would require an integrated pressure difference $(P_s - P_1)$ over the area A of 5 per cent of the pressure drop $(P_t - P_1)$. In no case have our static-pressure measurements yielded a difference approaching this value.

The commonly accepted practice of disregarding the second factor of Equation [5] and along with it the need for measurement of pressure P_s, and defining φ simply as the first factor of Equation [5] appears justifiable, at least for subacoustic velocity work and will therefore be adopted.

Accordingly

$$\varphi = \frac{F_1}{W} \div \frac{F_t}{W_t} = \frac{C_1}{C_t} \dots\dots [6]$$

where C_1 is a fictitious mean velocity defined as shown by the actual net force on the blade pack and the actual flow rate. It is from this expression that the term φ receives the name velocity coefficient. The more general use in turbine calculations of energy expressions than velocity expressions has caused the square of the velocity coefficient φ^2 to be more often used as a criterion of passage performance than is φ itself. Energy coefficient or efficiency are names frequently given to φ^2. Regardless

[5] Refer to A. G. S. Sandison's comment in discussion of (4) and authors' closure.

of name, it is important to remember that φ^2 is the square of a momentum coefficient which is analytically the basic quantity.

Summarizing, the elimination of the terminal static pressure P_s restricts interpretation of results to the degree of perfection of an indeterminate expansion combined with an isentropic adjustment of pressure and velocity to the environment. To the extent that this latter adjustment is negligible, velocity coefficient is a true barometer of passage losses.

Following Stodola (3) the flux of energy per second through cross section $h \times s$ in the plane of the exit edges of the blades in Fig. 3 may be equated to the available energy less the aggregate friction losses per second.

$$\int_0^A \left[\frac{C^2}{2g} + \int_{P_1}^{P_s} \frac{dp}{\gamma}\right] dW = \int_0^A \left[\int_{P_1}^{P_t} \frac{dp}{\gamma_t}\right] dW - Q \quad [7]$$

Assuming isentropic compression at the impact tube and

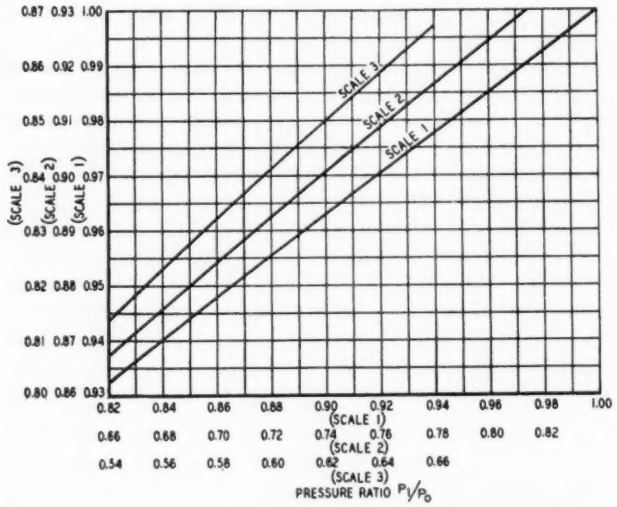

FIG. 5 COMPRESSIBILITY FACTOR AS FUNCTION OF PRESSURE RATIO FOR AIR

$$\left[\left(1-\frac{P_1}{P_0}\right)(k-1)\right] \div k\left[1-\left(\frac{P_1}{P_0}\right)^{(k-1)/k}\right] \quad k = 1.4$$

dividing through by the first term of the right-hand member of Equation [7] we may write

$$\frac{\int_0^A dW\left[\int_{P_1}^{P} \frac{dp}{\gamma}\right]}{\int_0^A dW\left[\int_{P_1}^{P_t} \frac{dp}{\gamma_t}\right]} = 1 - \sigma \quad [8]$$

where σ is aggregate friction loss in per cent of the available energy.

For any elementary filament along which the flow rate is dW, an expression for the efficiency becomes

$$\frac{\int_{P_1}^{P} \frac{dp}{\gamma}}{\int_{P_1}^{P_t} \frac{dp}{\gamma_t}} = 1 - \delta \quad [9]$$

Efficiency has been purposely written (1 — losses). The possibility of direct-loss measurements in the impact test is an advantage not to be overlooked.

The integrations indicated in Equation [9] may be performed by making use of the pressure-volume relationship for isentropic behavior of a perfect gas, yielding Equation [10] in which the only unknown quantity is γ, the density at the muzzle of the impact tube where the air is brought to rest. The quantities χ

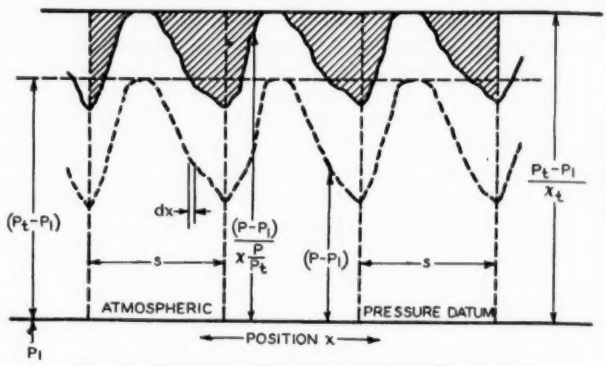

FIG. 6 PITCHWISE TRAVERSE AT SAME POSITION y (Loss area shaded.)

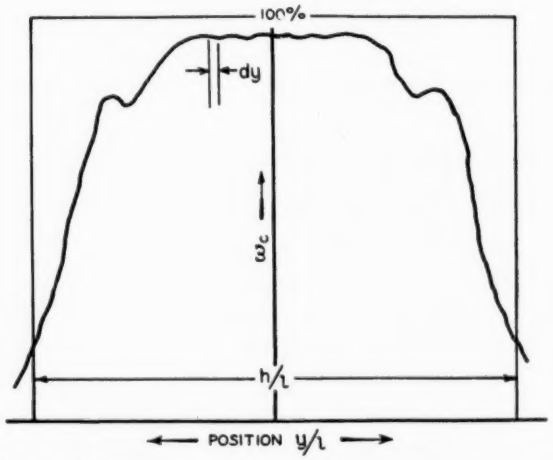

FIG. 7 REPRESENTATIVE EFFICIENCY-DISTRIBUTION DIAGRAM

and χ_t in Equation [10] are compressibility factors defined by Equation [11]. For a gas with a fixed ratio of specific heats, the compressibility factor is a function of pressure ratio and may be evaluated for $k = 1.4$.

$$1 - \delta = \frac{P - P_1}{\chi\gamma} \div \frac{P_t - P_1}{\chi_t\gamma_t} \quad [10]$$

$$\chi_0 = \frac{\left(1 - \frac{P_1}{P_0}\right)(k-1)}{k\left[1 - \left(\frac{P_1}{P_0}\right)^{(k-1)/k}\right]} \quad [11]$$

To eliminate the unknown density γ, it may be observed that, along any filament, the air starts from rest in the reservoir and comes to rest at the impact-tube muzzle without doing any external work. Furthermore it will be assumed that there has been no heat transfer from neighboring filaments. The cycle of expansion and compression may therefore be considered a throttling and, since the medium is nearly a perfect gas, the temperatures at densities γ will be constant and equal to the initial temperature T_i. Equation [12] follows directly

$$\gamma = \gamma_t \frac{P}{P_t} \quad [12]$$

Substituting for γ in Equation [10], gives an expression for

efficiency at a point in terms of measurable pressures and the compressibility factors.

$$1 - \delta = \frac{P - P_1}{\chi \frac{P}{P_t}} \div \frac{P_t - P_1}{\chi_t} \quad \ldots\ldots [13]$$

A pitchwise traverse at some position y along the blade pack would appear as the dotted curve in Fig. 6, where pressures are plotted as functions of positions x with linear scales on both axes. Using the compressibility factors χ and χ_t, and the pressure ratio P/P_t it is possible to correct the pressure traverse, point by point, as has been done in Fig. 6, yielding the full-line curves. The integrations

$$\omega_e = \frac{\int_{-ns/2}^{ns/2} (1 - \delta) dx}{\int_{-ns/2}^{ns/2} dx} \quad \ldots\ldots [14]$$

indicated by Equation [14] may be performed graphically. The value of ω_e so determined is a coefficient of an elementary slice dy of n pitches of the blade pack. Values of ω_e may thus be determined for many slices until the entire height h has been traversed.

An efficiency-distribution diagram, such as Fig. 7, is obtained by plotting ω_e vs. y/l. The result of a second graphic integration Ω_e defined by Equation [15] has been shown in an appendix to

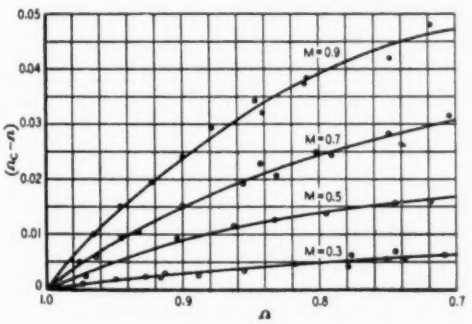

FIG. 8 COMPRESSIBILITY CORRECTION

this paper to be very nearly equal to φ^2 where φ is defined by Equation [6].

$$\Omega_e = \frac{\int_{-h/2}^{h/2} \omega_e dy}{\int_{-h/2}^{h/2} dy} \quad \ldots\ldots [15]$$

LIMITATIONS OF THE METHOD

With aspect ratios in excess of unity, a value of Ω_e, established according to the method described, is substantially invariant with small changes in Δw or with changes in the limits of integration of the numerator of Equation [15] from $\pm h/2$ to $\pm \infty$. Under these conditions, no significant incompatibility with theory arises as a result of arbitrary selection of a test plane and traversing limits, and the measured value of Ω_e has the status of an efficiency measurement in the plane of the exit edges of the blades for which $\Delta w = 0$.

As aspect ratios decrease below unity, impact measurements, intended to represent losses in the passage but made at a small distance Δw above the exit plane, become increasingly inaccurate due to difficulties encountered in eliminating the entrainment-velocity field which becomes an appreciable part of the whole, or in attempting to take it into account. The only satisfactory method that has been devised to handle these cases is to run traverses at decreasing values of Δw, stopping with the minimum physically attainable and, by extrapolation, to determine Ω_e at $\Delta w = 0$. The accuracy of this process is dependent upon how close to the blades the last reading can be obtained.

Attempts have been made to measure Ω_e at some arbitrary value of Δw by traversing beyond the passage ends to values of ω_e near zero as suggested by Tollmien and performed on long thin slots by Förthmann (9). The over-all efficiency established thereby on blade packs appears too high. Reference to the end view of the grid in Fig. 3 shows why this may be so. Secondary flow in the passages to which reference will be made later seems to be a factor in preventing an orderly entrainment of stagnant air

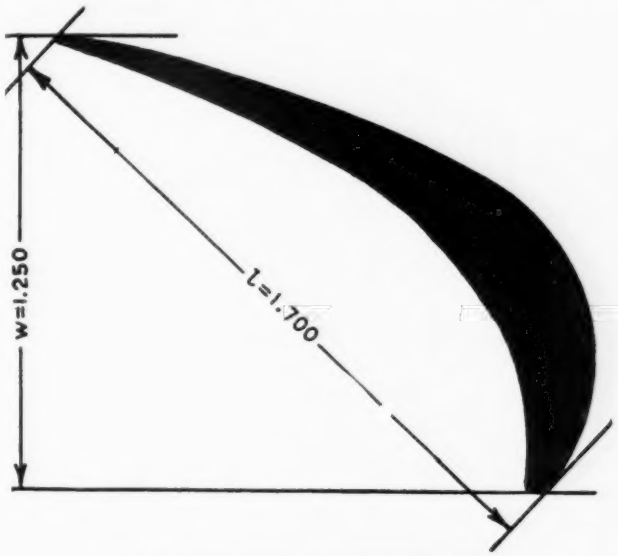

FIG. 9 REACTION BLADE, TWICE FULL SIZE
(These blades were always assembled with the width dimension shown and therefore, may be called constant-orientation blades.)

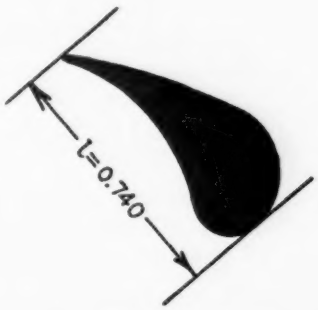

FIG. 10 STREAMLINED REACTION BLADE, TWICE FULL SIZE
(The width dimension was varied in the several assemblies employing these blades, which, therefore, may be called variable-orientation blades.)

by the escaping jet. A fair measurement of impact pressure can be made on those entrained filaments closely adjacent and moving in essentially the same direction as the motive flow. In the arbitrary plane, however, traversing must extend theoretically to infinity and hence include filaments flowing obliquely and frequently backward. A zone of such disturbance cannot be accurately explored with a fixed-tube orientation and, lacking partial compensation for readings obtained in the region of orderly flow, integration of the whole distribution diagram leads to optimistic results. It is for this reason that we have restricted traversing

to the projected area $h \times s$ in a plane at minimum distance Δw from the blade edges.

Mechanization of the Impact-Traverse Test

It was observed that integrations of the pressure traverses alone gave values of ω and Ω differing from ω_e and Ω_e by small amounts dependent only upon the Mach number and the indicated efficiency. By indicated efficiency is meant the integrated result from the pressure record. Thus, from a great number of tests on all kinds of blade sections at various pitches, orientations, heights, entrance angles, and Mach's numbers, it was found possible to plot compressibility corrections as in Fig. 8.

This step permitted an evaluation of Ω_e in any case by just adding a correction to Ω determined by double integration of the pressure traverses and allowed complete mechanization of the traverse test. The expressions for ω and Ω are the simpler forms related to incompressible fluids thus

$$\xi = \frac{P_t - P}{P_t - P_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots [16]$$

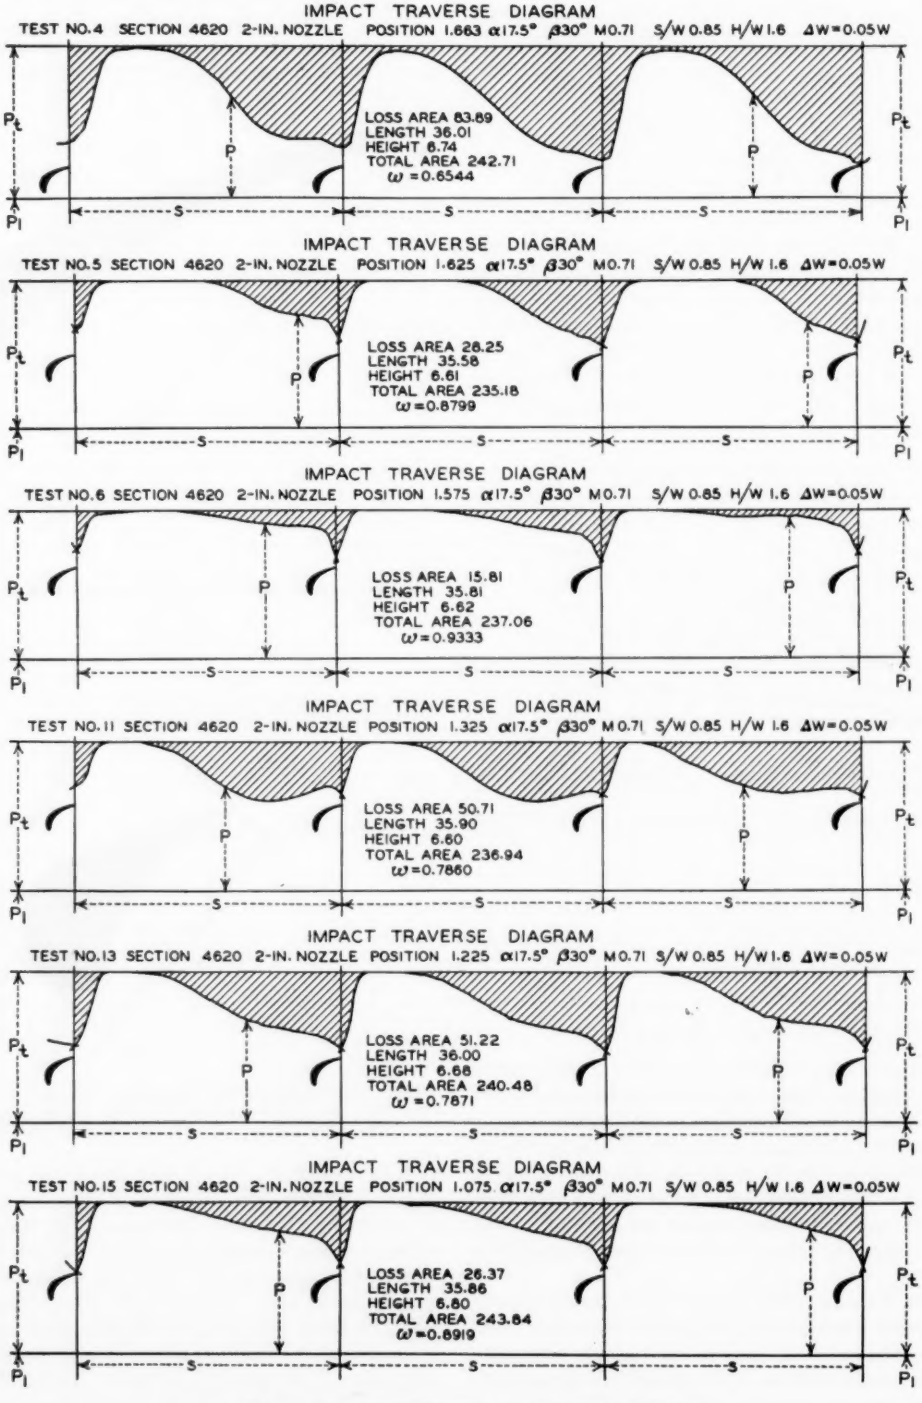

Fig. 11 Traverse Records for Inefficient Flow

$$\omega = 1 - \frac{\int_{-ns/2}^{ns/2} (P_t - P)dx}{(P_t - P_1)\int_{-ns/2}^{ns/2} dx} \quad \ldots\ldots\ldots\ldots [17]$$

$$\Omega = \frac{\int_{-h/2}^{h/2} \omega dy}{\int_{-h/2}^{h/2} dy} \quad \ldots\ldots\ldots\ldots\ldots [18]$$

Equation [16], which follows from Equation [13] by neglecting the denominators of the right-hand member, reveals the simplicity of direct-loss measurements. It was simple to construct a pressure mechanism for actuating the strain gage with displacements proportional to a pressure difference. However, it would not have been so simple had we been forced to work entirely with the terms involving pressure ratios to some power of k, which occur when compressibility of the medium must be considered.

Results, Discussion, and Conclusions

From the foregoing exposition of the measurement and evaluation of impact pressure over the exit plane of a turbine element, it follows that the traverse record taken in the direction of pitch s for different constant positions y along the blade height h is indicative of the energy losses. Its structure is of fundamental origin revealing the extent of friction and, therefore, responds to favorable and detrimental stimuli such as strong acceleration of particles in the direction of flow and loss of fluid contact with walls, respectively. The structure of the traverse record should respond only secondarily to changes in the geometry of the test pack. On the other hand, the efficiency-distribution diagram, which is a plot of the mean efficiencies from traverse records as a function of position along the blade height, is indicative of the extent and localization of the losses. Its structure changes in a characteristic way with the geometry of the pack and test conditions. These two types of plots give exhaustive information on the nature and magnitude of the energy losses. The change required to produce an improvement in efficiency is nearly always evident, although it may sometimes be impractical of attainment.

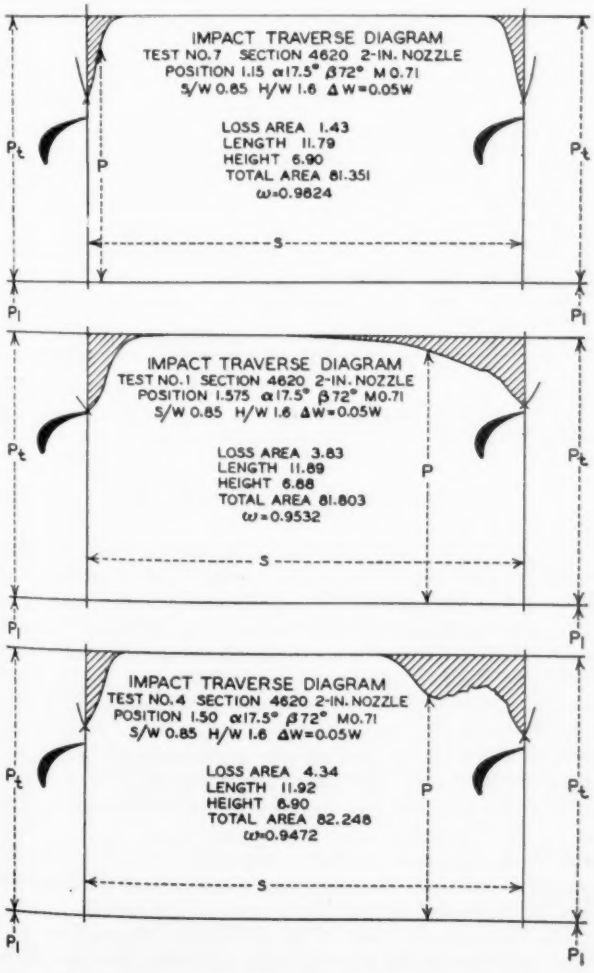

Fig. 12 Traverse Records for Efficient Flow

Cross sections of the foils on which the tests presented were obtained are given as Figs. 9 and 10. These profiles are fairly representative of extremes in mechanical strength required in ordinary reaction stages and will be referred to simply as a reaction blade, Fig. 9, and a streamlined reaction blade, Fig. 10. The former with thin leading edge might be expected to exhibit efficiencies more dependent upon the direction of approach of the fluid than the latter. Fig. 9 could, therefore, be called a fixed-orientation blade, whereas Fig. 10 would be called a variable-orientation blade. Since each of the sections shown is one of a series of geometrically similar shapes, covering a range of sizes, the discussion applies to the entire series rather than to the one blade size.

The traverse records, consisting of a group of 3-pitch traverses in Fig. 11, and a group of single-pitch traverses in Fig. 12, have been selected from a file of several thousand as samples of the type of record obtainable. The group in Fig. 11 represents successive slices of the foil in Fig. 9, assembled as indicated on the records and fed at an entrance angle of 30 deg at Mach's number 0.7. In Fig. 12, the entrance angle has been increased to 72 deg, everything else remaining the same. The smaller entrance angle corresponds to a flow with a large component of impingement on the concave surface of the foil and an eddy field at the convex surface. The larger entrance angle is near the optimum for the blades in question. For a fixed-orientation blade, the width dimension w is chosen as a reference length instead of the chord dimension l for forming the dimensionless ratios s/w, h/w, etc. For a variable-orientation blade, l is used since it is a dimension of the profile itself and is therefore independent of how the profiles are set in the row. Designating the end of the blade pack remote from the search tube as zero the term "position" on the traverse records is simply y/w. Since h/w for the pack was only 1.6, the records for tests Nos. 4 and 5, Fig. 11, were obtained in the entrainment field beyond the pack end.

It will be observed that the chief difference between the traverse records is the rapidity of the impact-pressure recovery at the convex surface of the foil. The loss area associated with the convex surface can vary from a narrow cusp indicative of only a viscous-friction boundary layer to a large irregular pattern emerging from the entire passage with fluctuations attesting the existence of severe eddies. The loss area associated with the concave surface is nearly always of the type attributed to viscous friction. A rational explanation of this basic difference lies in a consideration of the relative stability of streamlines near the two walls. It has been found that the flow conditions prevailing in the boundary layers dictate whether the flow in the entire passage shall be relatively efficient or inefficient (6).

In curved passages centrifugal force causes a pressure increase and velocity decrease at the concave surface of the blade and a pressure drop and velocity rise at the convex surface, compared with the pressure and velocity prevailing at the central filament. Proceeding along a streamline through the passage near the

concave surface, the fluid particles experience a falling pressure. In this boundary layer the pressure gradient provides a motive force on the particles, overcoming the friction drag of the wall, and there is less tendency toward stagnation. The fluid-friction drag transmitted from more rapidly moving particles in the center is in the same direction as the pressure drop. There is no tendency for the flow to leave this wall and the boundary layer is thin and stable. The small loss area on the record reflects these favorable conditions.

Proceeding along a streamline through the passage near the convex surface, the fluid particles may not experience a falling pressure and may even encounter a pressure rise, depending upon the severity of the vortex arising from passage curvature. There may be no motive force on the particles in this boundary layer in the direction of flow other than that transmitted by shear from the body of the stream. Wall friction brings the outside layer of particles to rest, establishing a local reverse-pressure gradient which forms a couple with the drag forces transmitted to these particles from the more rapidly moving adjacent layers. A small

eddy results; the boundary layer becomes unstable and leaves the wall. Disturbances growing from such elementary losses of fluid contact may fill the entire passage with devastating effect on the energy of translational flow. It is the purpose of the remaining paragraphs and efficiency-distribution diagrams to show the dependence of both ω and Ω on the five important variables selected at the beginning of this paper.

Operation at other than the optimum velocity ratio has the largest effect on passage efficiency of the variables considered. This may be accomplished statically by varying the entrance angle of the flow. In Fig. 13 are shown five distribution diagrams for the highly efficient, heavy-duty type of reaction blade shown in Fig. 10. Owing to symmetry about the mid-height of the blade, the diagrams are shown from the center line to one end only. The spacing and orientation of the blades in the pack and the aspect ratio are average for the section considered. In the turbine, groups of these blades normally operate at a Mach number of 0.3 and this value was accordingly chosen for the air test. The range of entrance angles selected would about cover the extremes encountered in marine practice from maneuvering to full-load propeller speeds. Tests on a pack of very different proportions are represented by the diagrams in Fig. 14. Here the foil with thinner leading edge shown in Fig. 9 has been assembled and tested under conditions simulating its performance in the stationary element of an unsymmetrical stage near the high-pressure end of a turbine where aspect ratios are small. Complete assembly information and integrated results are given on each figure. Each point on every distribution diagram resulted from one traverse record, samples of which are shown in Figs. 11 and 12.

Figs. 13 and 14 reveal a more orderly retardation of the flow heightwise than pitchwise. Particularly in the case of large aspect ratio, but also discernible in Fig. 14, is a tendency for a central region of uniform loss flanked by extreme localized losses at passage ends. With decrease in the entrance angle, end losses become more severe and reach further into the passage until they

eventually bridge over, reducing the uniform central region to a point, or even annihilating it altogether. The localization of losses at the passage ends was recognized early in the course of our tests as a manifestation of secondary flow attributable to the same vorticity that augments the losses along the entire convex surface of the foil. In the auxiliary sketch in Fig. 13, if the rectangle represents the minimum area of a passage, the curved arrows indicate the direction of the secondary flow. The pressure built up at the concave surface of a blade diminishes at the passage ends as a result of the heightwise velocity distribution. This pressure gradient along the blade seeks relief in transverse flow at the passage ends to the low-pressure region at the convex surface of the adjacent blade, where it enters substantially normal to the main flow, forcing a partial loss of fluid contact with the wall and attendant destruction of useful energy.

The characteristic shape of all distribution diagrams for passages above a certain limiting value of aspect ratio permits a separation of the losses into two distinct classes. It appears

almost certain that the uniform central portion of the diagram would not improve with indefinite extension of the passage height. This portion may be termed profile efficiency analogous to the profile drag used in aeronautics, and may be considered the efficiency limit with infinitely long foils assembled at the given pitch

and gaging and operating at the chosen entrance angle and Mach's number. The secondary-flow losses may be treated as a correction factor for finite aspect ratios. The correction factor, as well as the profile efficiency, is a function of the other four variables. It resembles the induced-drag term in aeronautics. For chosen values of the variables, distribution diagrams at various aspect ratios have been superimposed in Fig. 15. For aspect ratios above that exhibiting a profile flow at the center of the pack, a good approximation of Ω_c can be obtained by making use of the fact that the end losses are inversely proportional to the aspect ratio. This is expressed

$$\frac{1 - \frac{\Omega_c'}{\omega_p}}{1 - \frac{\Omega_c}{\omega_p}} = \frac{h/l}{h'/l} \quad \ldots\ldots\ldots\ldots\ldots\ldots [19]$$

Passages with aspect ratio so small that no profile flow develops are of great importance in the high-pressure ends of steam turbines. In such cases, a chaotic merging of the secondary flows takes place with increase of the losses faster than indicated by the linear relationship in Equation [19]. The intended orderly flow is not approached even remotely, and efficiency as a function of the several variables can be determined only by test.

Distribution diagrams showing the effects of variation in pitch and gaging, gaging alone, and Mach's number are shown in Figs. 16 to 18, respectively. Sufficient data are given in each case to identify the test. In general, pitch increases improve the profile efficiency just as increases in aspect ratio improve the over-all

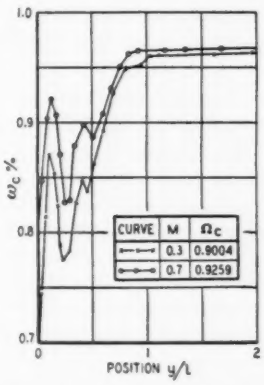

FIG. 18 DISTRIBUTION OF TRAVERSE EFFICIENCY AT VARIOUS MACH'S NUMBERS FOR A STREAMLINED REACTION-BLADE SECTION

efficiency by diluting the loss concentrations at boundary walls with larger regions of potential flow. The term potential flow is used advisedly here. Meticulous observations of the pressure difference $(P_t - P)$ over large portions of the area of efficient packs, using a differential column with light oil as indicator, reveal losses in the reservoir pressure head only in the order of a few hundredths of one per cent. This is entirely negligible and justifies the practice of considering friction losses in turbine elements as boundary conditions surrounding a core of fluid in which energy exchange is isentropic (3). Pitch increases aggravate the end losses and are in this respect similar to a decrease in the entrance angle. Affecting the two basic-loss divisions oppositely, it may be seen that improvement in efficiency can result from increasing or decreasing the blade pitch, depending upon the particular combination of other variables encountered. This conclusion has been repeatedly checked by experiment.

Variation in blade pitch and gaging is frequently an easy way to improve efficiency at little expense. The method is, therefore, very appealing in practice. The qualitative explanation for a large reduction of losses is usually very simple, resting upon some extensive change in the structure of the secondary flow which is apparent on the efficiency-distribution diagram. Thus, in Fig. 16, an improvement in efficiency of more than 4 per cent results from a 20 per cent reduction in the pitch of the foils, together with the 9 per cent reduction in gaging, obtained by simply moving the foils closer together in a groove of uniform width w.

Increase in the Mach number means stronger acceleration of the fluid particles and, hence, less stagnation at any wall, reverse flow, or the building up of eddies. The foregoing exposition of the mechanism of eddy formation contrasted with stable boundary layers indicates an improvement in efficiency with increase in Mach's number. Experiments seem to confirm this reasoning but, until further results have been accumulated in which the influ-

ences of compressibility and viscosity are separated, little more can be said about the dependence of efficiency upon Mach's and Reynolds' numbers.

Little has been done about the extension of traverse tests to superacoustic velocities. The fact that most steam-turbine power is generated at subacoustic velocity justified thorough exploration of this field before attempting interpretation of results complicated by the phenomenon of compression shock. The possibility of efficient utilization of supercritical speeds with attendant reduction in size per kilowatt output is, however, a problem worthy of investigation and a legitimate extension of this project.[6] Regardless of methods employed, the value of some accurate quantitative work in this practically untouched field can scarcely be overestimated, and even fragmentary results will be of interest.

Acknowledgments

The efforts of Carl Deiner, who builds all of the test packs and maintains the equipment herein described in perfect working order, are recognized as a very significant contribution to the success of the entire venture. Much credit for the orderly prosecution of various test programs belongs to J. H. Borton, and the group of laboratory assistants without whose cooperation and painstaking attention to detailed application of the method, results would have been impossible. Finally, the author wishes to accredit the work of Anderhub, Loliger, and others who, as pupils of Stodola, were among the first to recognize the value of the traverse test, and to pay tribute to H. L. Wirt and the joint authors B. Hodkinson and A. E. Devey, who in later years extended application of the method and capably analyzed some results.

An appendix containing derivations to which reference is made in this paper, has been prepared by the author and is available upon request.

Discussion

Ronald B. Smith.[7] The static-air test, similar to that described by the author and others, is one of the most useful research tools available to the turbine designer. When used intelligently it yields at worst a good approximation to most of the hydrodynamic questions that a turbine builder faces. The degree to which the results are approximate is measured by how faithfully the model tests reproduce the hydrodynamic conditions which exist in the turbine. Because certain conditions of similarity cannot be satisfied statically, the judgment of the designer is, as always, the important consideration.

Deviations from dynamic similarity in tests of this nature are of two types; fundamental deviations which are largely academic in interest, and practical deviations which are probably the ones of greatest importance and yet are the most difficult for the designer to evaluate.

Dynamic similarity for a submerged body exists, providing the model is geometrically similar to the original and providing an equality exists between the model and the original in respect to Reynolds' number, Mach's number, atomic number (as mentioned by the author), and in addition a heat-transfer number. Providing the flow losses are small or the turbulence low, it is reasonable to neglect the dimensionless heat-transfer criterion. With the aid of the variable-density test equipment, the author is able to differentiate between the influence of the Reynolds number and the Mach number but, in regard to the criterion prescribed by the atomic number, the situation is not as clear. Equality of atomic number necessitates that the tests be conducted with a medium having the same ratio of specific heats as in the original turbine. If the tests are made in air and the original operates in steam, it is obviously impossible for the specific-heat ratios to be equal. As far as the writer is aware, the only attempt to evaluate the approximation resulting from a neglect of this criterion has been made by Ackeret and his associates. They conclude that for reasonable velocities, say below about one-half the acoustic, no appreciable discrepancy exists. The author mentions tests extending to velocities which approach the acoustic without apparent consideration of what effect this more or less academic dissimilarity may have.

Dissimilarities of a practical nature which exist between the flow around the blade and that in the turbine arise from a number of causes. If the steam velocity is less than the acoustic, then pressure disturbances are transmitted by waves traveling at the velocities of sound both upstream and downstream from their source. This means that a blade in any location receives pressure impulses originating from disturbances at the blades both upstream and downstream from it, and the flow around any blade is in consequence influenced by these results. This is a condition which is obviously not met in a static assembly and at abnormal velocity ratios is probably one of importance.

Another point of practical dissimilarity arises when the blades are distributed circumferentially around the rotor of a turbine and in the static test they are assembled parallel. Actually, in the flow through the turbine, the pressure drop which exists between a stationary blade and its rotating partner is not uniform. Even though the areas are not laid out for a potential flow with constant circulation, the fluid, adjusting itself to the easiest course, attempts to approximate this condition. There usually exists a greater pressure drop over the tip of the rotating blade than at its base, and a greater pressure drop over the base of the stationary blade than over its tip. These pressure variations must have a marked effect on the secondary flow in the passage; it is certain that they introduce an effect which is difficult to approximate on a static test.

The efficiency of impulse-type blading is affected by the ejector and entrainment losses of the working fluid at the ends of the buckets. This condition arises from the fact that the bucket

[6] As this paper goes to press we have concluded our first year's detailed study of the performance of turbine elements at supersonic velocities. This exploration involved many problems not encountered in the subsonic velocity work.

[7] Development Engineer, Elliott Company, Jeannette, Pa. Mem. A.S.M.E.

overlaps the nozzle. The end losses which exist are difficult to simulate by static test, while their magnitude, at least for buckets not specially sealed at their ends, is for certain velocity ratios as great as the ordinary aspect-ratio correction which the author finds for individual nozzles or reaction blades.

The work delivered by a given turbine blade depends upon the change in momentum in the direction of motion. This momentum change involves not only a knowledge of the efficiency of the passage but a measure of the angle of efflux. The author does not discuss this feature in connection with the test, although it is a consideration to which the designer must devote some attention. These angles cannot be measured with great accuracy; in addition they vary considerably over the discharge section. While it is true that as long as the angle is small, an appreciable error in its determination can be tolerated, since the cosine of the efflux angle is the variable at point, on low-pressure blading and on impulse buckets, the angles are larger and an accurate measurement is of considerable significance. In this connection it might be well to mention the problem of blade pitch. When the aspect ratio is large it is not uncommon to find that the suggestion is made that an increase in the pitch of the blading will improve the efficiency. This suggestion has for its base the mutual interference between blades and has been applied with marked success on the Kaplan runner and on propeller fans. While it is frequently true that an increase in efficiency in the passage is realized with larger pitch, it is also true that this is generally accompanied by an increase in efflux angle so that the final work done in the row is not increased as rapidly as one might at first expect.

In conclusion, it should be emphasized that the author's paper is a worth-while contribution to the art. The remarks of the writer are not intended as a criticism but are merely offered to show that the results derived from static-test equipment, while of real value, must be interpreted with discrimination by the designer because the static test does not always approach conditions which are similar to those met in the final machine.

J. R. Weske.[8] From theoretical investigations by the writer on the interference of successive rows of turbine blading, it appears that for modern high-efficiency blades the dynamic effects are of such magnitude that they cannot be neglected if satisfactory correlation of static-test results and stage efficiency is desired. A brief exposition of the essence of these investigations follows:

When plotting instantaneous-velocity diagrams on the basis of the velocity traverse obtained from static tests, it is seen that the subsequent blades operate in a stream of cyclically varying direction. This produces corresponding variations of circulation around the blades, which in turn cause a sheet of vortexes with axes parallel to the blade to leave the trailing edge of the blade. These vortexes are related to the starting vortex on airfoils and, like the latter, they produce an additional drag on the blade corresponding to the energy consumed by them. The effect of these vortex sheets upon airfoil grids in cascade arrangement has been investigated by Ackeret and Keller.[9]

Another approach to the theoretical determination of interference between successive blade rows can be made through investigation of what is known in aerodynamics as the Katzmayr effect.[10] This effect refers to deviations of the direction of the lift force on an airfoil with change of angle of attack and its effect upon drag or, in the case of turbine blades, upon pressure drop across the row. Calculation of this effect is complicated by phase lag and hysteresis effects at high frequency.

The writer has not been able to check his calculations experimentally. However, he believes that his assumptions will be confirmed in a qualitative way, by photographic investigations with the aid of moving-picture films of two-dimensional flow at low Reynolds' numbers, samples of which were shown in connection with the oral discussion.

J. I. Yellott.[11] This paper is particularly valuable because of the detailed manner in which the author sets forth the theoretical background on which these tests are predicated. It is to be hoped that in his reply to the discussion the author will elaborate somewhat upon the mechanism used for recording and interpreting the impact data. The technique of testing with great rapidity and yet with very high accuracy by means of electromechanical devices is extremely valuable. The taking and interpreting of such data by the more usual methods would be a task of impossible magnitude.

The author does not mention static traverses, and it would be interesting to know whether any such traverses have been made. Although the absolute accuracy of such measurements would be questionable, they would probably reveal the existence of unexpectedly low pressures behind the convex sections of the buckets. At high initial pressures, this reduction of static pressure might well be enough to cause the velocity at these points to be superacoustic. The usefulness of the impact tube for measuring velocities near the acoustic velocity has been discussed,[12] at some length. An earlier investigation[13] in the superacoustic field is that of T. E. Stanton. The Rayleigh theory, commented upon by Stanton, indicates that there should be only a slight error in using the impact tube for Mach's numbers up to 1.3.

Author's Closure

It is a pleasure to acknowledge the value of the discussions, both written and oral, which by their quality, and not mere wordiness, have done much to amplify and improve the author's communication to the profession. To generalize, it seems appropriate to state that a number of the points brought out by the contributors were mentioned, and some were treated at length, in the parts of the original manuscript which were deleted before publication in the interest of brevity.

In the presentation of the paper, more attention than accorded in the text was given to emphasizing the three categories into which known similarity criteria may be grouped, namely, geometrical quantities, fluid-dynamics quantities or properties, and turbulence, which being concerned with temporal as well as spatial variation of velocities seems to deserve a separate rank. The discussers recognize, of course, that the results presented dealt almost entirely with the effects of variation in the geometry of the turbine stage and, therefore, in no wise constituted a complete picture. The geometrical variables are, however, the first concern of the turbine designer.

Note. A joint discussion by G. B. Warren of this paper and the paper, "Automatic Integrating Pressure-Traverse Recorder for Study of Flow Phenomena in Steam-Turbine Nozzles and Buckets," by H. Kraft and T. M. Berry, appears on page 479 of this issue of the Transactions.

Variable-fluid-density equipment is practically indispensable in separating the influences of viscosity and compressibility. It was pointed out that we are not yet prepared to publish our measurements in this field, but that tests had been in progress for quite some time, and had, in fact, yielded some significant results. Atomic number seems to deserve little more than mention in subsonic-velocity investigations and, with the influence of turbulence, we have only recently begun to work. Aerodynamical physicists in this country have spent the better part of 10 years studying the effects of turbulence on the flow of fluids through passages and around obstacles. Strangely enough, however, it seems safe to say that few steam-turbine engineers are even now remotely acquainted with the meaning of turbulence in the sense in which that term is employed in the more critical analyses of fluid-flow problems.

The author rests his conviction in the value of air tests of the type described on the fact that they make possible a systematic prosecution of a broad program embracing both the nature and magnitude of energy losses in turbine elements and their mode of dependence upon all the key variables involved. Recognition of the dependence of stage efficiency upon from 5 to perhaps 10 variables (depending upon how meticulous we want to be) automatically eliminates the possibility ever of obtaining adequate design information from conventional turbine-economy tests alone. The alternative rather generally adopted consists of orderly examination, by one or more of several exploratory methods available, of the flow through the fundamental elements interspersed by verification tests in an experimental turbine on a workable synthesis of many of the most promising features yielded by the basic investigations. Aeronauticists will quickly recognize that this course is quite parallel to the one they have pursued so profitably. Static tests carefully conducted and skillfully analyzed almost invariably lead to correct comparisons.

It is from the combined study of the experimental turbine performance and the preceding static tests relating thereto that one may partially evaluate the practical deviations of the latter from complete dynamic similarity. Effects totally missing or materially distorted in static tests have been outlined by Mr. Smith. The author strictly avoided implication that over-all turbine-economy tests could be dispensed with. The point of view is rather that their interpretation must rest upon detailed knowledge of the behavior of individual elements as revealed by the more flexible research methods developed.

The results of static-pressure traverses, which play such an important role in the formulation of the method for numerical evaluation of the search-tube studies, had to be condensed into the few statements given in the paper. A brief description of our mechanism for recording and intergrating the impact-tube data, requested by Mr. Yellott, has been made a part of the author's discussion of the paper[14] by H. Kraft and T. M. Berry.

The employment of the so-called "Fales technique," and the method of plaster casts for visualizing velocity distribution in turbine passages, and even the earlier search-tube studies themselves were crude, as Mr. Warren has stated. We seldom trust surface markings now for anything but the roughest kind of check as to whether some change has been beneficial or detrimental.

Photoelastic Analysis of Stresses in a Steam-Turbine Blade Root

By J. J. RYAN[1] and J. T. RETTALIATA,[2] MILWAUKEE, WIS.

The analysis of the stresses in steam-turbine blade roots by photoelastic methods has particular reference to the determination of the loadings on the multiple steps. In this paper, from a comparison of test and calculated values, the stress-concentration factors are obtained for the neck and step sections.

Description of Problem

THE development of large-capacity steam-turbine-generator units has created the necessity for new studies in stress distribution throughout the high-speed rotating elements. This analysis of present-day structures makes possible the new projects in machine construction which are to be developed in the future.

The photoelastic method of analysis is recognized as a reliable means for determining stress values. This method was applied in the determination of stress distribution at the roots of the steam-turbine blade and spindle sections of one of the largest-diameter high-speed steam turbines in service. In the last stage of the low-pressure element of this 3600-rpm turbine, the revolving blading is 18 in. in length and is mounted on a drum $40^1/_2$ in. in diameter. A construction having these proportions approaches the limit of present-day design practice.

Fig. 1 shows a single blade, and Fig. 2 the steam-turbine spindle disk to which it is fastened by means of a multiple-step root. In Fig. 3 is shown the completely bladed low-pressure spindle. The weight of the blade is $4^1/_2$ lb and its centrifugal force at the normal speed of 3600 rpm is about 42,000 lb. As there are 110 blades on the periphery of the rotating drum, the necessity for compact design of the blade roots limits the shape and size of the sections. By calculation and test those sections must be chosen which have the most favorable stress distribution. In general, such a condition requires:

1 A system which is susceptible to calculation and to complete analysis.

2 Adjustment of loading and proportioning of parts to maintain calculated stresses below a given limit.

3 Maximum stress concentrations not exceeding the elastic limit of the material at overspeed operation.

It is the purpose of this paper to indicate how these factors were considered in the design of the last-row blade roots in a modern 35,000-kw 3600-rpm tandem-compound steam turbine.

Description of Apparatus

The model of the cross section of the steam-turbine blade root was made to several times full scale of transparent bakelite. In order to obtain stresses in the spindle portion between the blade roots, three blade models were set in parallel positions, the radial angle between blades in the machine not being sufficient to warrant consideration.

Machining the spindle slots and blade roots in the model was performed by toolmakers who shape the broaches and gages for finishing the turbine rotor and blades. More than ordinary care was observed in matching the respective loading elements of the model, and satisfactory fits were secured as evidenced by the symmetrical fringe patterns obtained. A short specimen bar of the bakelite material was machined for calibration purposes. An illustration of the completed model and the calibration bar is shown in Fig. 4.

The model was mounted in the photoelastic polariscope in the machine-design laboratory of the mechanical-engineering department, Institute of Technology, University of Minnesota. This polariscope,[3] shown schematically in Fig. 5, is the conventional transmission type of prism polarizer but is unusual in detail and size, having a 7-in-diam light field and a length of 18 ft. The light source is a mercury-vapor lamp used in conjunction with a Wratten 77A filter which transmits green light with a wave length of 5460 A. Thus the light emerging from the filter is monochromatic. The water cell is employed to cool the light rays, the heat of which would otherwise affect the polarizing prism. The axes of the polarizer and analyzer prisms are set at right angles to each other so that the plane-polarized light leaving the former will not be transmitted by the latter. If the bakelite model is placed in the light path between the two prisms and stressed, it becomes doubly refracting which causes bands of light to pass through the analyzer prism. Thus the construction of the model and the degree to which it is stressed determine the pattern of the fringes or stress bands from which an analysis of the stresses existing in the prototype can be made.

A triple-lever system, Fig. 6, supported on knife-edges loaded the three blades equally in the stressing frame. The spindle element, in one piece, was fastened to the top of the frame. Rigid supports prevented lateral movement of the sides. A view of the assembly in the polariscope is shown in Fig. 7.

Test Procedure

In order to determine the optical constants of the bakelite, a calibration bar of rectangular cross section was placed in the loading frame of the polariscope and subjected to pure bending. This resulted in the fringe pattern shown in Fig. 8. As the load applied to the calibration bar was known, the stress at its outer edge was easily determined. From Fig. 8, it was observed that there were five fringes from the neutral axis to either edge of the calibration bar. Thus, for the particular bakelite material of which the model was made, the increment stress per fringe was equal to the stress as determined by the foregoing means divided by five. These fringes are lines representing constant difference of the principal stresses $(P - Q)$ at any point.

The principal stresses are of particular importance in the photoelastic analysis of stress in models. Given a rectangular plate of unit thickness oriented in the x and y coordinate directions

with distributed forces along the sides as shown in Fig. 9 (*a*), the direct stresses P and Q are the maximum and minimum stresses, respectively, that may exist in the plate, and are therefore called the principal stresses. If the plate is rotated an angle θ with respect to the coordinate axes, as shown in Fig. 9 (*b*), other stresses normal to sections along the coordinate axes are found to exist. The resulting stress normal to the x-axis would be N_y, and normal to the y-axis would be N_x. Shearing stresses along both axes would have the value S_{xy}.

The coordinate stresses N_y and N_x change in value during rotation of the plate, as indicated by the dashed lines, approaching stresses P and Q at coincidence of the axes. The shearing stresses S_{xy} are zero in the direction of the principal stresses, Fig. 9 (*a*), and vary as the function sin 2 θ, Fig. 9 (*b*), where for $\theta = 45$ deg, they are maximum and equal to one half the difference of the principal stresses.

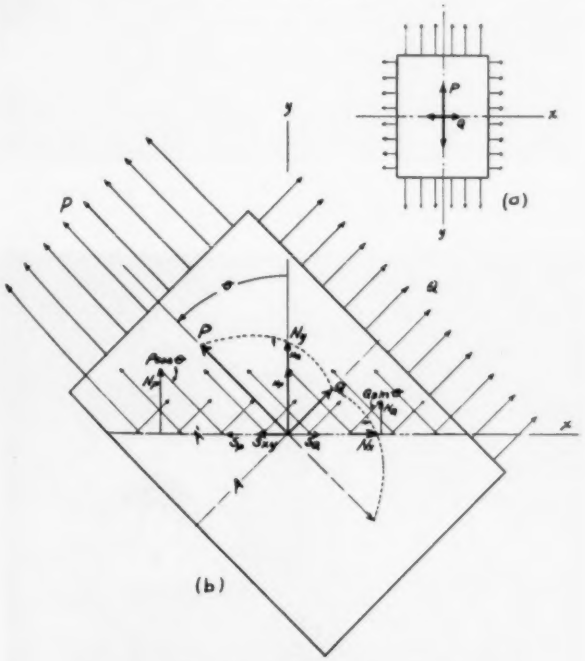

FIG. 9 DEMONSTRATION OF PRINCIPAL STRESSES

Principal stresses exist at every point in a stressed body. In the photoelastic analysis of suitable transparent materials, polarized light establishes interference bands or fringes which are proportional to the difference in value between the principal

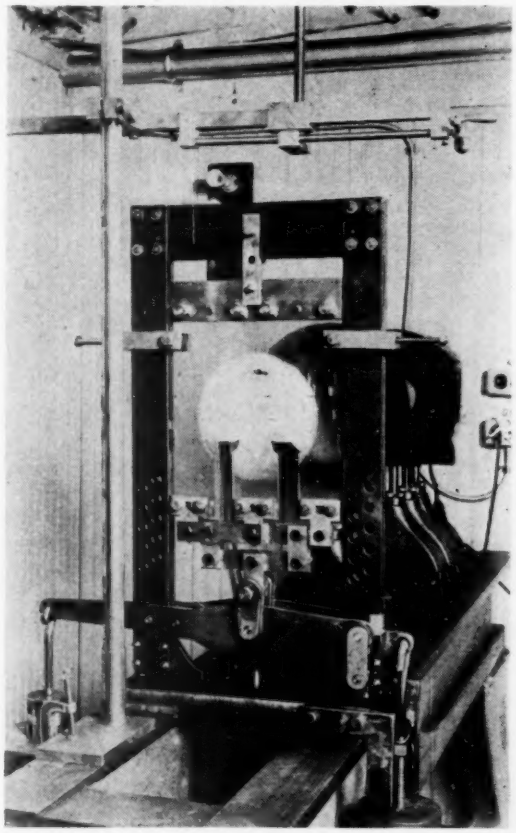

FIG. 7 BLADE-MODEL ASSEMBLY IN FRAME ON POLARISCOPE

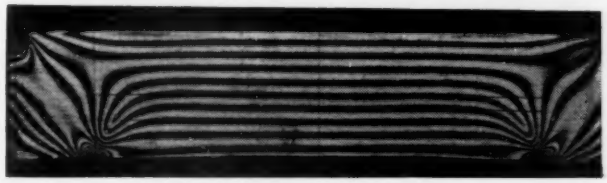

FIG. 8 FRINGE PATTERN RESULTING FROM PURE-BEND TEST ON CALIBRATION BAR

stresses, denoted figuratively as $P - Q$. An adjustment in the polarized condition of the light further obtains values of the angle θ, thus determining directions of the principal stresses.

To calculate the value of the individual principal stresses P and Q, with the difference known at any point, the sum of the principal stresses $P + Q$ must be obtained. This is usually accomplished by measuring the change in thickness at the same points on the photoelastic model, since the sum of the principal stresses is proportional to the change in thickness.

This change in thickness, due to application of load to the cali-

bration bar, was measured by a Huggenberger extensometer.[4] The extensometer, shown in Fig. 10, has a magnification of 1206 and is read to 0.01 unit. Thus the stress at the outer edge of the calibration bar divided by the number of units change in thickness under load represented the stress per unit change in thickness. A compression at a point was measured as negative thickness change, and tension a plus change. From the change-of-thickness readings, the calibration for the sum of the principal stresses $(P + Q)$ was thus determined.

[4] "Fatigue of Shafts at Fitted Members, With a Related Photoelastic Analysis," by R. E. Peterson and A. M. Wahl, *Journal of Applied Mechanics*, Trans. A.S.M.E., March, 1935.

After these necessary measurements on the calibration bar had been made, the actual model was put under a light load to determine the points of contact on the steps of the root elements. It was necessary, first, to obtain symmetrical patterns of stress at the several sections, so that comparative data would be obtained and, second, to eliminate surface roughness at regions where stress concentrations of no general importance existed. As little additional fitting as possible was performed on the model since at higher loads inequalities would tend to adjust themselves.

The model was considered satisfactory when at very light loads indications of stress were shown at all the contact surfaces and at heavy loads the stress pattern was adequately symmetrical.

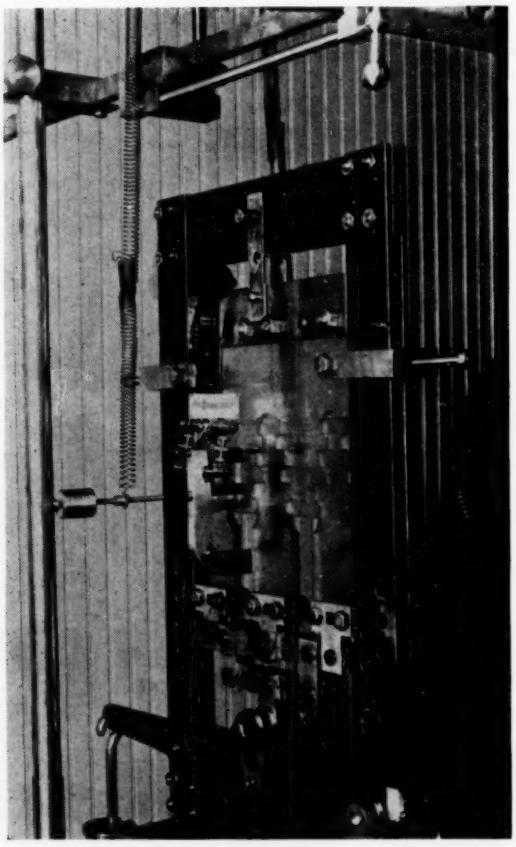

FIG. 10 EXTENSOMETER IN USE ON MODEL

FIG. 12 ISOCHROMATIC PHOTOGRAPH OF STRESS DISTRIBUTION IN MODEL UNDER 780-LB LOAD

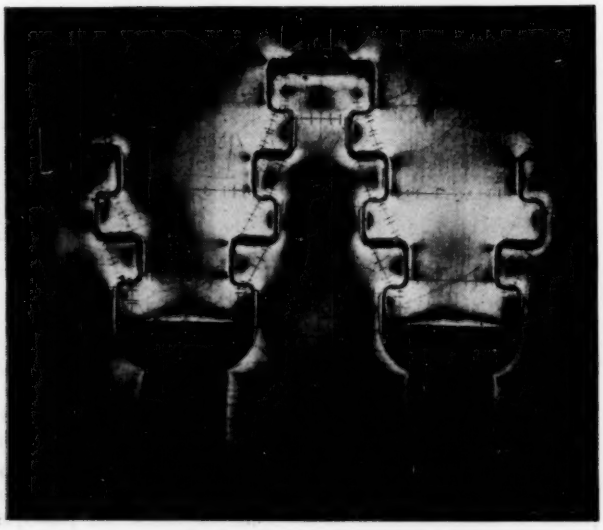

FIG. 11 PHOTOELASTIC PHOTOGRAPH OF MODEL UNDER LIGHT LOAD

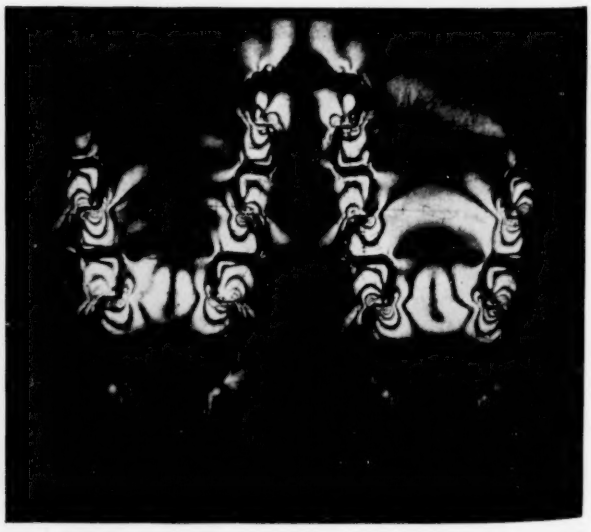

FIG. 13 PHOTOGRAPH OF 0-DEG ISOCLINICS; FULL LOAD

Lines, from points of tangency of the fillets, were scribed on the model at the sections of maximum stress and crossmarks were located at intervals to establish absolute positions.

The stressing frame was adjusted to support freely a live weight of 38.76 lb, the loading mechanism having a magnification of 20. The weight was suspended on a lever for ease in relieving and applying the load during the tests.

The photoelastic or isochromatic photograph of the model under light load is reproduced in Fig. 11. The stress distribution in the model with a force of 780 lb is given on the isochromatic photograph Fig. 12. From this illustration the difference of the principal stresses and the values of maximum shear are determined.

For complete stress analysis it is necessary to determine the isoclinics in the model. An isoclinic is a line which represents the locus of all points in the model having principal stresses in the same directions. To find the isoclinics, the quarter-wave plates were removed from the optical system and the prisms rotated together for given angular intervals. Isoclinic photographs were made for angles of 0, 15, 30, and 45 deg. Fig. 13 shows a photograph of the 0-deg isoclinics.

The method for finding the values of the principal stresses occurring at any point will now be described. To determine the number or order of the fringe, at the particular point where the stresses are desired, the fringes that cross this point as load is applied are counted progressively. This number is multiplied by the stress per fringe as found from the calibration bar, and the value obtained is the difference of the principal stresses $(P - Q)$. The maximum shear at this point is $(P - Q)/2$ and thus can be obtained immediately. The number of units change in thickness at the point, measured by the extensometer as shown in Fig. 10, multiplied by the stress per unit change in thickness, as obtained from the calibration bar, determines the sum of the principal stresses $(P + Q)$. The individual values of P and Q can be found by solving simultaneously. P and Q are principal stresses. To find the coordinate stresses, a Mohr diagram must be plotted as shown in Fig. 14. The angle 2θ is twice the angle which is represented by the isoclinic occurring at the given point in the model.

A sketch of the central root element is given in Fig. 15, showing the sections at which the thickness measurements were made. Complete stress data were then determined for the fourteen sections listed.

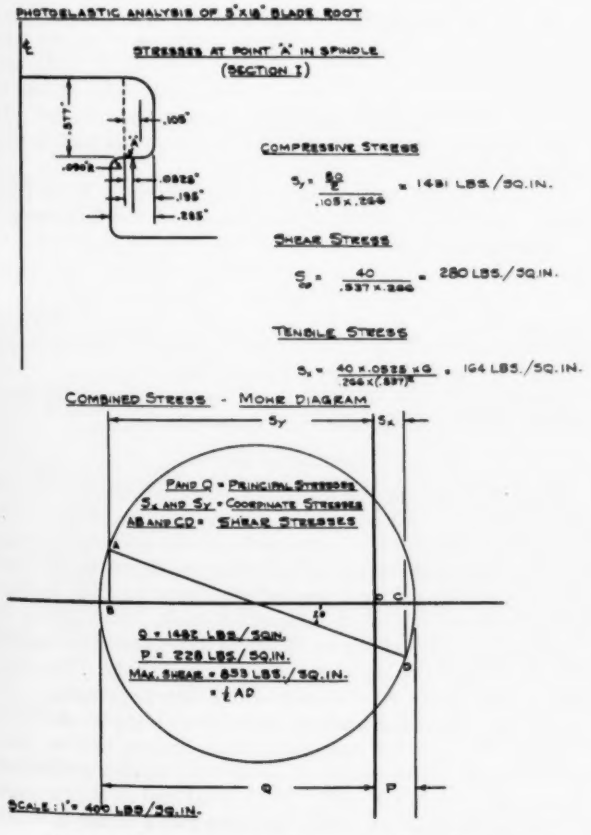

FIG. 14 CALCULATION OF STRESSES IN STEP SECTIONS

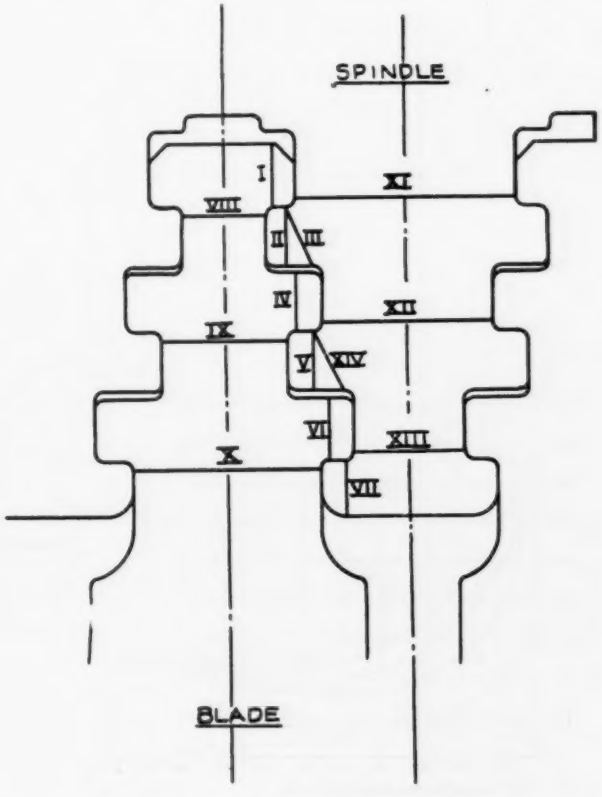

FIG. 15 LOCATION OF ROOT SECTIONS TESTED

Test Data and Curves

The tests of the calibration bar for bakelite material 0.226 in. thick established values of 324 lb per sq in. for each photoelastic band or fringe; and 64.8 lb per sq in. for each 0.01-division change in thickness measured by the extensometer.

The investigation of stress distribution in the model was conducted on three primary cross sections. In Fig. 15, sections I to VII, excluding section III, were analyzed to determine combined stresses on the loaded steps; sections VIII to XIII were considered to ascertain the neck loadings on the step series and the concentrations at the edge fillets; and sections III and XIV were studied to observe the effect of the change in section with respect to the transmitted load.

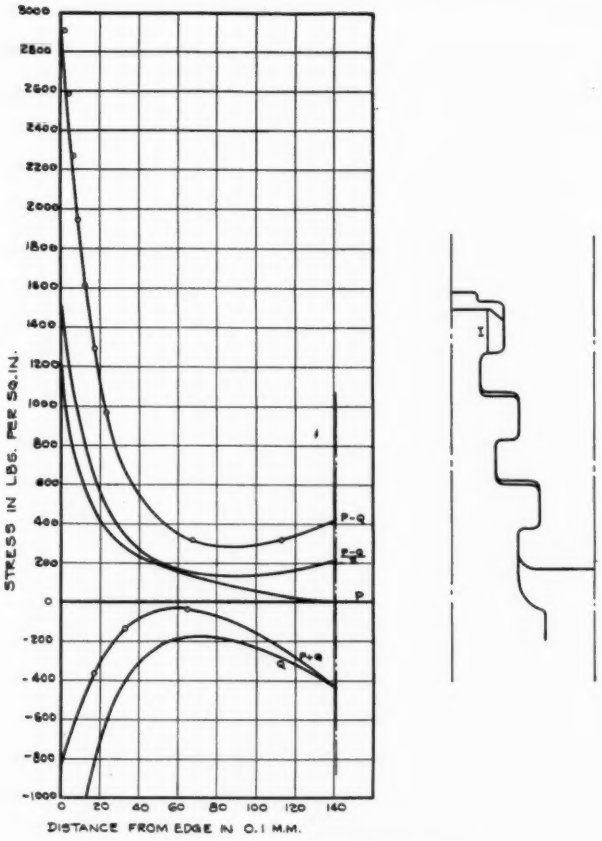

Fig. 16 Stress Curves for Section I

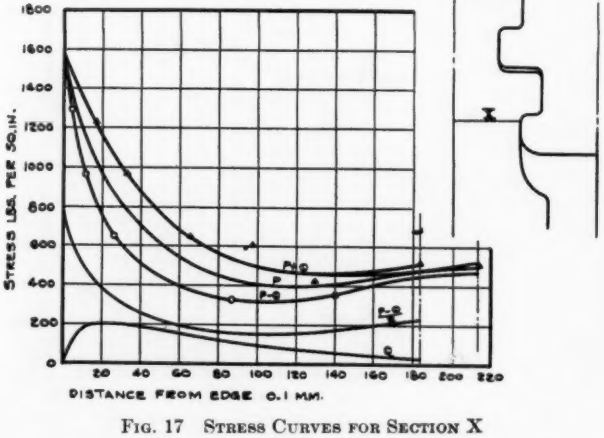

Fig. 17 Stress Curves for Section X

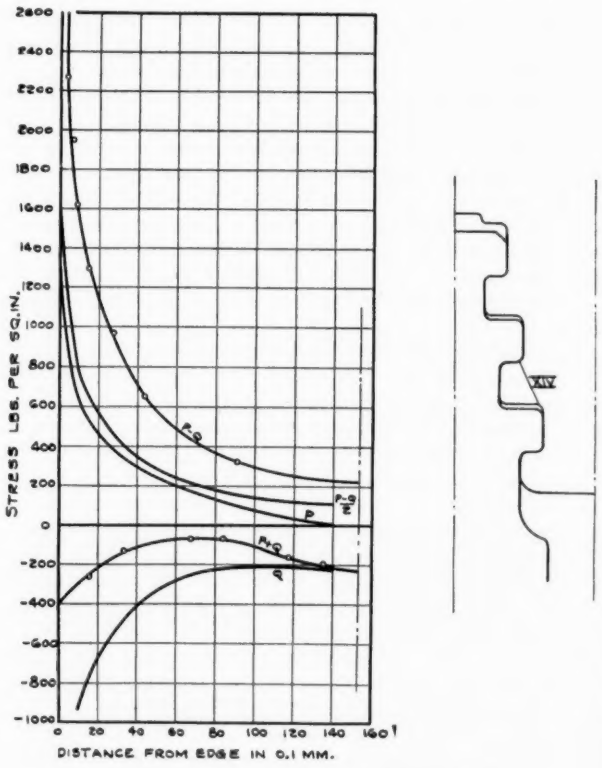

Fig. 18 Stress Curves for Section XIV

Examples of the original test data are given in Table 1 for sections I, X, and XIV. Measurements of the isochromatic photographs were made with a Brinell microscope adjusted to read in 0.1-mm divisions. The photoelastic data give the equivalent stress for the measured number of bands in units of 0.1 mm distance from the active fillets. The changes in thickness data were taken at the cross-marked points and converted into stress, with the same distance units as above.

Curves in Figs. 16, 17, and 18 are representative of the three primary sections I, X, and XIV, respectively.

Results of Tests

The first factor in the analysis of the test results was the investigation of the loads on the step sections in contact. The principal tensile stresses in the necks of the blade and spindle sections, largely in the vertical direction as shown by the zero isoclinics in Fig. 13, were integrated to determine the average stresses and the equivalent transmitted loads. Figs. 19 and 20 present a summary of the tensile-stress distributions in sections VIII to XIII of the blade and spindle, respectively. The areas under these curves were converted into average stresses, total loads, and differential loads at the various steps as shown in Table 2. Further, the maximum tensile stresses, and the ratio of the maximum-to-average stresses and the stress-concentration factors are given in the table. For a total load on the specimen of 780 lb, the load per blade would be 780/3 = 260 lb, which value was approached very closely by the stress analysis.

TABLE 2 FORCES AND TENSILE STRESSES IN NECK SECTIONS

							Avg	2.80

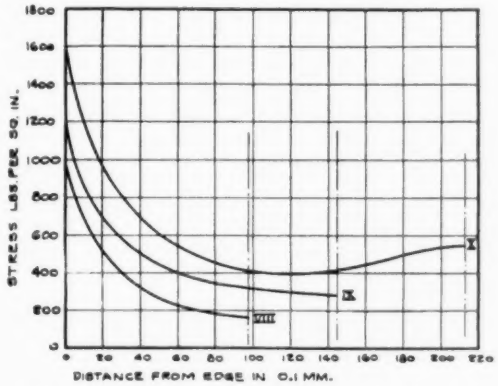

FIG. 19 TENSILE STRESSES IN NECKS OF BLADE

The theoretical calculation of stresses in the blade root and spindle is based upon the assumption of equal elongations between adjacent steps in contact. Thus, in Fig. 21, the elongation between surfaces A and B in the blade root is equal to the corresponding elongation in the spindle. A similar situation is observed between surfaces B and C. Thus, if loads P_A, P_B, and P_C are applied at the contact surfaces of the blade and spindle, certain elongations result. The relative values of the forces which create these elongations may be approximated from the root and slot dimensions. Given

$$e = \frac{PL}{AE} \qquad [1]$$

where e = elongation, in. per in.
P = load, lb
L = length between sections, in.
A = effective area, sq in.
E = modulus of elasticity, lb per sq in.

from Fig. 21, the elongations of the various elements are as follows:

$$\left.\begin{aligned} e_1 &= \frac{(B+C)\,0.561}{1.405E} & e_3 &= \frac{C \times 0.561}{0.938E} \\ e_2 &= \frac{(B+C)\,0.564}{1.125E} & e_4 &= \frac{C \times 0.564}{0.750E} \\ e_7 &= \frac{A \times 0.564}{1.17E} & e_9 &= \frac{(A+B)\,0.564}{1.731E} \\ e_8 &= \frac{A \times 0.561}{1.45E} & e_{10} &= \frac{(A+B)\,0.561}{1.92E} \end{aligned}\right\} \qquad [2]$$

$$\left.\begin{aligned} \text{Setting } e_1 + e_2 &= e_7 + e_8 \\ e_3 + e_4 &= e_9 + e_{10} \end{aligned}\right\} \qquad [3]$$

and solving, the following relationships are found

$$\left.\begin{aligned} B &= 0.351A \\ C &= 0.615A \end{aligned}\right\} \qquad [4]$$

TABLE 3 STEP LOADING

Totals	255	100.0	255	100.0

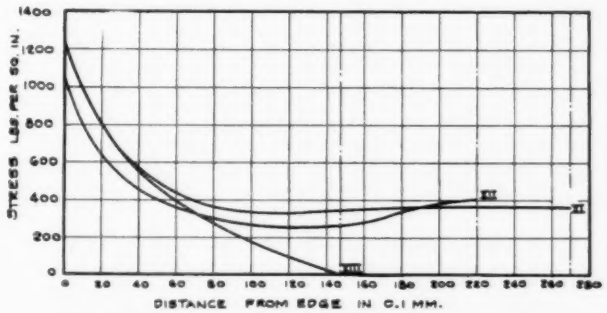

FIG. 20 TENSILE STRESSES IN NECKS OF SPINDLE

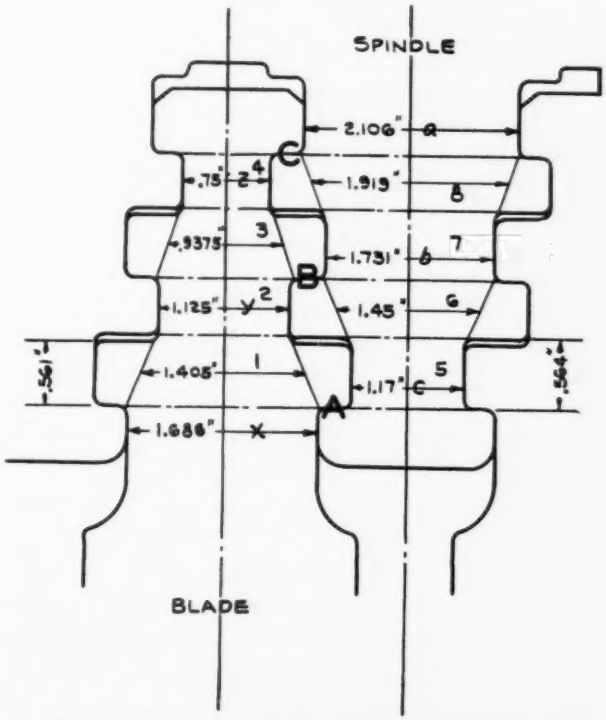

FIG. 21 DRAWING OF ROOT SECTIONS AS CALCULATED

From Table 3, it is observed that the measured average differential load carried by the first step at section X, and in the spindle at section XIII, designated in Fig. 21 as surface A, is 120 lb. Table 3 is then representative of the calculated loading, Equations [4], and the test data, with the percentage of total load carried on each section.

The determination of the loading on surfaces A, B, and C, Fig. 21, makes possible a comparison of calculated stresses with

test stresses on the step sections. Considering the average test loads on the three sections, combined tension, compression, and shear stresses may be calculated by standard equations or Mohr diagrams. A sample calculation for section I is shown in Fig. 14. It is assumed that the bending-moment load is concentrated at the middle of the contact section, while the compression and shear are uniformly distributed over their respective areas. In Table 4, the sections, loads, maximum principal stresses, and shear from test are tabulated with comparative values from calculations. For maximum shear the ratios of the test values and the calculated values determine the stress-concentration factors for the sections.

TABLE 4 STRESSES IN STEP SECTIONS

VII	Test	121	1750	−2750	2250	..
VII	Calc	130	370	−2410	1385	1.63
					Avg	1.70

The stress distributions for sections III and XIV are useful for comparison with the vertical sections in that the stress characteristics are influenced by the neck stresses at the change in width of the root elements. The maximum stresses are the same as for the vertical sections, but the curves for section XIV, Fig. 18, indicate higher average stresses.

Comparison of Blade and Spindle Stresses

The maximum tensile stresses in the blade root and spindle occur at the sections carrying the total load. At section X in the blade, Fig. 15, the average stress was 576 lb per sq in. (Table 2) and the maximum stress was 1600 lb per sq in.; at section XI in the spindle the average stress was 455 lb per sq in. and the maximum 1260 lb per sq in. Thus, in the model, the blade stress was 27 per cent higher than that in the spindle. The radii of the fillets are uniformly 0.090 in.

However, at the step sections, the greatest force on the contact surfaces occurs at section A. From Table 4, section VI in the blade has principal stresses of 1550 lb per sq in. tension, 2450 lb per sq in. compression, and 2000 lb per sq in. shear; while section VII in the spindle has stresses of 1750 lb per sq in. tension, 2750 lb per sq in. compression, and 2250 lb per sq in. shear. These sections are at the largest part of the blade and the smallest section of the spindle, respectively, and carry a load nearly equal to $^1/_2$ the total load. Thus the maximum stress in the spindle-step section is slightly higher than in the blade at this point.

In general, the maximum principal stresses in tension are the same for the neck and step sections in corresponding regions. However, the compressive stresses on the bearing surfaces of the steps are relatively high and therefore the combined shearing stresses are also high.

For the step sections, II and IV have about the same stress distribution, with sections V, VI, and VII, progressively higher in stress. Sections I and V have similar stresses. The maximum stresses (and loads) are carried in sections VI and VII.

Conclusions

In the model, the dimensions of the step sections for the blade and spindle were the same, whereas the neck depths for the blade were less than those of the spindle. This design was considered in order to take advantage, in the actual steam turbine, of a stronger material in the blades. However, as is observed from a summary of tests and calculations given in Table 5, columns 1 and 2, it is very difficult to favor one element and increase the stresses in the other without an unsymmetrical design with regard to both necks and steps. Thus it was necessary to adopt a design with equal necks and steps, resulting in equal loads on each step.

TABLE 5 COMPARATIVE DESIGNS OF BLADE ROOTS

Column	Test 1	Calculations 2	3	4
	Photo-elastic data	Original data	Equal loads, original step surfaces	Equal loads, increased step surfaces
Load, lb				
A	120	130	85	85
B	60	45	85	85
C	75	80	85	85
Dimensions blade, in. x	1.686	1.686	2.142	2.00
Dimensions blade, in. y	1.125	1.125	1.428	1.34
Dimensions blade, in. z	0.75	0.75	0.714	0.68
Spindle a	2.106	2.106	2.142	2.00
Spindle b	1.731	1.731	1.428	1.34
Spindle c	1.17	1.17	0.714	0.68
$a + z = c + x = b + y$	2.856	2.856	2.856	2.68
Step surface width, in.	0.105	0.105	0.105	0.198
Max principal tensile stress necks, lb per sq in.	1600	1730	1290	1350
Max principal compressive stress on steps, lb per sq in.	2750	2410	1575	860
Max combined shearing stress in steps, lb per sq in.	2250	2250	1540	1250

With equal loads on the step sections A, B, and C, it is necessary that the middle neck sections be equal, and the maximum and minimum sections are $^3/_2$ and $^1/_2$ of the mid-section, respectively. For the same depth of step section as on the model, these dimensions and stresses are computed and shown in Table 5, column 3.

An increase of the surface area at the step contact from 0.105 in. to 0.198 in. would produce smaller neck sections but considerably reduced compression stresses. Equal loads on the steps with balanced neck sections under this condition would give dimensions and stresses shown in Table 5, column 4.

It may be concluded from the foregoing that good agreement exists between calculated and test data. This relationship is established by the concentration factors of 2.80 for the tensile stresses in the neck sections, and 1.70 for the maximum shear stresses in the step sections. These factors agree closely with those of 2.76 and 2.16, respectively, obtained from a photoelastic test of a single T-tail root[3] of an alternator pole connector.

For increased blade loading of future designs, comparative dimensions are obtainable by the calculation methods and concentration factors suggested.

Acknowledgment

This problem was suggested by the steam-turbine department of the Allis-Chalmers Manufacturing Company, and the work was carried on through research and regularly scheduled classes in the mechanical-engineering department with grants from the Graduate School of the University of Minnesota.

Discussion

Stephen Bencze.[5] The authors have presented an interesting analysis of the stresses and stress-concentration factors in one particular steam-turbine blade root of the multiple-step type. However, this analysis is of little value to the turbine-design field, since it deals with one particular case only. Then, too, certain factors influencing the problem have been disregarded.

In Table 2, the authors list stress-concentration factors at various sections of both the blade root and the turbine spindle but make no mention of the conditions for which these factors are valid. It is a fact that stress-concentration factors for re-entrant fillets are influenced by such factors as fillet ratio

[5] Turbine Department, Elliott Company, Jeannette, Pa.

(ratio of fillet radius to neck width), ratio of neck width to flange width, and the ratio of flange width to flange depth. The authors do not give root dimensions and so it is impossible to arrive at the values of geometric ratios for which the reported stress-concentration factors have been determined.

In Fig. 14, a fillet radius of 0.090 in. is shown. Assuming this value to be constant for the various root and spindle sections analyzed, approximate values of fillet ratios for the reported conditions are shown in Table 6 of this discussion. The stress factors, also listed in this table, have been calculated from conditions reported by Timoshenko and Dietz.[6]

TABLE 6 APPROXIMATE VALUES OF FILLET RATIOS

Section no.	Section width, in.	Fillet ratio	Calculated stress-concentration factors
VIII	0.750	0.120	2.73
IX	1.125	0.080	3.45
X	1.680	0.054	4.49
XI	2.080	0.043	5.30
XII	1.700	0.053	4.55
XIII	1.140	0.079	3.48

M. Hetényi[7] reports minimum stress-concentration factors for T-heads for fillet ratios of 0.075 of approximately 3.50, which agrees very well with factors reported by Timoshenko and Dietz. However, factors reported by the authors are considerably lower than any of these.

M. Hetényi.[8] In any particular problem the amount of stress concentration depends upon the geometrical proportions of the sample. For this reason it is customary to discuss concentration factors as functions of the R/d fillet ratios, denoting by R the fillet radius and by d the diameter of the net section under consideration.

The authors, when listing in Table 2 the concentration factors obtained in 6 different sections of the root and spindle, have omitted to indicate the R/d ratios for each of these sections. Since it is stated in the paper that the radii of the fillets were uniformly 0.090 in. and, on the other hand, the d values of the sections are shown in Fig. 21, the R/d ratios can be readily computed. Doing this we find that for sections VIII–XIII the R/d values vary between the limits of 0.043 and 0.120. It is difficult to see what was the authors' justification in taking an average value of the concentration factors obtained in 6 different sections of so widely varying proportions and to suggest this average value $k = 2.80$ for design purposes.

In order to compare the magnitude of the authors' concentration factors with existing data, let us take for example the T-head ending of the spindle (section XIII) where the fillet ratio is $R/d = 0.090/1.170 = 0.0769$. It is known that even a simple tension member with such a fillet ratio can give a concentration factor $k = 2.7$ and this does not yet take into account some particular conditions existing in T-heads, namely, the proximity of the points of supports to the fillets, the shearing and bending action on the flanges of the head, which all tend to increase the concentration of the stress at the fillets. These latter effects naturally will depend upon the geometrical proportions of the head. Assuming that Fig. 15 of the paper was drawn to scale, we find that the proportions of the T-head ending of the spindle are approximately $D/d = 1.5$ and $h/d = 0.5$ where D is the width and h is the depth of the head. For such proportions and for $R/d = 0.075$ the writer obtained a concentration factor of 6.85, referring the maximum fillet stress to the average tensile stress in the neck section. This high value can be traced back to the additional stress sources existing in any T-head fastening.[7] This factor is more than twice as large as the one obtained by the authors for similar proportions. The writer agrees that the stress condition in a simple T-head is not quite identical with the one existing in the T-ending of a multistep spindle. Minor variations, however, could hardly account for the great difference found in this comparison and it is believed that the concentration factors of the authors are too low.

Though it is aside from the main topic of the paper it seems desirable to call attention to the fact that the dashed curve in Fig. 9 should be an ellipse, which is not apparent from the figure.

Authors' Closure

The question of stress concentration is of vital importance in the design of machines, and the authors welcome the discussion contributed by Stephen Bencze and M. Hetényi.

It is quite evident that the stress-concentration factors obtained at the neck sections from the scale model of the machine are not in harmony with the idealized investigation. This is shown in the respective photoelastic illustrations of stress distribution, Figs. 11 and 12 in the paper[7] by Hetényi, and in Fig. 12 of the authors' paper. For the model of the multiple root, the maximum stresses were not found to be concentric about the fillet arc, but were displaced toward the end of the fillet at the contact surface.

The difference between the photoelastic illustrations, exhibited as representative, indicates that the structures or their loadings are not equivalent. In the multiple-root model, all contacting surfaces were of the same material and mating steps were relatively symmetrical. Upon inquiry as to the method of loading and the type of materials in contact for the idealized investigation,[7] Dr. Hetényi advised us that thin cork strips were placed under the supports along the flanges to obtain uniform loading, but did not indicate the construction of the support mechanism.

Based on this information, it may be stated that, in the latter experiments, a particular type of distributed pressure was applied to the T-heads; while in the case of the multiple root, the pressure distribution on the contact surfaces, although not investigated, is presumably determined by the distortion of the mating elements.

The authors are of the opinion that the major part of the apparent discrepancy between the factors given in the paper and those of Hetényi is due to this difference in loading.

It is to be observed, however, that from the complete picture of stress distribution in the complex multiple-root model the stress concentrations which determine the design are those produced by the high contact pressures.

Permanence of the Physical Properties of Plastics

By J. DELMONTE,[1] CHICAGO, ILL.

Plastic materials are subject to certain changes in physical properties during their various applications. Particularly significant are the creep and cold-flow phenomena. In the paper a general equation is developed expressing plastic-deformation rate as a function of a coefficient of viscous resistance and of a coefficient of internal resistance. Data for laminated phenolics, polyvinyl chloride acetate, methyl methacrylate, polystyrene, and cellulose acetate are compared. Experimental evidence is presented to show that after a sufficient length of time plastic deformation assumes a constant rate, continuing indefinitely. The dual nature of the molecular structure of plastics is emphasized, in which true elastic deformation may occur, as well as a time-dependent plastic deformation, even at very low stresses. Further data are presented on the shrinkage of various plastics after exposure to elevated temperatures, and the swelling of these materials after exposure to high humidity or water immersion. Loss in impact strength upon exposure to high temperatures is also disclosed for laminated phenolics.

IN THE examination of the permanence of the physical properties of organic plastic materials, attention should be given to those operating conditions which are likely to produce changes in the materials. When these operating or service conditions have been analyzed, they should serve as the basis of comparison for the various plastics. As engineering materials, one of the most singular characteristics of organic plastics is their response to thermal influences. In fact, they are generally classified as thermoplastic or thermosetting, distinguishing between materials which are profoundly influenced by heat and those which are only slightly affected.

Another characteristic of plastics which has a decided influence upon the design and application of the materials is their behavior under applied stresses. A review of technical literature indicates that with few exceptions, very few factual data useful for engineering purposes are available on the creep and cold-flow characteristics of the various plastics. Variations in test methods; examinations confined to one material; failure to stress the material for a sufficient length of time; and failure to report fully the nature of the molecular structure, composition, or previous history of the material, are some of the reasons detracting from the value of the research. Plastic materials, more so than many other materials of construction, are subject to permanent deformation under stress and, hence, require systematic analysis along these channels.

The media in which the plastic materials are operating may also have a bearing upon their properties. Particularly noteworthy are such influences as the actinic rays of sunlight, high humidity, and the corrosive effects of chemicals, any of which may cause a loss in utility of the material. When the material is to be used in a severe corrosive medium, tests in that specific medium under the most rigid operating conditions are usually conducted by the organization contemplating use of the material. Only in that manner can it be ascertained whether the material will prove acceptable.

Consequently, in examining the permanence of the physical properties of plastics, the following tests may be pursued to evaluate the relative merits of the plastics:

1 Creep and cold-flow tests at various stresses and at various temperatures, for different lengths of time. Recovery upon removal of stress also to be observed.

2 Organic plastics at elevated temperatures:

(*a*) Properties of the plastics at these temperatures.

(*b*) Properties of the plastics after return to room temperature; after exposures for different periods of time.

3 Effect of immersion in water or high humidity upon the properties of organic plastics (or in lieu of water, the use of corrosive chemicals).

Creep and Cold-Flow Characteristics

In this paper, an analysis will be made of the creep and cold-flow characteristics of solid plastic materials, as they are available commercially, in sheet form. The need for data of this nature has been emphasized in recent years (1, 2).[2] Standard compression and tension tests must be modified to take into consideration time and temperature, for organic plastics, besides exhibiting elastic deformation, exhibit a time-dependent plastic deformation. There has been some doubt as to when plastic deformation first begins to make its appearance, when the stress is slowly applied to the material. It has been suggested recently by R. Houwink that for solid organic plastics, every stress will produce a certain amount of plastic deformation (3). The results of the present investigation show this to be the case for a number of plastic materials, even down to very low values of stress.

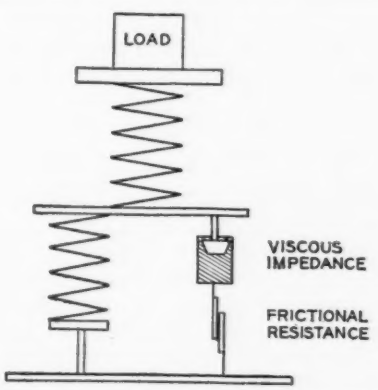

Fig. 1 Mechanical Analogy of Molecular Structure of Plastic Material

[1] Assistant to Chief Engineer of Research, Chicago Flexible Shaft Company. Jun. A.S.M.E.

Contributed by the Rubber and Plastics Subdivision of the Process Industries Division and presented at the Annual Meeting, Philadelphia, Pa., December 4–8, 1939, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

A convenient mechanical analogy of the structure of a typical plastic material is given in Fig. 1, based in part upon conclusions arrived at in this paper. Under constant load, this mechanical analogy presupposes the following to take place:

1 Upon placing the material under stress, there follows immediately a very rapid elastic deformation.

2 This is followed by a plastic deformation which depends upon the stress, temperature, and the time of application.

3 Under the continued application of load, the velocity of this plastic deformation will change with time. The internal structural elements contributing to this deformation characteristic are depicted in the mechanical analogy as possessing internal friction (as sliding friction between adjacent long chain molecules), and as possessing an inertia effect, depending upon the rate of change of deformation velocity (illustrated as a dashpot and cylinder).

4 Upon removal of the load, there is a rapid, immediate elastic recovery, followed by a relaxation period in which further recovery from deformation occurs, depending upon the manner in which the material was stressed.

5 Another condition, not apparent from the mechanical analogy of the internal structure, admits the possibility that the elastic structure can be deformed past its elastic limit, besides the plastic deformation exhibited by those elements not part of the main elastic structure.

The majority of these conditions has been recognized in previous studies (3, 4). A mechanical analogy for plastic materials employing the same elements, shown in Fig. 1, has also been suggested (5), though in an entirely different arrangement.

It is not entirely unexpected that new interpretations are necessary for such constants as elastic limit, yield value, proportional limit, and modulus of elasticity for materials possessing an internal structure capable of elastic and plastic deformation. Most stress formulas for beams and other structural members are developed for materials operating strictly upon the elastic portion of their stress-strain characteristics. It is obvious that these formulas must be modified when the permanency of the physical properties is a function of the material, its temperature, and time duration of stress. The creep and cold-flow data disclosed in this paper have been confined to a study of the influence of time under constant temperature conditions. Further studies are in progress to examine systematically the effects of temperature.

Researches in Plastic Deformation

Method. Many of the researches upon the plastic deformation of amorphous materials have employed methods designed to give uniform tensile or compressive stresses within the test materials, under uniform loading conditions. For example, some tests compare plastic materials on the basis of per cent change in height of a small cube of specimen under a predetermined load at 120 F, over a period of 24 hr (6, 7). This technique is also employed in the mechanical testing of rubber, where dead weights are applied for certain periods of time on rubber samples (8, 9). Other methods quite common employ ball-and-needle penetrometer techniques under certain loads at certain temperatures, for various time intervals. It has been the author's experience that such methods are particularly adaptable to materials which exhibit relatively large deformation for a given tensile or compressive stress. These materials would include those plastics which have been described as possessing rubber-like qualities such as plasticized polyvinyl acetals, plasticized polyvinyl chlorides, rubber-like alkyds, certain acrylic resins, etc. For example, under a constant tensile stress of 41 lb per sq in. at 85 F, the time-deformation characteristics of polyvinyl acetal are shown in Fig. 2. This material has also been examined for changes in its photoelastic qualities under similar test conditions (10). However, when the more solid materials of this investigation were examined under direct tension and compression, the time for appreciable plastic deformation to take place was very long, lessening the accuracy of the readings, and making it difficult to distinguish the various stages of plastic deformation.

Another procedure followed in observing creep phenomena is to load and unload materials within the proportional limit of the stress-strain curve (11, 28), measuring the creep as a function of the elastic-hysteresis loop. Of course this technique is important also in determining Poisson's ratio. However, this method does not permit a study of the effects of time duration of stress which is so highly important to plastic deformation, and is not readily adapted to the study of recovery phenomena, such as the elastic aftereffect.

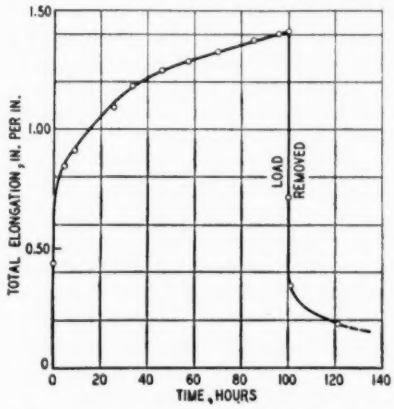

Fig. 2 Time-Deflection Curve for Polyvinyl Acetal

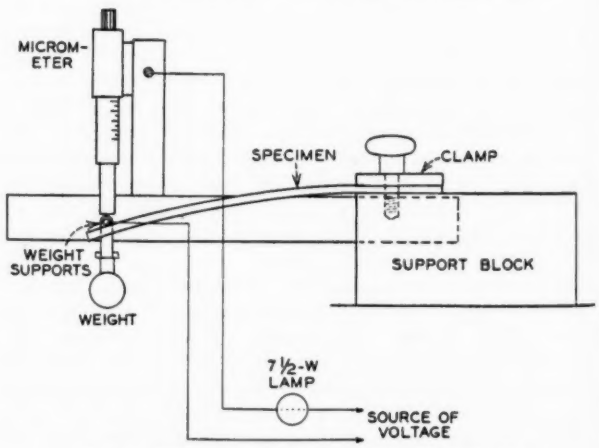

Fig. 3 Schematic Diagram of Test Apparatus

In this investigation samples of the plastic materials were supported as simple cantilever beams and loaded by dead weights at the end, Fig. 3. The apparatus designed by the writer tested four samples simultaneously, making it possible to observe materials under four different maximum fiber stresses during the same period of time. The equipment was enclosed within an insulated chamber, thermostatically controlled with air circulation, to 85 F plus or minus 2 F. Four micrometers attached solidly to the support block measured the end deflection of the specimens by electrical contact with the support for the weights, and completing the circuit with a 7.5 lamp placed in series. The micrometers were operated manually when readings were to be taken. The load applied by spring-actuated dial gages was too great to permit using them in these tests. The supports for the weights

were reduced to a minimum, weighing only 4 g. The micrometers were read when contact was made with the weight support, which was indicated by the lighting of the lamp. The readings were accurate to plus or minus 0.0003 in. The specimens were retained at their ends by 1/8-in. steel pieces, clamped down by two thumbscrews. In making stress calculations, the weights of the supports for the loads and the weight of the specimens were taken into consideration. Electrical connection to the weight supports was made through a fine, B.S. No. 34 enameled wire.

While the values of deformation observed are in fact an integrated value for all stresses up to the maximum fiber stress, a simple cantilever beam affords a simple method of ascertaining the elastic and plastic properties of materials. The simple cantilever beam has an advantage over other types of beams, inasmuch as its moment diagram for loads at the end is a straight-line function of the suspended length, and also possesses a uniform shear diagram. It may be readily seen that the simple cantilever beam by reason of its deflection at the end, acts as an amplifier of stress deformation in its fibers, in a ratio of some function of the length to the thickness of the material. There is much precedence for the use of a deflection of a beam as a measure of flow in solid bodies (12, 13, 14, 15). Trouton investigated flow in rods of pitch under the methods of tension, compression, and bending. His curves for sagging as a function of time show a distinct exponential relationship. In a majority of these earlier instances, tests were conducted upon bituminous substances or concrete, whereby the test specimens were placed upon two horizontal supports and deflection observed in the middle under the weight of the specimen or additional weights.

The deflection of a beam also serves as the basis of comparison for plastic materials in a heat-distortion test in an American Society for Testing Materials specification (16) where the temperature is raised slowly and the temperature noted at which a deflection of 10 mils occurs. In a similar British test specification, a simple cantilever test beam is employed to determine what is referred to as "plastic yield." The plastic yield is described as the specified allowable maximum deflection for a 5 × 5-mm specimen, 150 mm long, at a certain temperature (17).

Materials Tested. The following materials were included in this investigation and a comparison made of their relative deformation as a function of time, for various stresses induced in the materials when they were loaded as simple cantilever beams. The specimen lengths were selected at 5 in., with the exception of polystyrene, which was 2.5 in. long. The results of polystyrene were corrected to a 5-in. length. The widths of the specimens were approximately 1 in. and, while an effort was made to obtain uniform thickness, the laminated phenolic and polystyrene samples differed from the others.

Cellulose-acetate sheet: Specimens were cut from clear transparent sheet stock, approximately 0.089 in. thick; obtained from Fiberloid Corporation (now Monsanto Chemicals Company).

Polyvinyl chloride acetate: Specimens cut from a white, filled stock, 0.094 in. thick; obtained from Carbon and Carbide Chemicals Corporation, series V.

Methyl methacrylate: Specimens were cut from clear, transparent stock 0.09 in. thick; material obtained from Röhm and Haas Company.

Polystyrene: A flat injection-molded test bar 0.069 in. thick served as a test sample; obtained from Dow Chemical Company.

Laminated phenolic sheet, canvas base: Standard N.E.M.A. grade L material, 0.065 in. thick, employed in test.

Theory. Within certain stresses, the initial rapid deflection of the simple cantilever-beam test specimens is a truly elastic deformation, the magnitude of the deflection and the maximum fiber stresses being calculable from the following well-known formulas, which assume validity of Hooke's law and uniform distribution of stress-strain relations in compression and tension about the neutral axis

$$y_e(\max) = WL^3/3\,EI \quad [1]$$

and

$$M = SI/c \quad [2]$$

where y_e = true elastic deflection
W = weight supported at end of beam
L = distance from point of support to weight
E = modulus of elasticity
I = moment of inertia
S = maximum fiber stress
M = maximum bending moment = $W \times L$
c = distance from neutral axis to outermost fiber.

Immediately following the truly elastic deformation, the phenomena of creep and cold flow will commence, increasing the amount of deflection. There are two stages of plastic deformation which were observed for the materials under test:

Stage *A*—rate of change of deformation with time (dy/dt) changes from a maximum to a minimum constant rate.

Stage *B*—in which dy/dt remains constant for an indefinite time for a given fiber stress (or given integrated stress value).

Unlike crystalline materials which may work-harden, whereby dy/dt approaches zero, none of the plastics included in this test behaved that way, even at maximum fiber stresses as low as 500 lb per sq in. For the sake of definition, "cold flow" may be described as that constant rate of change of deformation with time, which a material will exhibit after being subjected to a certain stress for a certain period of time, at a constant temperature. In accordance with earlier suggestions,[3] "creep" may be described as that stage of plastic deformation where the velocity of the deformation rate changes with time (d^2y/dt^2). Creep experiences its greatest value following the elastic deformation, becoming zero when true cold flow finally occurs. From the data presented in this paper, it will be seen that considerable time elapses before creep becomes zero, depending upon the maximum initial fiber stress. In general, it was observed that the lower the maximum fiber stress, the sooner creep was terminated and pure cold flow commenced.

The existence of plastic deformation as a separate phenomenon from elastic deformation is brought out in the mechanical analogy given in Fig. 1. This admits the possibility that part of the stress is carried by nonelastic elements, which may also be in parallel with some of the elastic elements. This last consideration is borne out when one considers that the elastic aftereffect upon removal of load derives its energy from an elastic structure which is retarded in its recovery by the plastic elements.

A general expression for plastic deformation may be developed in the light of creep and cold-flow phenomena. Assuming the two stages of deformation for amorphous materials, we have the following

$$y(\text{total}) = y_e + y_p \quad [3]$$

where y_e = elastic deformation
y_p = plastic deformation

The elastic deformation is defined by Hooke's law within the elastic limit of the material

$$y_e = S/C \quad [4]$$

where C = elastic constant
S = stress required to produce y_e.

[3] Reference (3), p. 188.

Expressing y_p as a function of time and stress, the following formula may be applied

$$S = RV + M\frac{dV}{dt} \quad [5]$$

where $$V = dy_p/dt \quad [6]$$

and M = coefficient of viscous impedance

R = coefficient of internal resistance of molecules.

As a solution to Equation [5], we have the following expression for V, which is the rate of plastic deformation with time

$$V = \frac{S}{R}(1 - e^{-Rt/M}) \quad [7]$$

When t becomes very large, V is equal to the cold flow

$$V = S/R \quad [8]$$

Integrating Equation [7], we obtain an expression for the plastic deformation as a function of time

$$y_p = \frac{St}{R} + \frac{SM}{R^2}(1 + e^{-Rt/M}) \quad [9]$$

From the general solution for plastic deformation as a function of time at constant temperature, it is possible to make the necessary corrections in the calculations of beam deflections. This may be done by assuming that this time-deformation function determines the apparent instantaneous value of the modulus of elasticity. Further, for each material there will be a characteristic coefficient of viscous impedance, M, and a coefficient of internal resistance R. These coefficients will be largely determined by the structural characteristics of the molecules, such as the degree of polymerization; method of polymerization; whether a linear or three-dimensional polymer is present; presence of plasticizing agents; influence of fillers; etc. For further discussion on factors influencing flow characteristics of plastics, there are several papers which may be referred to (18, 19, 20). The coefficients mentioned may be calculated from a time-deformation curve at a stress below the elastic limit of the elastic portion of the structure.

The question would naturally arise, in view of the creep and cold-flow characteristics of the plastics, as to what interpretation should be given to the modulus of elasticity. Strictly speaking, it would be made a function of stress, strain, temperature, and time, inasmuch as the exact location of the elastic limit is open to some question. In the bending of beams beyond the proportional limit, Timoshenko has proposed in the well-known formula $M = EI/p$, that E be replaced by E_r, a variable modulus of elasticity to be determined from the stress-strain relationships in a step-by-step method (21).

In spite of the dual nature of the strain characteristics of the plastic materials, whereby one portion of the molecular structure exhibits true elastic deformation, and the other portion is susceptible to plastic deformation even at the smallest stresses (these effects are evenly distributed throughout the structure), we can with justification employ the straight-line portion of the stress-strain relationship to determine the modulus of elasticity under certain circumstances. These conditions demand a short-time loading of the material, and the existence of an elastic deformation considerably in excess of plastic deformation (which was true for most of the materials tested). On the other hand, when time or permanency is a factor, modifications must be made in accordance with the general relationship established for plastic deformation, which is also verified by experimental results of this paper. The necessity for altering the values of the moduli of elasticity has been recognized by other investigators, one proposing a high initial modulus of elasticity for amorphous materials and a low modulus of elasticity after plastic deformation (22). Better yet, the time dependence of the modulus of elasticity should be determined (23), a sentiment in which the author concurs.

Relaxation. The next point to consider is the relaxation upon removal of stress. If the molecular structure were such that elastic phenomena and plastic phenomena operated independently of one another, a rapid elastic recovery would ensue with no further recovery. However, such a condition does not exist and the energy for the plastic recovery (sometimes referred to as the "elastic aftereffect") is derived from a portion of the elastic structure. The rate of recovery will still depend upon a coefficient of viscous impedance and a coefficient of internal friction, both cooperating to make the rate an exponential function of time. This observation has been made by other investigators (4, 24).

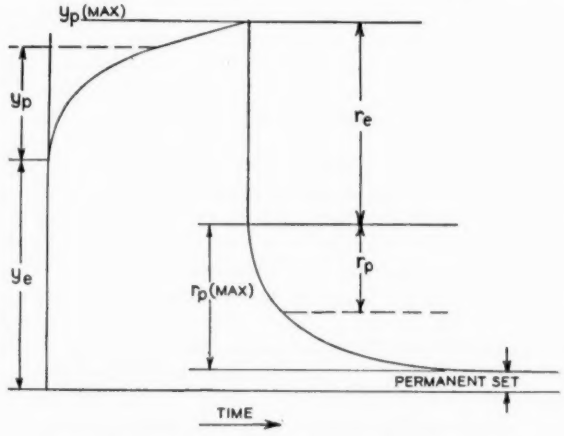

FIG. 4 TYPICAL TIME-DEFORMATION CHARACTERISTIC

Further, when a constant deformation is maintained under loading conditions, we may expect an exponential recovery of stress. Steinberger observed this condition for some cellulose esters, expressing the recovery of stress in an exponential equation (11).

It will also be observed that the recovery from deformation will not be 100 per cent, due to a permanent set which occurs as a result of the loss of stored energy from the elastic structure. Likewise when the stress is great enough to exceed the proportional limit of the elastic structure, the permanent set is very much greater. Thus the permanent set in the material will be a function of the time of stress application, temperature, and the amount of stress to which the material has been subjected. This behavior has been corroborated by the results of this investigation. Houwink also points out the influence of thermo-recovery upon permanent set, wherein a further recovery from deformation ensues when the material is placed at a temperature higher than that at which it was deformed.[4]

If we admit the existence of a true elastic portion of the molecule, how then are we to determine correctly its true elastic limit if the results for the whole structure are susceptible to plastic influences even at low stresses? Grouping the deformation and recovery phenomena, there is the following:

Elastic deformation (y_e) + plastic deformation (y_p) =

elastic recovery (r_e) + plastic recovery (r_p) + permanent set.

If upon the removal of the load, $r_{p\,max}$ exceeds $y_{p\,max}$ we have

[4] Reference (4), p. 7.

then exceeded the true elastic limit of the material, for it is only through a nonelastic deformation of the true elastic structure, resulting in a retardation of the elastic recovery, that this condition would be true, Fig. 4. Thus the true elastic limit of amorphous materials may be defined as follows: When stress is applied such that the elastic deformation y_e exceeds the elastic recovery r_e the applied stress exceeds the elastic limit of the material. This definition is true regardless of how long the stress is applied though the longer the stress is applied the greater is the difference. For example under the conditions of the test, the following results were noted for polyvinyl chloride acetate and methyl methacrylate. Elastic recovery was determined after 50 hr and 100 hr of applied stress, respectively.

Maximum fiber stress, lb per sq in.	Ratio of y_e/r_e	
	Polyvinyl chloride acetate	Methyl methacrylate
500	1.00	1.06
1000	1.00	1.06
2000	1.01	1.20
3000	1.90	1.64

Similar relationships of y_e and r_e were observed for all of the other materials. Thus in applying the definition of elastic limit given in the last paragraph, when y_e begins to exceed r_e at an increasing rate, the elastic limit of the material is exceeded. The longer the stress is applied, the greater will be this distinction, enabling the observer to readily determine the elastic limit of the elastic portion of the molecule. From this tabulation, we find that the elastic limit of polyvinyl chloride acetate lies between 2000 and 3000, and the elastic limit of methyl methacrylate lies

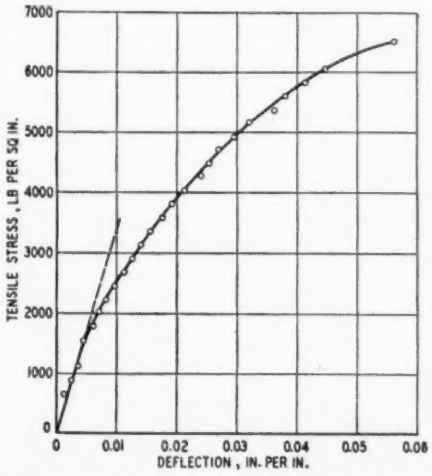

FIG. 5 STRESS-STRAIN CURVE FOR METHYL METHACRYLATE

between 1000 and 2000 lb per sq in. To check this result very careful measurements were made of the direct-tension stress-strain relationships of methyl methacrylate (see Fig. 5), and from these data the elastic limit between 1000 and 2000 pounds per square inch was verified.

Temperature. No results were available at the time of preparing this paper on the characteristics of the materials at different temperatures. Aside from the phenomenon of thermorecovery, already mentioned, also of note are the observations of Hetényi, who pointed out that at temperatures of 110 C, the phenol-aldehydic plastics behaved as true elastic materials. He emphasized also that the speed of deformation is greatly dependent upon the temperature (25). These observations were conducted on test beams supported at two points and under a given stress for a period of 5 hr. The true elastic behavior of plastics at high temperatures was also noted by Houwink (26). Other results on the temperature dependence of plastic deformation are also enlightening (27, 28).

MAKING DEFORMATION TESTS

In preparing the data which are presented in the accompanying set of curves the following procedure was maintained in every case:

Due to very rapid changes in deformation, following the application of the fixed weights serving as the load, a full 60 sec

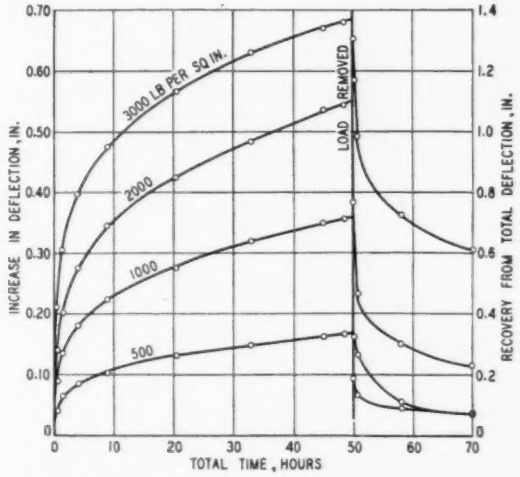

FIG. 6 TIME-DEFORMATION CURVE FOR CELLULOSE ACETATE, 50 HR

were allowed to elapse before the first reading was taken. This value was assumed to be y_e (true elastic deformation). Likewise, very rapid changes in deflection occurred upon removal of load, and again 60 sec were allowed to elapse before the first reading in the recovery curve was taken and r_e (true elastic recovery) measured. Another assumption is the designation of maximum fiber stress above each curve during the loading period, which is correct only for the true initial elastic deformation. This value of maximum fiber stress was obtained from Equations [1] and [2], and naturally will change during time. However, it serves as a comparative indication of how the loads were selected for the materials. The value will be even less significant when the true elastic structure is deformed, which is the case for example, with cellulose acetate at 3000 lb per sq in. maximum fiber stress. Actually the recovery from maximum fiber stress in this one case is so great that there is a smaller separation of deflection ordinates between 2000 and 3000 lb per sq in. than between 1000 and 2000 lb per sq in., Fig. 6.

All values of deflection in the curves are measured at the end of a 5-in. simple cantilever beam which was adopted as a standard

TABLE 1 COLD-FLOW AND CREEP CHARACTERISTICS OF VARIOUS PLASTICS[a]

Material	At maximum fiber stress of 1000 lb per sq in.					
	Total initial elastic deformation (y_e), in.	Total plastic deformation (y_p) — At 1 hr		At 100 hr		Coefficient of resistance to cold flow (R)[b]
		In.	Per cent, y_e	In.	Per cent, y_e	
Polyvinyl chloride acetate	0.407	0.020	4.9	0.106	26.0	1.66×10^4
Polystyrene	0.370	0.012	3.2	0.090	24.0	2.5×10^4
Cellulose acetate	0.727	0.117	16.1	0.480	66.0	0.5×10^4
Laminated phenolic (fabric base)	0.166	0.012	7.2	0.036	22.0	9.08×10^4
Methyl methacrylate	0.446	0.030	6.7	0.065	14.6	4.54×10^4

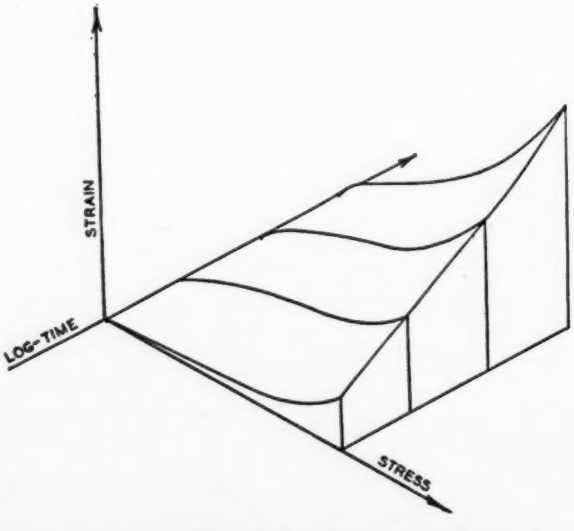

FIG. 9 STRAIN-STRESS-LOG TIME CURVE FOR METHYL METHACRYLATE

for comparison. It is not possible, either, to compare curves of materials with different thicknesses, unless data are presented as per cent of the original deflection. Results are plotted as the "increase in deflection" for various time durations of loads. The increase in deflection over the initial elastic deformation is in fact the plastic deformation Y_p. The elastic deformation was not plotted on the curves, inasmuch as it was desired to compare

the plastic-deformation properties primarily, though the value may be estimated from Equations [1] and [2] readily. They are also given in Table 1. Further, upon the attainment of various time intervals, 50 or 100 hr, the load was removed and 60 sec allowed to elapse before the first reading in the recovery curve was taken. This reading would, of course, be a measure of true elastic recovery r_e, and further measurements denoted as recovery from total deflection are in fact plastic recovery r_p. To facilitate measurements upon the slopes of the curves at the initial deflection and initial recovery periods, the same data are plotted for shorter time intervals. For further analysis, a typical stress-deflection-log-time curve in three dimensions is plotted for laminated phenolics and methyl methacrylate, Figs. 8 and 9. Both of these curves were plotted according to the same ordinates. The smaller the volume, the more desirable the cold-flow and creep characteristics. The other materials give similar plots, only occupying greater volumes for the same ordinates. All of these data are for a given temperature of 85 F. Figs. 10 to 16 are the deflections in bending, for certain time durations of various stresses for the various materials.

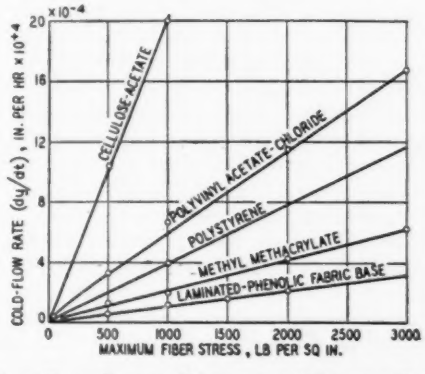

FIG. 17 COLD-FLOW RATE AS FUNCTION OF MAXIMUM FIBER STRESS
(Cold-flow constant dy/dt for given maximum fiber stress, corrected for 0.09-in. thickness, length 5 in., slope of cold-flow characteristics when dy/dt becomes constant at maximum fiber stress.)

For every material the two stages of plastic deformation are quite noticeable, more so in some instances than others, namely, where dy/dt is changing (creep) and where dy/dt becomes constant (cold flow). For higher values of stress, the longer is the time required to attain cold flow. The time required to attain cold flow differs considerably in the various materials. For example, methyl methacrylate attains cold flow at a much earlier period than polyvinyl chloride acetate. The fact that the cold-flow rates of methyl methacrylate are considerably smaller than polyvinyl chloride acetate would indicate that the former is to be preferred for applications involving the imposition of stress

over long periods of time. On the other hand, the smaller initial deflections of polyvinyl chloride acetate occurring during the early stages of plastic deformation, would mark this material as better suited to short-time applications of stress as compared with methyl methacrylate.

The attainment of constant dy/dt may be shown in Equation [8] after long periods of time have elapsed. This condition was observed for all of the materials under test, and is highly significant, for it means that the cold-flow rate is a straight-line function of the stress. The slopes of the time-deflection curves were measured after cold flow commenced, and plotted as a function of the stress to give Fig. 17. Agreement with theory was observed in every case. We may also deduce from Fig. 17 that cold flow occurs even at very low stresses, as the line has its inception at the origin.

In connection with the tests upon methyl methacrylate, it is also interesting to note the results of other creep tests conducted upon the same type of material, which agree with the results of this test (29). These specimens were loaded for 20 min and unloaded for the same length of time, obtaining the time-deformation characteristics. The investigators suggested the following formula for the deformation:

$$y = Ae^{-at} + B \log_e (1 + t)$$

where A and B are functions of the load.

As a basis of comparing the creep and cold-flow characteristics of the materials, Table 1 has been prepared from the data shown in the accompanying curves. For data upon casein plastics, there has been a recent survey of the elastic properties of 60 types of rennet casein (30). In Table 1, low ratio of plastic deformation to elastic deformation may be deemed desirable, as well as high values of the resistance coefficient R.

Effect of Structure. While insufficient types of the same materials were tested to permit a comprehensive analysis of the effect of molecular structure upon cold-flow characteristics, a few results may be reported. For example, when laminated phenolics were baked at 275 F for 24 hr and then tested under cold flow, a marked decrease was observed, indicating of course that further polymerization had removed from the molecular structure some of those elements susceptible to plastic deformation. Tests upon hot-molded phenolics, which were prepared from more reactive phenolic constituents than employed in the preparation of the laminated materials, exhibited less creep and cold flow than the laminated, and considerably less permanent set.

As for the effect of orientation of long chain-like molecules present in polystyrene, for example, a few tests conducted to date indicate less cold flow with the unoriented molecules. Another theory has also been advanced that the shorter the chain length, the less the internal frictional resistance to cold flow (24).

While cold-flow and creep phenomena throw much light upon the relative merits of the commercially available materials, the full answer will not be realized until the effect of molecular weight, molecular orientation, and the effects of extraneous materials such as fillers and plasticizers are fully examined under the same conditions. It is also interesting to note that plastic flow will occur in metals, even at ordinary temperatures at stresses below their elastic limit (31), though the ratio of plastic deformation to elastic deformation is very much smaller than with the plastics.

Shrinkage of Molded Plastics at Elevated Temperatures

Always a factor in determining the permanency of the physical properties of the plastics is the effect of temperature upon the shrinkage of the materials. This aftershrinkage occurs in addition to the normal thermal shrinkage of the material when it is removed from the mold. Failure to take it into consideration has sometimes caused serious discrepancies in design values. A few results are reported in the curves, Figs. 18 and 19, for various plastics. These results are of particular interest to the thermosetting urea and phenolic plastics which are often exposed to higher temperatures than the thermoplastic materials, which are limited by their low heat-distortion point.

It has been generally assumed that further thermal polymerization (with certain temperature ranges) of thermoplastic and thermosetting compounds results in improved physical properties, though some exceptions have been noted (19). In phenolics, for example, the additional polymerization incurred on exposure to elevated temperatures, is accompanied by internal shrinkage in the material as the phenolic constituents attach themselves to the main primary bond structure through methylene linkages.

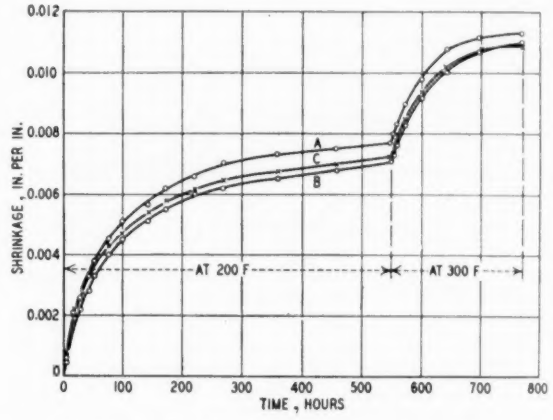

Fig. 18 Shrinkage of Molded Phenolics on High-Temperature Exposure for Different Cures
(*A*, 1 min cure; *B*, 2 min cure; *C*, 10 min cure.)

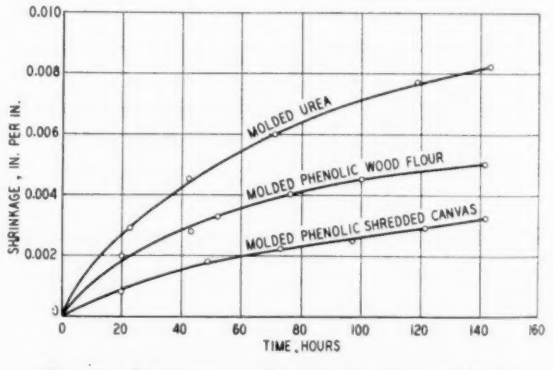

Fig. 19 Shrinkage of Molded Plastics at 200 F

Nevertheless, the results of Fig. 18 are quite interesting, for only slight differences were noted for a molded article with 1-, 2-, and 10-min curing periods in the mold. The measurements were made with a 4- to 5-in. micrometer upon a 4.5-in-diam molded ring and are accurate to plus or minus 0.0001 in. It was expected that the poorly undercured 1-min sample would shrink considerably more than the overcured, whereas only a slight difference was recorded. This observation has been corroborated by other investigators (32).

Application of excessive temperatures of 500 F produced swelling in a very short period of time due to the thermal disintegration of the resin molecule. One must assume that the prime molecular structure of the materials is developed during the period the material is molded under heat and pressure. Further changes in polymerization outside of the mold must result in a reduction of soluble stage "B" resin constituents which Houwink assumes as

being present within a strong, polymerized primary molecular structure (4). Chemical, electrical, and physical properties may be expected to improve through a reduction of these constituents, providing the temperature is not too high to be detrimental to the resin or its filler. For a discussion of other possible effects produced by aging in phenol-formaldehyde products, there are other studies (33).

In summarizing the discussion of the shrinkage of hot-molded phenolics and urea plastics, the significance of time and of temperature must be pointed out again. For example in Fig. 18 (which employed bakelite molding composition No. 8041), a limit in the amount of aftershrinkage was indicated when the material was maintained at 200 F. Continuance of the temperature exposure at 300 F after 550 hr revealed more than a 50 per cent increase in aftershrinkage. After the specimens were removed from test and left to stand in the atmosphere, a slight swelling was observed after several weeks, due to the absorption of moisture, though this new over-all dimension was considerably smaller than the original dimension.

The effects of increasing temperature upon thermoplastic materials are quite marked. If they are under stress, they will distort readily, particularly as the temperature approaches their heat-distortion point. If not under mechanical stress, as for example an electrical insulating coil bobbin, they may be used above their heat-distortion point. It must be pointed out,

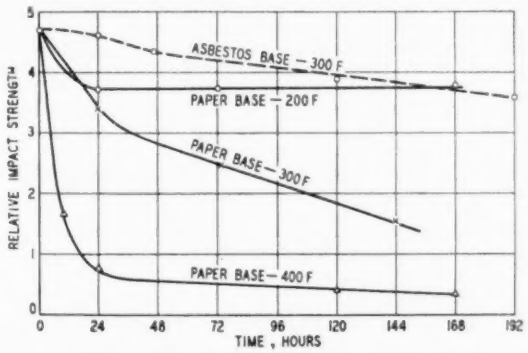

FIG. 20 EFFECT OF TEMPERATURE EXPOSURE ON IMPACT STRENGTH OF LAMINATED PHENOLICS

however, that cellulosic products which are usually highly plasticized, will suffer a loss of plasticizer content and residual solvent and become embrittled if exposed to excessive temperatures for too long a period. Shrinkage in molded cellulose-acetate articles will also be due to loss of moisture content. In comparison with other materials shown in Fig. 19, an injection-molded cellulose-acetate article showed a shrinkage of 0.013 in. per in. in 24 hr, though it does not change much after this. It is noted further that the actual shrinkage was dependent upon which portion of the article measurements were taken, with respect to the injection gate.

Cast products of polystyrene and methyl methacrylate are susceptible to further contraction during aging, due in part to further polymerization. In casting these materials from their monomeric form, there is a 15 to 20 per cent reduction in volume. Tests upon articles cast of methyl methacrylate revealed that as much as 0.020 in. per in. shrinkage took place over a 24-hr period at 200 F.

RETENTION OF PHYSICAL PROPERTIES AFTER HIGH-TEMPERATURE EXPOSURE

What of the physical properties of the plastics after they have returned to room temperature after being exposed to high temperatures for long periods of time? If thermoplastic in nature and they have suffered a loss of volatile materials which contributed to their impact strength, we may of course expect a diminution of the physical properties. For thermosetting materials, much depends upon the temperature in which the material was operating and the time at that temperature. For temperatures up to 275 F, an improvement in physical properties has even been noted for some of the laminated phenolics. In Fig. 20 some interesting data are given to show the effects of high-temperature exposure upon the physical properties of laminated phenolics. Most of the results are for grade-XX paper-base laminated phenolic plastics, though for comparison, the decrease in impact strength of an asbestos-base material at 300 F is included. Considerations, such as those which reveal a marked loss in impact

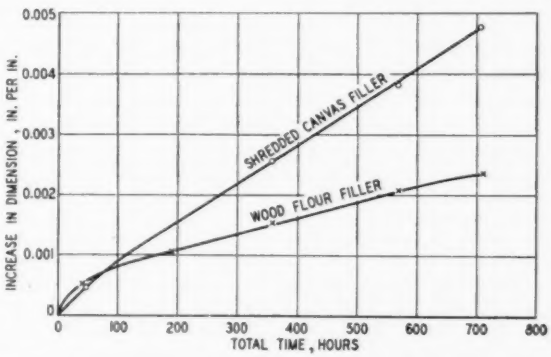

FIG. 21 DIMENSIONAL STABILITY AT HIGH HUMIDITY FOR HOT-MOLDED PHENOLICS

strength after being placed in service for a certain length of time, necessitate the provision of ample factors of safety. The significance of the previous history of the material has been emphasized by more than one investigator (34).

EFFECT OF MOISTURE ON PERMANENCY OF PHYSICAL PROPERTIES

A few remarks on the effects of moisture on the physical properties will serve to emphasize this important influence on the permanency of the characteristics. Much study has been given to the changes in physical dimensions of various organic plastics upon exposure to moisture (35, 36). This consideration of permanency is of particular import when the molded articles are to operate in high humidity or in water. For example, laminated phenolic bearings operating in water must be designed with adequate shaft clearance to prevent seizure when the materials swell slightly in the course of time. The author has conducted several tests in a highly humid atmosphere to illustrate the effects of high humidity upon dimensional stability of typical molded

articles, Figs. 21 and 22. These data are given primarily for illustrative purposes, as no attempt was made to investigate thoroughly the question of moisture absorption. The designer is cautioned to make adequate allowance for swelling when the plastic parts are operated in water or high humidity. Particularly noteworthy is the more rapid permeation of moisture in the cellulose structure than with the molded phenolics. Under the same conditions of test, polyvinyl chloride acetate and methyl methacrylate showed no measurable change in 48 hr.

In conclusion it must be emphasized once again that there are many factors affecting the permanency of the physical properties of plastics. This paper has attempted to deal with the fundamental aspects of one of the most significant factors, plastic deformation under stress. Further, the reader's attention was called to other significant phenomena such as shrinkage at high temperatures, and swelling in moisture for various molded articles, though the analysis of these conditions was not pursued as actively as for the creep and cold-flow phenomena.

Discussion

E. H. Hull[5] and A. J. Nerad.[5] It would appear that, in order to account for permanent set in the mechanical analogy given in Fig. 1 of the paper, another friction device should be added which has no spring across it. If the load in Fig. 1 is removed the lower spring will recover completely, since it is spanned by a viscous impedance.

Our experience with rubber and with steels at high temperatures and moderate stress indicate that time-deflection curves do not reach a constant slope within a reasonable length of time.

[5] Research Laboratory, General Electric Company, Schenectady, N. Y. Mems. A.S.M.E.

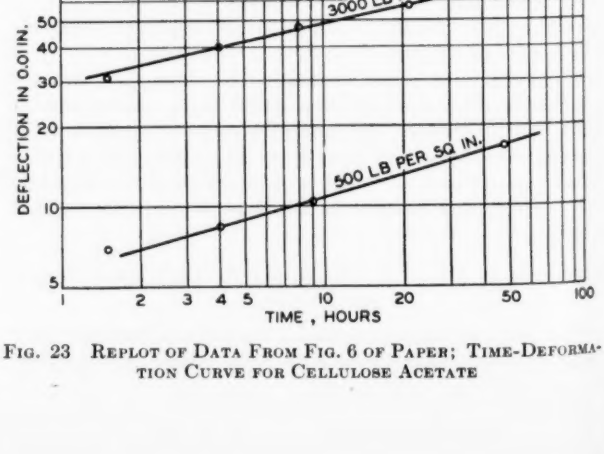

Fig. 23 Replot of Data From Fig. 6 of Paper; Time-Deformation Curve for Cellulose Acetate

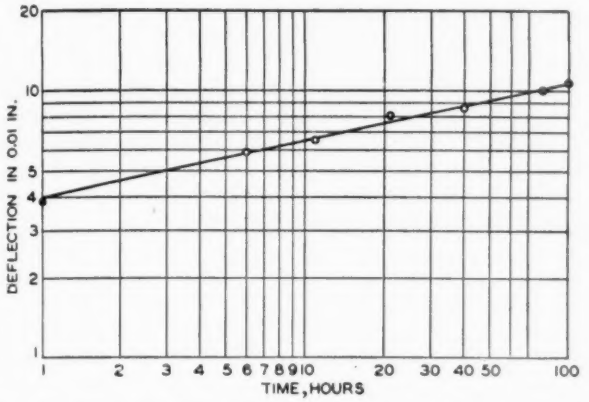

FIG. 24 REPLOT OF DATA FROM FIG. 13 OF PAPER; TIME-DEFORMATION CURVE FOR LAMINATED PHENOLIC PLASTIC

For example, if the data from Figs. 6 and 13 of the paper are plotted on log-log paper as in Figs. 23 and 24, straight lines are obtained with a slope considerably less than unity. An expression of the following form will represent this straight line

$$\gamma = KT^n$$

where γ = deflection, in. at any time T, hr
K = deflection at 1 hr
n = slope of line.

Differentiating this expression we have

$$\frac{d\gamma}{dt} = nKT^{n-1}$$

which will also give a straight line when plotted on log-log paper.

Since n is considerably less than unity, this expression indicates that the change in deflection per unit time decreases with time. This point has been made for steel by Hanson[6] and Zschokke.[7]

C. W. MACGREGOR.[8] The close similarity between the test results for plastics given in the paper and those obtained for the creep of metals is apparent. For the creep curves in Figs. 13 and 15, there is at first a portion of each curve having a diminishing creep rate followed by a region through which the creep rate is constant. In the creep of metals, these regions have been called the primary and secondary stages of creep or primary and secondary creep, respectively. The term "cold flow" used in the paper for the secondary stage of creep appears to be somewhat undesirable not only from the standpoint that this type of creep occurs at different temperatures also, but because the second portion of the creep curve has no distinguishing temperature condition from the initial stage. In metals, it is felt that the constant creep rate in the second stage is due to a balance between the annealing effect which tends to increase the slope and the strain-hardening which has the effect of decreasing the slope. A somewhat similar condition may be present for plastics.

A third stage of creep is obtained for metals if they are subjected to sufficiently high temperatures and stresses. This region is characterized by a rapidly increasing creep rate until fracture occurs. It would seem that a similar stage would be received for plastics if the tests were run for sufficiently long periods of time at higher temperatures than those used in the investigation under discussion.

Metals also show similar creep-recovery phenomena.[9] It is interesting to note that for the higher stressed plastics, after a sufficient time has elapsed, most of the creep has been recovered. From these tests it is evident that creep recovery is a pronounced function of stress at least and that, if the recovery curves were plotted for longer times, they might become nearly asymptotic.

Concerning the method of test, the use of four-point loading or so-called "pure bending," where the bending moment is constant over a considerable length having also zero shear, would seem to have certain advantages over the cantilever method of testing where the bending moment varies linearly and there is a constant shear present. In case four-point loading is used, the deflection of the portion of the beam under a constant bending moment from the inside loading points, i.e., the deflection of the center of the beam from the chord drawn between the inside loading points, could be obtained readily. It would also appear desirable to reduce the width of the specimen from 1 in. to about $^1/_2$ in. or less, since plate action is introduced in the wider cases and the test piece is essentially a cantilever plate, the length-to-side ratio of which is 5 to 1, and not a beam as we ordinarily define it to which Equation [1] in the paper applies.

AUTHOR'S CLOSURE

The differences of opinion which exist as to the attainment of a constant slope in the time-deflection curves of materials under stress are brought out by the two discussions of this paper. Mr. MacGregor presents evidence which agrees with the results disclosed by the paper, while Mr. Hull and Mr. Nerad indicate results to the contrary. It appears to the author that the problem is a fundamental one in materials and that cognizance must be given to the nature of elastic and plastic reactive forces appearing in the material under stress. Direct comparisons of steel which behaves more closely to an elastic body than organic plastics are difficult, primarily because of such phenomena as strain-hardening. By the same token, it would not be propitious to compare directly materials which closely approach true plastic behavior, even though the attainment of a constant slope of load deflection occurs in a very short period of time.[10] Reiterating, it is the author's experience with organic plastics that, under test conditions involving no chemical changes in the material, and under constant stress per unit area loading, for all practical purposes a constant slope in the deflection-time curve will be observed.

Concerning the formulas and replotting of data by Messrs. Hull and Nerad, it should be noted that an actual calculation of n from data presented in the text shows that n is a function of K, and K is dependent upon a reference-time point. A more satisfactory manner of representing the time dependence of the rate of change of deflection with time for true plastic flow is shown in Equation [7] of the text, a substantially constant rate being achieved after long periods of time.

Their comments concerning Fig. 1 of the paper are quite correct, for the mechanical analogy indicated was merely a simple representation of a considerably more complex system. The correct picture would show a friction device between each coil of the lower spring. As in the graphical method of indicating distributed capacitance between the turns of a coil, the friction elements are combined into one illustrative element.

Mr. MacGregor's suggestions for the method of test are inter-

esting, particularly the desirability of reducing specimen width to 1/2 in., which is slightly more satisfactory. Tests upon polystyrene were conducted with this width, and the author contemplates adopting this size for the others. Regarding the four-point loading, the constant bending moment is in its favor. However, the means of attachment of the loading weights which usually require some hole or notch in the specimen would present a discontinuity at the point of maximum bending moment, whereas, in the case of the simple cantilever beam, the point of attachment is located at the minimum bending moment. Furthermore, shorter specimens may be more easily handled by the cantilever method.

Extensions of the recovery curves show an asymptotic relationship. In fact for given values of applied stress during the loading period, there may be plotted a relationship between permanent set and applied stress, for a given time. Further, an interesting relationship exists between permanent set and time of applied load, for a given stress and temperature.

Laminar-Flow Heat-Transfer Coefficients for Ducts

By R. H. NORRIS,[1] SCHENECTADY, N. Y., AND D. D. STREID,[2] WEST LYNN, MASS.

In this paper, theoretically derived values of the heat-transfer coefficient for flat ducts with constant surface temperature are presented and compared with the corresponding results for round ducts which have been previously published. A few test data for air in flat ducts are compared with the theoretical results. For both flat ducts and round ducts the results are presented both in customary terms and in terms of the logarithmic-mean temperature difference. The latter results provide a consistent basis for comparisons with heat-transfer data for turbulent flow. Some limiting values of the local heat-transfer coefficient for both constant surface temperature and constant heat input per unit length are tabulated, and some equations pertinent to very short ducts are included.

Nomenclature

A = surface area of that part of duct which transfers heat (for a flat duct it includes both sides if both are transferring heat), sq ft
S = cross-sectional area for fluid flow, sq ft
b = minimum distance from center to wall of duct, ft
c = specific heat (at constant pressure), Btu per lb per deg F
C_1 = constant in Equation [12] tabulated in Table 2, dimensionless
D = equivalent diameter = $4LS/A$, ft
g = acceleration of gravity = 4.17×10^8, ft per hr per hr
G = $w/S = \rho V$ = weight velocity, lb per sq ft per hr
G_r = $D^3\rho^2\beta\,\Delta t_a g/\mu^2$ = Grashof number, dimensionless
h = heat-transfer coefficient, based on particular temperature difference indicated by subscript used with h, as defined by Equation [1], Btu per hr per sq ft per deg F
h_a = h on arithmetic-mean-temperature basis (see Equation [1])
h_i = h on inlet-temperature-difference basis (see Equation [1])
h_L = h on logarithmic-mean-temperature basis (see Equation [1])
h_x = h on local-temperature-difference basis (see Equation [1])
j = $\dfrac{h_L}{cG}\left(\dfrac{c\mu}{k}\right)^{2/3}$ = heat-transfer factor, dimensionless
k = thermal conductivity of fluid (subscripts, of same meaning as those for μ), Btu per hr per sq ft per deg F per ft
L = length of duct or plane, or distance from leading edge or entrance of heated portion of duct, ft
q = total heat-transfer rate, Btu per hr
R_D = $\dfrac{\rho VD}{\mu} = \dfrac{GD}{\mu}$ = Reynolds' number, dimensionless
t = fluid temperature, deg F
t_m = transverse mean (mixing-cup) temperature of the fluid (1),[3] deg F
t_1 = t_m at inlet, deg F
t_2 = t_m at outlet, deg F
Δt_a = $t_w - (t_1 + t_2)/2$, deg F
t_w = wall temperature, deg F
t_{w1} = wall temperature at inlet, deg F
t_{w2} = wall temperature at outlet, deg F
V = $w/\rho S$ = mean velocity, ft per hr
w = total weight flow of fluid, lb per hr
x = axial distance from the entrance to any given point in duct, ft
β = coefficient of volumetric expansion of fluid, (deg F)$^{-1}$
μ = viscosity of fluid, lb per ft per hr
μ_f = viscosity at mean film temperature, as defined by Colburn (4), lb per ft per hr
μ_m = viscosity at fluid temperature t_m, lb per ft per hr
μ_w = viscosity at wall temperature t_w, lb per ft per hr
ρ = density of fluid, lb per cu ft
ϕ = empirical correction factor, defined by Equation [24], dimensionless
Φ = cGD^2/kL, dimensionless

Purpose of Heat-Transfer Study

Heat transfer to fluids in laminar flow in ducts is amenable to exact mathematical analysis provided constant fluid properties and reasonably simple flow conditions, concerning temperature distribution along the duct walls and velocity distribution across the duct, may be assumed.

For round ducts, on the basis of these assumptions, a number of expressions (1, 2, 3),[3] derived analytically for the heat transfer, have been available for some years; and empirical correction factors (4, 5) have more recently been developed to correct these equations for the effects of the discrepancies between the assumptions used and the actual conditions in practical applications. Each of the various theoretical expressions is theoretically accurate only within its own appropriate range of the major variable, however, and no convenient combined summary of all these ranges of application seems to be available.

For flat ducts, on the other hand, no theoretical results for assumptions reasonably representative of practical conditions have been available, in spite of the importance of flat-duct problems in such applications as air flow between fins and the flow of cooling oil in narrow annular or flat ducts. Although Nusselt (6) has calculated the heat transfer to a liquid film of constant thickness flowing down a flat plate with the same assumption of velocity distribution (parabolic) which is reasonable for flat ducts, the application of his results to flat ducts has not been made.

This paper has three purposes which are: (*a*) To present for flat ducts theoretical results covering the complete range of variables, based largely on Nusselt's method; (*b*) to present for round ducts similarly complete theoretical results, showing how these are selected from different sources by applying results from each source to a different, specific range of the major variable; and (*c*) to express all these results in terms of alterna-

tive bases of correlation, together with certain simple approximations, for convenience for different applications.

For simplicity, the words "flat duct" are used throughout this paper to denote the case of flow between flat parallel plates of infinite extent perpendicular to the flow direction. This represents the limiting case of a duct of rectangular cross section when the ratio of the longer to the shorter side becomes very large.

Theoretical Assumptions

The theoretical results presented in this paper should be used with an understanding of the assumptions on which they are based. Although these assumptions will not be discussed in detail, the effects of the major practical variations from them will be considered later. The assumptions are:

1 The transverse velocity distribution is parabolic with zero velocity at the wall.

2 The duct wall is at constant temperature, unless specified otherwise.

3 The fluid properties (c, ρ, and k) are constant.

4 Heat conduction in the direction of flow is negligible.

5 Temperature conditions do not change with time.

Theoretical Results Shown Graphically and Numerically

One convenient form of correlation of results is in terms of the dimensionless group h_aD/k, as a function of the dimensionless group $\Phi = cGD^2/kL$. For round ducts, many authors have used a different dimensionless group wc/kL, which is related to Φ as follows

$$\Phi = \frac{4}{\pi} \times \frac{wc}{kL}$$

The variable Φ is used in this paper because it is applicable to flat ducts as well as to round ones.

Table 1 presents numerically the theoretical results for this form of correlation, as well as for certain other forms discussed later. Understanding of the sources of the results in Table 1 is facilitated by consideration of Fig. 1, where the results from each source are shown graphically.

Plotted in Fig. 1, for both round and flat ducts, are two theoretically derived solutions for h_aD/k, one of which, the Graetz solution (2) or its numerical equivalent (6), is applicable for low values of Φ, and the other, Lévêque's approximation (3), is applicable for high values of Φ. The range of values of Φ, for which each solution is accurately applicable, is evident from inspection of Fig. 1, and the results in Table 1 were selected accordingly, as explained in the following:

For round ducts, the numerical values of h_aD/k in Table 1 were calculated by the authors from Graetz's original equations (2) for values of Φ below 150, and from Lévêque's approximation (3) for the values of Φ above 2000. For the intermediate values of Φ (150 to 2000), a linear interpolation on the log-log plot was used, as shown by the dashed line in Fig. 1.

For flat ducts, the values of h_aD/k in Table 1 for values of Φ up to 400 were obtained from a numerical solution as calculated by the authors using the method described by Schmidt (7), before they learned that Nusselt (6) had presented the same sort of solution. The authors' results were later found to agree with Nusselt's results over this range of Φ. This agreement should increase confidence in their validity. For values of Φ above 400, the data in Table 1 were calculated from Lévêque's approximation (3), as modified by the authors to make it applicable to flat ducts.

Alternative Temperature Bases

Four alternative temperature differences and the relations between the heat-transfer coefficients based on them are

$$\frac{q}{A} = h_a\left[t_w - \frac{t_2 + t_1}{2}\right] = h_i\,[t_w - t_1]$$

$$= h_L\left\{\frac{(t_{w1} - t_1) - (t_{w2} - t_2)}{\log_e\,[(t_{w1} - t_1)/(t_{w2} - t_2)]}\right\}$$

$$= (1/L)\int_0^L h_x(t_w - t_m)dx \qquad [1]$$

The coefficient h_a based on the arithmetic-mean temperature difference, has heretofore been used widely (5, 8, 9). The coefficient h_i, based on the inlet temperature difference simplifies the evaluation of the total heat q but, as shown later, the coefficient h_i itself cannot be represented by a simple approximate equation over as large a range of values of Φ for round ducts as the coefficient h_a.

The coefficient h_L, based on the logarithmic-mean temperature difference has been previously used in the literature, not for laminar flow, but only for turbulent flow where it is always equal to h_x which does not vary with x (except as changes of mean temperature with x affect fluid properties and thereby affect h_x). Because laminar flow h_x varies with x and its true mean value (1) is represented by neither h_L, h_a, nor h_i, all three of these coefficients may be considered as equally arbitrary choices. Nevertheless, h_L has several advantages over h_a. As shown later, the maximum error introduced by certain convenient approximate equations for h_L and h_a is either smaller for h_L than for h_a, or at least the same, and the direction of this maximum error makes the calculated heat transfer too low instead of too high. Then too, the use of h_L for laminar flow permits comparison with turbulent-flow data on a consistent basis. Finally, for decreasing values of Φ, h_LD/k approaches asymptotically a lower limit, which is not zero but is the same as the lower limit for h_xD/k, whereas h_aD/k decreases linearly with Φ toward zero. This behavior of h_aD/k is likely to be misleading. For example, for values of Φ below 8, a decrease in D will be found to decrease h_a, which may seem at first glance undesirable, whereas actually, it is likely to be desirable, since it will increase h_x and h_L and thereby permit a reduction in the surface area required for a given total heat transfer q.

The local coefficient h_x is useful when the conditions at a particular part of the duct, rather than for the duct as a whole, are to be considered.

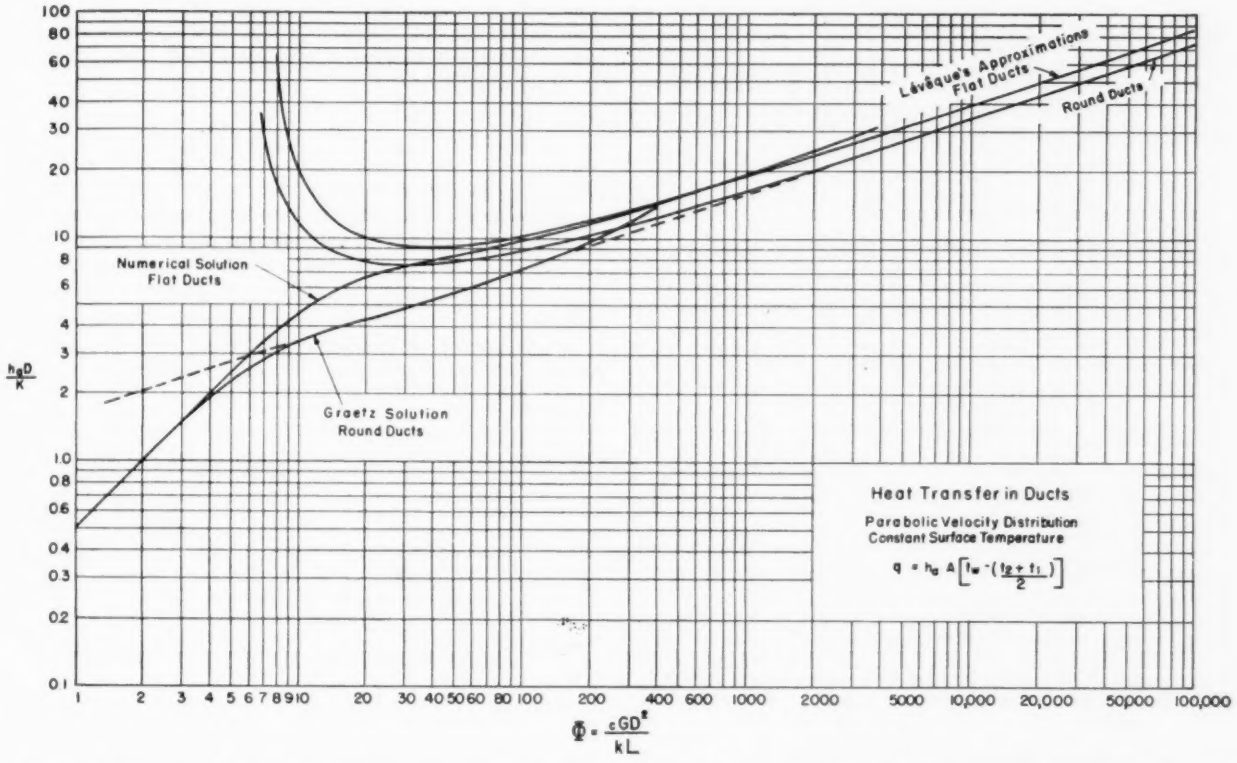

FIG. 1 THEORETICAL HEAT-TRANSFER CORRELATION FOR LAMINAR FLOW ON ARITHMETIC-MEAN TEMPERATURE-DIFFERENCE BASIS, SHOWING RESULTS OF VARIOUS ANALYSES FOR CONSTANT WALL TEMPERATURE AND PARABOLIC VELOCITY DISTRIBUTION

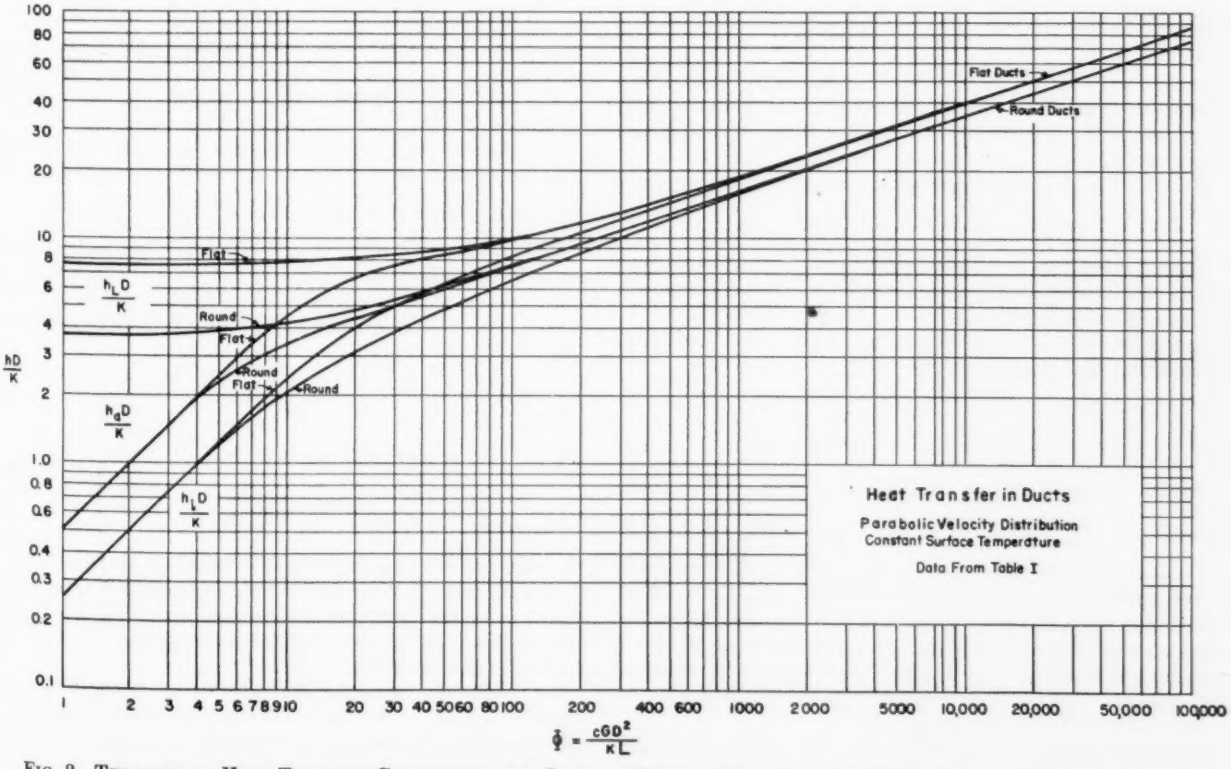

FIG. 2 THEORETICAL HEAT-TRANSFER CORRELATION FOR LAMINAR FLOW IN BOTH FLAT AND ROUND DUCTS; RESULTS SHOWN ON LOGARITHMIC-MEAN, ARITHMETIC-MEAN, AND INLET-TEMPERATURE-DIFFERENCE BASES
(Data from Table 1.)

Table 1 and Fig. 2 (which is based on Table 1) present the theoretical results for h_a, h_i, and h_L, for both flat and round ducts. Results for h_x are discussed later.

The results in this paper do not include explicit values for the ratio of the temperature rise of the fluid to the initial temperature difference, but such values may be obtained from the relation

$$\frac{t_2 - t_1}{t_w - t_1} = 4\,\frac{h_i D/k}{\Phi} \quad \ldots\ldots [2]$$

Approximate Equations for Theoretical Results

The range of applicability specified in the following approximations has been determined by comparison with the complete results in Table 1 and Fig. 2.

Arithmetic-Mean Temperature-Difference Basis. For round ducts, it is a fortunate coincidence that the single simple relation

$$h_a D/k = 1.615\Phi^{1/3} \text{ for } \Phi > 10 \quad \ldots\ldots [3]$$

represents the theoretical results within 5 per cent for the surprisingly large range of Φ indicated. This equation is shown as the dashed line in Fig. 1.

For flat ducts, no simple relation as Equation [3] is available for such a wide range of values of Φ but, for very large values of Φ, the following relation is applicable within 3 per cent

$$h_a D/k = 1.85\Phi^{1/3} \text{ for } \Phi > 2000 \quad \ldots\ldots [4]$$

For sufficiently low values of Φ, the theoretical results practically coincide with their asymptote, so that

$$h_a D/k = \Phi/2 \text{ for } \left\{\begin{matrix} \Phi < 3 \text{ for round ducts} \\ \Phi < 6 \text{ for flat ducts} \end{matrix}\right\} \quad \ldots\ldots [5]$$

which represents conditions existing when all the fluid reaches the wall temperature.

Inlet-Temperature-Difference Basis. For round ducts, Lévêque's approximation (3)

$$h_i D/k = 1.615\Phi^{1/3} \text{ for } \Phi > 2000 \quad \ldots\ldots [6]$$

is applicable but, for lower values of Φ, it deviates from the theoretical results, as indicated in Fig. 1, where it has been expressed in terms of $h_a D/k$.

For flat ducts, Lévêque's method, applied by the authors, gives

$$h_i D/k = 1.85\Phi^{1/3} \text{ for } \Phi > 400 \quad \ldots\ldots [7]$$

Logarithmic-Mean Temperature Difference. The entire range of values of Φ can be covered by the following set of approximations with a maximum error for round ducts of 18 per cent (near $\Phi = 12$), and for flat ducts of 17 per cent (near $\Phi = 70$), and these errors always make h_L too low, not too high

For round ducts $h_L D/k = 1.615\Phi^{1/3}$ for $\Phi > 12$ ..... [8]

and $h_L D/k = 3.66$ for $\Phi < 12$ ..... [9]

For flat ducts $h_L D/k = 1.85\ \Phi^{1/3}$ for $\Phi > 70$ ..... [10]

and $h_L D/k = 7.60$ for $\Phi < 70$ ..... [11]

For the arithmetic-mean temperature difference, the limits of Φ in the approximations of Equations [3], [4], and [5] could be modified to cover the entire range of Φ also, but if so, the maximum error for flat ducts would be 26 per cent instead of 17 per cent, and for round ducts, although the maximum error would be the same, it would make h_a too high, not too low, which is not conservative for design purposes.

Limiting Values for Local Coefficient. The local heat-transfer coefficient in ducts with laminar flow varies greatly with position in the duct (this variation is usually inappreciable in turbulent flow). However, at a sufficiently long distance from the duct inlet (small value of Φ), the local heat-transfer coefficient h_x approaches asymptotically (from above) a limiting value independent of velocity

$$h_x = \frac{k}{b/C_1} \quad \ldots\ldots [12]$$

where b is the distance from the duct wall to the center of the duct and C_1 is a numerical constant, depending upon the shape of the duct and the assumed velocity distribution, as given in Table 2. The physical significance of b/C_1 is that it represents the thickness of a stationary fluid film having a thermal resistance corresponding to the limiting value of h_x. This thickness represents the mean distance the heat has to travel through the fluid. Table 2 shows that this thickness is about one half the distance b, from the wall to the center of the duct.

TABLE 2 VALUES OF CONSTANT C_1 OF EQUATION $h_x = \frac{k}{b/C_1}$ REPRESENTING VALUES OF LOWER LIMIT OF LOCAL HEAT-TRANSFER COEFFICIENT h_x

	Uniform velocity distribution	Parabolic velocity distribution
Round duct; constant wall temperature	2.90[a]	1.83[a]
Round duct; constant heat input per unit length	4.00[b]	2.18[c]
Flat duct; constant wall temperature	2.47[a]	1.90[b]
Flat duct; constant heat input per unit length	3.00[b]	2.06[b]

[a] Reference (1), Bibliography.
[b] Values derived by authors.
[c] Reference (10), Bibliography.

Limiting values of the local heat-transfer coefficient can be obtained by simple analysis not only for constant wall temperature but also for constant heat input per unit length (10). The values for the latter condition are useful in estimating the maximum temperature which will occur on the surface of an electrically heated duct.

The smallness of the range of the values of C_1 shown in Table 2 has practical significance, for it indicates that the values of C_1 for other duct shapes or other surface temperature distributions, not yet analyzed, would not be likely to depart widely from this range. This significance extends also to the coefficient h_L, since the lower limit of h_L can be shown to be the same as that for h_x.

No values of the local coefficient h_x, other than the limiting value, are given here but some will be found in the literature (1).

Comparison Between Laminar and Turbulent Flow

A comparison of heat-transfer coefficients covering both laminar and turbulent flow in terms of the same variables is often desirable. One such comparison was made by Colburn (4), who plotted the dimensionless quantity called the "heat-transfer factor"

$$j = \frac{h}{cG}\left(\frac{c\mu}{k}\right)^{2/3} \quad \ldots\ldots [13]$$

as a function of Reynolds' number

$$R_D = \frac{GD}{\mu} \quad \ldots\ldots [14]$$

The heat-transfer coefficient h, was based on the logarithmic-mean temperature difference for the turbulent-flow data, but it was based on the arithmetic-mean temperature difference for the laminar-flow data. This change of basis has certain disadvantages to be discussed later.

Fig. 3 for round ducts and Fig. 4 for flat ducts show the heat-transfer factor j, based on the logarithmic-mean temperature difference for both laminar and turbulent flow, as a function of Reynolds' number, as computed from the data elsewhere in this paper.

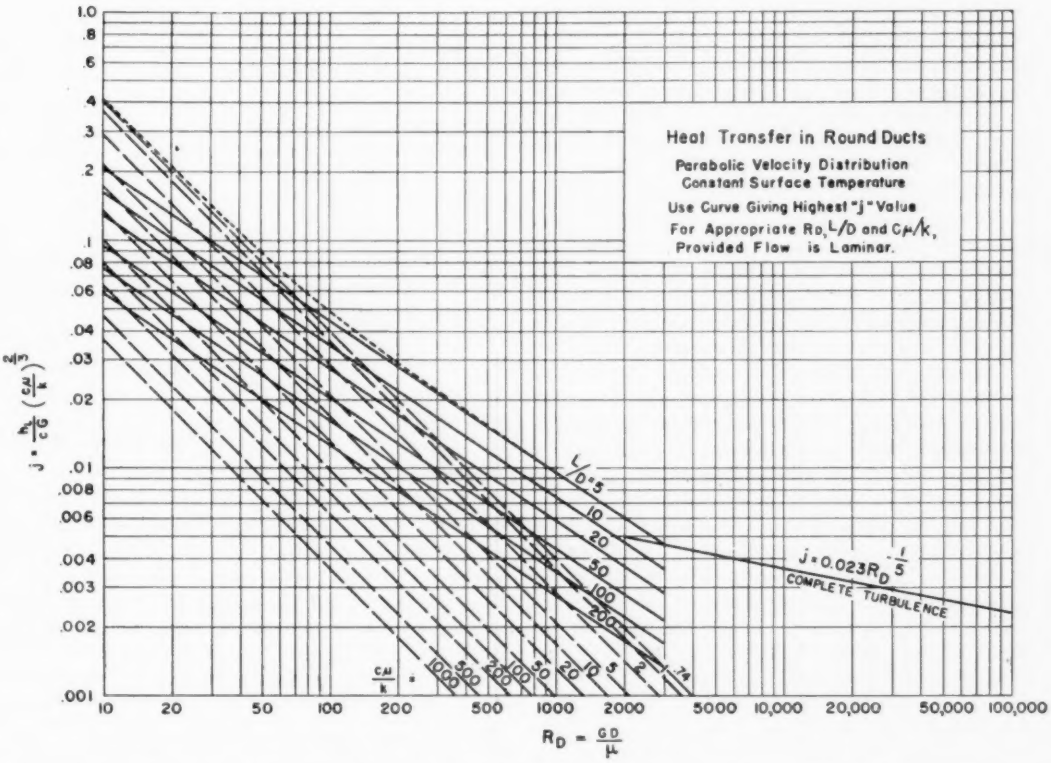

FIG. 3 THEORETICAL CORRELATION OF HEAT-TRANSFER FACTOR AND REYNOLDS' NUMBER FOR ROUND DUCTS, FOR FLOW WHICH IS DEFINITELY LAMINAR OR DEFINITELY TURBULENT

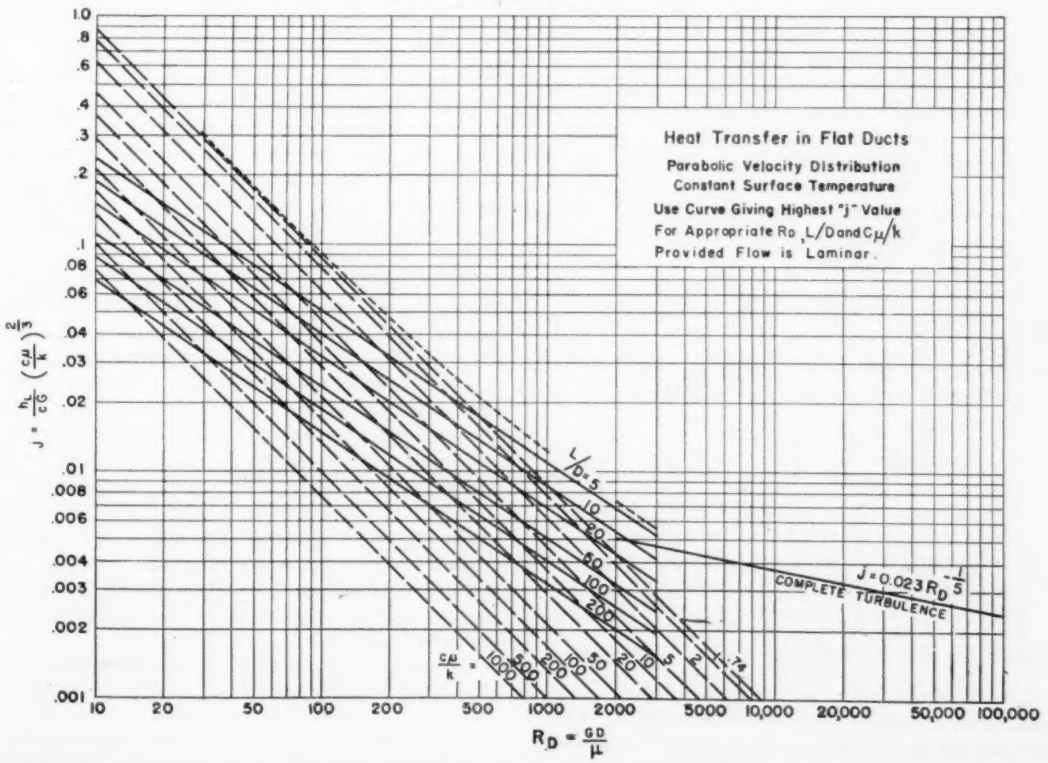

FIG. 4 THEORETICAL CORRELATION OF HEAT-TRANSFER FACTOR AND REYNOLDS' NUMBER FOR FLAT DUCTS FOR FLOW WHICH IS DEFINITELY LAMINAR OR DEFINITELY TURBULENT

When the flow is definitely turbulent, the data for all fluids may be approximated by a single curve, as is well known. This was one of the original reasons for choosing j and R_D as the variables. This single curve is shown in Figs. 3 and 4, for values of Reynolds' numbers above 2000, although often the flow may not be definitely turbulent unless Reynolds' number is much greater than 2000.

For laminar flow, the analytical results in terms of j and R_D are not correlated by a single curve unless two parameters, L/D (a function of the duct proportions) and $c\mu/k$ (a function of the fluid properties) are maintained constant. Families of curved lines would be necessary to show completely the effects of different values of these parameters. Only one of these curved lines is shown in Figs. 3 and 4, namely, the curved line shown dotted for $L/D = 5$, and for $c\mu/k = 0.74$ (the value for air). The curved lines for other values of L/D and of $c\mu/k$ are not shown, but instead are represented, as will be explained, by the two sets of straight lines which they approach asymptotically as limits.

The straight lines of one set, all parallel, approximate the analytically exact curves for sufficiently low values of R_D; the lines of the other set, likewise parallel but of different slope from the first set, are the approximation for sufficiently high values of R_D (provided the flow remains laminar). For values of R_D, where the steeper asymptote represents the curve, the duct proportion L/D has no effect on the relation between j and R_D, so that the location of this asymptote varies only with $c\mu/k$, as indicated in Figs. 3 and 4. The location of the asymptotes of the other set, however, varies with L/D but is unaffected by $c\mu/k$. For any one particular value of L/D and of $c\mu/k$, the curve of j versus R_D is a curved line joining the asymptote of one set to the asymptote of the other. This curved line is identical in shape to the one shown dotted and is merely transposed in position to fit the proper asymptotes.

Fortunately, the maximum error introduced by ignoring the transition curve and using instead, for any particular case, the appropriate asymptote of each set up to the point of intersection of these two asymptotes is only 13 per cent for round ducts and 17 per cent for flat ducts. This error can be reduced to less than 4 per cent by estimating the location of the appropriate transition curve by the use of a pair of dividers.

Both the magnitude and direction of these errors give the logarithmic-mean basis the same advantage over the arithmetic mean for the asymptotic correlations of j versus R_D, as previously mentioned for the asymptotic correlations of $h_L D/k$ versus Φ. The change from one of these pairs of dimensionless variables to the other pair changes neither the magnitude nor direction of the error in the heat-transfer coefficient computed from the asymptotic correlation.

The relations between the variables j and R_D used in Figs. 3 and 4, and $h_L D/k$ and Φ used for other correlations are

$$R_D = \frac{\Phi\left(\frac{L}{D}\right)}{\left(\frac{c\mu}{k}\right)} \quad \ldots\ldots\ldots\ldots\ldots\ldots [15]$$

$$j = \frac{\left(\frac{h_L D}{k}\right)\left(\frac{c\mu}{k}\right)^{2/3}}{\Phi\left(\frac{L}{D}\right)} \quad \ldots\ldots\ldots\ldots\ldots\ldots [16]$$

For laminar flow, the equations for those asymptotes in Figs. 3 and 4 which depend on $c\mu/k$ (those applicable at low values of R_D) are obtained from Equations [9] and [11] by the foregoing relations, and are

$$j = \frac{3.66}{R_D\left(\frac{c\mu}{k}\right)^{1/3}} \text{ (round ducts, Fig. 3)} \ldots\ldots\ldots [17]$$

$$j = \frac{7.60}{R_D\left(\frac{c\mu}{k}\right)^{1/3}} \text{ (flat ducts, Fig. 4)} \ldots\ldots\ldots [18]$$

The equations for the asymptotes which depend on L/D (applicable at high values of R_D, provided the flow remains laminar) are obtained from Equations [8] and [10] by the use of Equations [15] and [16], and are

$$j = \frac{1.615}{(R_D)^{2/3}(L/D)^{1/3}} \text{ (round ducts, Fig. 3)} \ldots\ldots [19]$$

$$j = \frac{1.850}{(R_D)^{2/3}(L/D)^{1/3}} \text{ (flat ducts, Fig. 4)} \ldots\ldots [20]$$

The curved lines joining the asymptotes for $c\mu/k$ of 0.74 and L/D of 5, shown dotted in Figs. 3 and 4, were obtained by the use of Equations [15] and [16] and the comparatively exact relation between $h_L D/k$ and Φ shown in Table 1 and Fig. 2. The corresponding curved line joining any other two asymptotes will have the same shape as this dotted curve, but will be transposed, as previously explained.

For completely turbulent conditions, a formula proposed by Colburn (4) on the basis of test data for round ducts from many sources, as a convenient approximation is

$$j = 0.023(R_D)^{-1/5} \ldots\ldots\ldots\ldots\ldots [21]$$

This relation is shown as the single straight line in the right-hand portions of Figs. 3 and 4.

Transition Between Laminar and Turbulent Flow

The flow may, however, be neither laminar nor completely turbulent, but of an intermediate nature, in which case the heat-transfer coefficient will be between the value calculated for laminar flow and the value for turbulent flow. The range of Reynolds' numbers covered by this transition begins not far from a Reynolds number of 2300, but depends also on μ_m/μ_f as explained by Colburn (4), and may extend upward as high as a Reynolds number of 10,000 for large values of L/D, but not as high for smaller values of L/D.

Unfortunately, a set of curves representing the transition from the curves of j versus R_D for laminar flow to the curve for completely turbulent flow are not available for flat ducts, and for round ducts only the tentative empirical transition curves proposed by Colburn (4) are available. The latter curves, although themselves on the logarithmic-mean basis, were chosen to fit the curves for laminar flow based on the arithmetic-mean temperature difference, a procedure which, while useful as a temporary expedient, is not fundamentally sound. Availability of the present correlation on the logarithmic-mean basis gives opportunity for a revised choice of these transition curves on a sounder basis. No further consideration is given this choice here, however, since it is a major problem in itself, requiring both critical study of extensive existing data and experiments to obtain additional test data, particularly for flat ducts.

In practical applications of the foregoing analytic results, deviations from the assumptions used in the analyses require consideration. The likelihood and effect of deviations from constant wall temperature, from constant fluid properties, and from parabolic velocity distribution are considered subsequently. Deviation from the other assumptions are generally negligible.

Variation of Wall Temperature

If the wall temperature is not constant, the data presented here do not apply, in general, but if the variation of the wall temperature is linear, the approximation given by Equation [6] for round ducts remains valid for values of Φ above 2000, according to Lévêque's analysis (3), providing the wall temperature is taken as

$$t_w = t_{w1} + \frac{3}{5}(t_{w2} - t_{w1}) \quad [22]$$

This same expression for t_w should also apply to the approximation Equation [7] for flat ducts, for values of Φ above 400, by reasoning similar to Lévêque's. For lower values of Φ, Equation [22] has sometimes been used to correlate data in the absence of any rational or empirical basis.

If the heat input per unit length is constant, the wall temperature will in general be neither constant nor linear. In the limiting case for very small values of Φ, however, it will become linear, and analysis of the heat-transfer phenomena becomes relatively simple. The results are here expressed, however, not in terms of an equation for the wall-temperature variation, but in terms of the local heat-transfer coefficient, the significance and values of which have already been discussed.

Free Convection and Variation of Fluid Properties

The relations derived previously, assuming parabolic velocity distribution, do not take account of the transverse and longitudinal variation of fluid properties with temperature. The variation of viscosity will tend to produce nonparabolic velocity distribution, and the variation of density will tend to produce free convection currents in large ducts at low velocities of flow. The change in the velocity distribution has recently been analyzed (11), but not its effect on the heat transfer.

To allow both for the effects of free convection in horizontal round ducts and for the transverse nonuniformity of viscosity, Colburn (4) suggested an empirical correction factor ϕ which appears in the approximate Equation [3] as follows[4]

$$\frac{h_a D}{k_f} = 1.615\left(\frac{cGD^2}{k_f L}\phi\right)^{1/3} \quad [23]$$

where

$$\phi = \frac{\mu_m}{\mu_f}(1 + 0.015G_r^{1/3})^3 \quad [24]$$

Later, Sieder and Tate (5) proposed, as an alternative to Equation [23], the empirical equation

$$\frac{h_a D}{k_m} = 1.86\left(\frac{cGD^2}{k_m L}\right)^{1/3}\left(\frac{\mu_m}{\mu_w}\right)^{0.14} \quad [25]$$

which is equivalent to multiplying $h_a D/k_m$ from the approximate Equation [3] by a correction factor of 1.15 $(\mu_m/\mu_w)^{0.14}$. The analytically derived equations modified by these correction factors seem preferable to the empirical equations proposed earlier by King (8) and McAdams (9).

For flat ducts, correction factors similar to those for round ducts are presumably appropriate, provided the proper constants are used. For air, the variation of viscosity with temperature is too small to justify evaluation of these constants from the available test data, which are discussed later. For liquids, some significant data have been published by Bays and McAdams (12) for the heat transfer to a falling oil film which, if they were correlated by the proper theoretical relations given in this paper (Table 1 or Fig. 2) might indicate the proper constants for the correction factors. Until these constants are determined, the use for flat ducts of the correction factors for round ducts is suggested.

[4] The coefficient of Equation [23] as published in Colburn's paper (4) was 1.5, an empirical value, not 1.615, but reference to the original source (3) and to other authors indicates that 1.615 is the theoretically correct value.

Nonparabolic Velocity at Entrance

The analytical solution for parabolic velocity distribution should be applicable, according to the subsequent considerations, even to cases where the velocity distribution at the entrance of the heat-transferring duct is not parabolic but uniform, except when the duct is extremely short.

It is known that the velocity distribution, if initially uniform, gradually changes to parabolic with increasing distance from the entrance. In the initial part of this transition, the heat transfer and velocity distribution can be analyzed by the methods which have been established for a plane surface with fluid flowing parallel thereto (13). The correlation for a plane (14), expressed in terms of Φ is for laminar flow

$$\frac{h_i D}{k} = 0.664(\Phi)^{1/2}\left(\frac{c\mu}{k}\right)^{-1/6} \quad [26]$$

It can also be shown that the heat transfer will in general exceed (or, in the limit, equal), both the value given by the formula for the plane (of the same length as the duct) and the value given by the formula for the duct with parabolic velocity distribution. Hence, whichever of these two formulas gives the higher value should be used, and even this higher value may be somewhat low.

A reasonable choice for the value of L/D to divide short round ducts, where Equation [26] is preferable, from longer ducts, where Equation [3] or [6] is preferable, is the value where Equation [26] and Equation [6] give the same result. It can easily be shown that this choice corresponds to

$$\frac{L}{D} = 4.8\,\frac{R_D}{1000} \text{ (for round ducts)} \quad [27]$$

For substantially complete establishment of parabolic velocity distribution, the minimum value of L/D is only 35 per cent higher (9).

For flat ducts, similar analysis, applied to Equations [7] and [26] gives

$$\frac{L}{D} = 2.1\,\frac{R_D}{1000} \text{ (for flat ducts)} \quad [28]$$

Since R_D cannot usually exceed 2300 with laminar flow, Equation [26] requires consideration only for round ducts where L/D is less than 11, and for flat ducts where L/D is less than 4.8, conditions which are relatively rare.

Test Data for Heat Transfer in Flat Ducts

In connection with another development, the authors had occasion to test the heat transfer for laminar flow of air in relatively flat ducts. The ducts were 0.311 in. × 2 in. in cross section and 6 in. long, formed by a group of parallel flat copper fins maintained at approximately constant temperature. The results of these tests are shown in Fig. 5, R_D being calculated by using the viscosity of air at the mean film temperature. In the test results, $\frac{c\mu}{k}$ was used as 0.74, since air was used, and this value is practically independent of temperature. The L/D for these ducts was 11.1. Although they were not wide enough to be considered perfect "flat ducts," the use of their equivalent diameter in L/D should tend to offset this discrepancy. The air was thoroughly mixed after leaving the duct before the temperature was measured.

Additional data are available from some tests conducted by G. L. Younts of the General Electric Company in 1936. The ducts were 3 in. wide and from 4 in. to 36 in. long, ranging from $^1/_4$-in. to $^1/_{64}$-in. spacing between plates. Particular precaution was taken to eliminate turbulence at the inlet to the ducts by using well-rounded approaches. The results of these tests are shown in Fig. 5 for an L/D ratio of 8.7, 26, and 50. Again R_D was calculated using the viscosity of air at the mean film temperature.

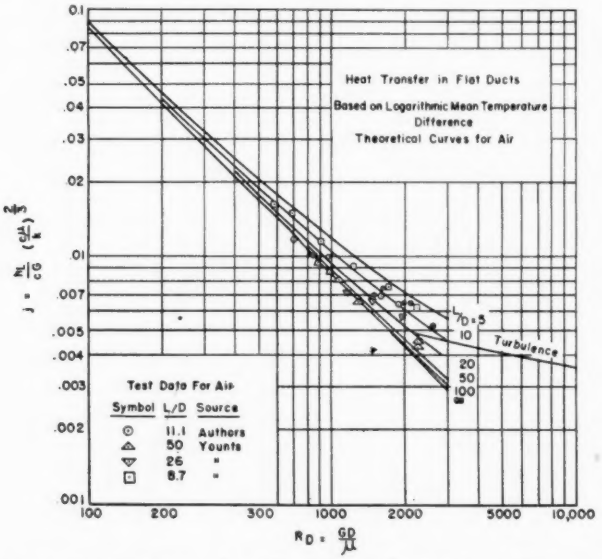

FIG. 5 COMPARISON OF TEST DATA WITH THEORETICAL CORRELATION OF HEAT-TRANSFER FACTOR AND REYNOLDS' NUMBER FOR LAMINAR FLOW OF AIR IN FLAT DUCTS

Although in these tests provision was not made for thorough mixing of the air before measuring its outlet temperature, the trend of the results for the range of the points shown is nevertheless consistent with the theoretical curves.

Some test data for air in flat ducts, by Washington and Marks (15) are in fair agreement with the theoretical curves in Fig. 5 for Reynolds' number above 2000 in the laminar region. However, for lower values of Reynolds' number their data droop below the theoretical curves. Because their technique of measuring outlet-air temperatures at low flows is of questionable accuracy, however, their data are not considered as reliable as the other test data and the theoretical curves given in this paper, and accordingly are not shown in Fig. 5.

Some test data for falling-oil films have been published by Bays and McAdams (12) but require further analysis as already explained to determine the effect of nonparabolic velocity distribution caused by the variation of viscosity with temperature.

The theoretical curves shown in Fig. 5 are the results for laminar flow of air as obtained from analysis as outlined in this paper. The agreement between the test data shown and these theoretical curves seems reasonably good. There is insufficient evidence, however, from these test data to verify completely the analytical curves for flat ducts. More tests, particularly for other fluids than air and other L/D ratios are necessary before these theoretical results can be considered well established for practical conditions.

For round ducts, test data are not considered here, since their agreement with the theoretical results has been extensively reviewed by others (4, 5, 16).

SUMMARY

Heat-transfer data for laminar flow in both round and flat ducts are presented on various bases of correlation, as specified in the following:

The theoretical results, obtained under specified assumptions, expressing hD/k as a function of cGD^2/kL are presented on three different temperature-difference bases (inlet difference, arithmetic mean, and logarithmic mean) as shown graphically in Figs. 1 and 2; numerically in Table 1; and, for restricted ranges of the variables, by Equations [3] through [11]. Convenience in any particular application determines which basis is to be used.

Theoretical lower limits of the local heat-transfer coefficient far from the duct entrance are presented in Table 2, both for constant wall temperature and for constant heat input per unit length.

The theoretical results are also correlated, in Figs. 3 and 4, in terms of the heat-transfer factor j, as defined by Colburn (4), as a function of Reynolds' number, using the logarithmic-mean temperature-difference basis. Figs. 3 and 4 provide a consistent and convenient basis for comparisons between laminar-flow and turbulent-flow heat-transfer data.

Corrections to the theoretical results to account for practical deviations from the assumptions are reviewed. Lévêque's correction (3) for the variation of wall temperature is given by Equation [22]. The corrections for free convection and for the transverse variation of viscosity proposed by Colburn (4) and by Sieder and Tate (5) for round ducts are presented in Equations [23], [24], and [25]; the validity of these for flat ducts is not known. Equation [26] is given for the heat-transfer coefficient close to the duct entrance. This equation is to be used for ducts shorter than specified by Equations [27] and [28] if parabolic velocity distribution is not already established at the entrance.

Test data for laminar flow of air in flat ducts are presented in Fig. 5 and seem to confirm the theoretical results, but the narrow range of variables covered by these test data is insufficient to verify completely the theoretical results.

Discussion

MAX JAKOB.[8] One item of this valuable paper coincides with a calculation recently published by the writer,[9] i.e., the formula $h_z = C_1 k/b$ for the case of homogeneous heating of a long duct from outside. The writer has determined C_1 for an annular space, the thickness $s = 2b$ of which is so small compared with the radius that the curvature can be neglected, i.e., for an infinitely extended plane duct.

For the case of heating the conduct from one side only, whereas the other side is perfectly insulated, the factor 13/35 in the writer's Equation [17][6] corresponds to $1/2C_1$ in the foregoing formula, so that $C_1 = 35/26 = 1.35$.

For heating from botb sides by analogous calculation instead of 13/35, the factor 17/70 is obtained and from this it follows $C_1 = 35/17 = 2.06$, which is in complete agreement with the last value in Table 2 of the authors' paper.

The authors mention the effect of free convection currents. The writer wishes to point to an analysis[7] of Holden and White's experiments on a viscous liquid, which was heated from outside. Assuming very different distributions of velocity, we calculated the temperature distributions at the end of the tube, and found that the measured values could be explained only by the assumption of radial-flow components in the liquid which were due to local changes of viscosity with temperature and were directed outward after the inlet, and inward close to the end of the tube.

AUTHORS' CLOSURE

The value of the constant C_1 supplied by Dr. Jakob for the case of a flat duct heated from only one side, is a useful addition to data provided in the paper. It is interesting to note that the value of 1.35 thus given for C_1 is about 66 per cent of the value 2.06 applicable for heating from both sides, whereas one might expect at first thought that it would be nearer 50 per cent, since the maximum distance the heat has to travel transversely from the heated surface is twice as great when only one side is heated. The excess of 66 per cent over 50 per cent represents the influence of the differences in the velocity distribution, relative to the heated surface, for the two cases.

The existence of radial-flow components produced by free convection, mentioned by Dr. Jakob, is one of the deviations from the theoretical assumptions which the empirical correction factors represented in Equations [24] and [25] are intended to take account of. Although quantitative knowledge of these components is of interest, it seems likely that the distribution of the free convection flow is too complex to justify analytic deviation of the correction factors, so that correction factors obtained empirically from heat-transfer tests will have to continue to be used, although improvements in accuracy may perhaps be obtainable.

The use of the logarithmic-mean temperature-difference basis for laminar flow heat-transfer data has an additional advantage, over the use of the more customary arithmetic-mean basis, which may not be sufficiently obvious in the paper. When the temperature distribution of the surface is not uniform, and, in general, not even known, as is likely to be the case in electrically heated surfaces such as those of oil-cooled transformers, it is helpful to use a temperature difference basis (such as the logarithmic mean) which makes the mean heat-transfer coefficient for the whole surface approach the same limit, and be of the same order of magnitude, as the local heat-transfer coefficient at the hottest part of the surface (at or near the fluid outlet).

Performance Characteristics of Dye Jigs

By W. B. HEINZ,[1] BOUND BROOK, N. J.

Examination of the tension, speed, and power characteristics of regular and "tensionless" dye jigs shows conclusively that the tensionless type maintains more uniform low tension in the cloth with less operator attention. However, it is impracticable to maintain as high a tension as in a regular jig, in spite of the larger motor which must be used. Although the cost of power is at least twice as much as for a regular jig handling the same production the difference is usually not of commercial importance. The cloth speed is not constant. When rolling a 30-in. roll on to a 6-in. beam, the cloth speed more than doubles after the start. The present paper derives formulas which may readily be used for computing the performance of any jig and batch of cloth. Thus are disclosed ways toward improvements in both types of jigs which should overcome their respective disadvantages. Such methods of improvement are believed to be of interest both to manufacturers and to users of dye jigs.

Nomenclature

THE following nomenclature is used in the paper:

- B = width of cloth, ft
- f = total friction torque in each roll, lb-ft
- dF = radial force acting on area Bds, lb
- P = total power output of motor, ft-lb per sec
- q = driving torque, winding roll, lb-ft
- q_b = driving torque, unwinding roll, lb-ft
- Q = main drive torque, lb-ft
- r = instantaneous radius of winding roll, ft
- r_b = instantaneous radius of unwinding roll, ft
- r_1 = radius of beam (empty), ft
- r_2 = radius of roll containing entire batch, ft
- s = circumferential distance along surface of roll, ft
- T = tension in cloth, lb
- U = time per pass (for an end to pass from one roll to the other), sec
- W = energy delivered to jig by motor while an entire end passes from one beam to the other, ft-lb
- β = torque applied by brake to unwinding roll, lb-ft
- θ = angular measurement in cross section of roll, radians
- δ = thickness of cloth on roll, ft
- π = 3.1416 (ratio of circle circumference to its diameter)
- ω = winding-roll speed, radians per sec
- ω_b = unwinding-roll speed, radians per sec
- Ω = main-drive speed, radians per sec
- eu = conventional energy unit
- fu = conventional force unit
- pu = conventional power unit
- tu = conventional cloth-thickness unit

Fundamental Considerations

With few exceptions, dye jigs of today are fundamentally the same as they were in the early days of the textile industry. Most of the improvements which have been incorporated consist almost exclusively in better design and construction of the same simple mechanism, namely: Two sets of shafts and bearings capable of carrying rolls of cloth, a means of driving each of them in turn so that the cloth will wind upon it from the other; and a means of preventing the unwinding roll from overrunning. It might be thought that nothing new could be learned about such a simple arrangement by a theoretical study of its mechanics. As it frequently happens, however, a mathematical analysis has been found useful because it produces quantitative information concerning factors which heretofore have been judged qualitatively by watching machines operate.

Not so simple is the behavior of the so-called "tensionless" jig in which both beams are driven simultaneously through a differential gear. Probably most users of these new machines have contented themselves with qualitative observations of their effect upon cloth speed, tension, power requirements, and final over-all results in quality and rate of production. They may not feel too certain about the actual importance of some of the characteristics as compared with regular jigs, nor of the actual amounts of such differences.

As an early step in the development of certain fundamental improvements to both kinds of jigs, it was found essential to compare their several traits in reliable quantitative terms. The differentially driven jig was analyzed first, with illuminating results. Before these results could be compared with corresponding data for an ordinary jig, it was necessary to apply the same methods to the latter.

The author hopes that the analyses and comparisons of the results given in this paper will stimulate new interest in the finishing industry.

Tensionless Jig

The differentially driven dye jig became known as a tensionless jig because, among its other characteristics, it can run cloth back and forth through the bath with practically zero tension. However, the brakes can be adjusted for considerable cloth tension also, within the practical limitations of motor power and brake cooling capacity.

Although there are certain undeniable advantages in the differential-drive arrangement, a prospective purchaser should not overrate them in comparison with corresponding disadvantages. In the first place the speed is not constant, as claimed. A larger motor is required; and even with the larger motor, it cannot operate at as high tension as a regular jig because the brakes heat too much. Although the user may not notice it, the cost for power to drive tensionless jigs is more than twice what it would be for regular jigs doing the same work.

A mechanical analysis provides means for computing exact information about advantages and disadvantages. How nearly constant is the cloth tension, the brake setting being left always the same? How much does the cloth speed change from beginning to end of each pass? What is the maximum tension that the jig can handle with a certain-size motor and brakes? How much larger will its power bill be than that of a regular jig when operating under prescribed tension? All these questions can be answered definitely by putting numbers into formulas which have been developed. They all follow from simple fundamentals,

most of which appear directly from an examination of Fig. 1. Symbols are explained in the nomenclature at the beginning of the paper.

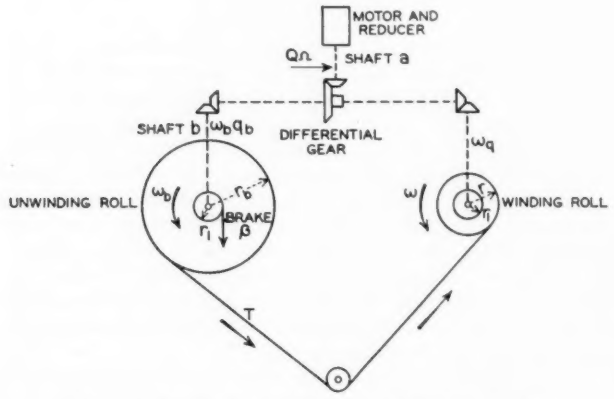

FIG. 1 SCHEMATIC DIAGRAM OF TENSIONLESS JIG

The Differential Gear

The differential gear is exactly the same in principle as that which is used in every automobile. To simplify the analysis, however, most of the speed reduction is assumed to be incorporated with the motor and reducer which drives the shaft a. In the differential gear itself, there is a 2:1 reduction such that the speed of the two driven beams (when turning at the same speed) is half the speed of the driving shaft a. At all beam speeds, their sum is equal to the speed of a.

Symbolically

$$\omega + \omega_b = \Omega \quad [1]$$

This is an inherent characteristic of any differential gear with a 2:1 ratio.

Another inherent characteristic of this gear is that the torques in all three shafts are equal at all times (small differences in friction being neglected).

Thus

$$Q = q = q_b \quad [2]$$

Torques acting on the unwinding beam are the applied torque of the motor, the torque caused by the cloth pulling with tension T at the radius r_b of the unwinding roll, and the opposing torques of bearing and brake friction. Corresponding torques act on the winding beam except that its brake is not in action. These torques on the unwinding and winding beams are related according to Equations [3] and [4], respectively

$$q_b + r_b T - \beta - f = 0 \quad [3]$$

$$q - rT - f = 0 \quad [4]$$

From Equations [2], [3], and [4], we find how the cloth tension depends upon the roll diameters

$$T = \frac{\beta}{r + r_b} \quad [5]$$

The cloth speed $r\omega$ is always equal to the peripheral speed of either or both rolls.

$$r\omega = r_b\omega_b$$

Combining with Equation [1] and solving for $r\omega$, we find that

$$\text{Cloth speed} = r\omega = \frac{\Omega r r_b}{r + r_b} \quad [5a]$$

The torque delivered by the main drive can also be computed from the same equation

$$Q = f + \frac{\beta r}{r + r_b} \quad [6]$$

The power required to drive the jig follows directly, by multiplying the main-drive-shaft torque by its speed.

Thus

$$P = Q\Omega = \frac{\Omega}{r + r_b}\left[\beta r + f(r + r_b)\right] \quad [7]$$

The power computed from Equation [7] represents the instantaneous power delivered by the main drive. It changes continuously as the roll diameters change. It cannot simply be multiplied by the time the jig is in operation to find the energy consumption (kilowatthours) which fixes the power bill. The total energy must be computed by summing up the products of all of the instantaneous power readings, multiplied by the intervals of time they continue. In terms of the calculus, this is done by an integration

$$W = \int_{r=r_1}^{r=r_2} P\,dt \quad [8]$$

In order to express the increment of time dt, in terms of the winding-roll radius r, we must find a relationship showing the rate at which the radius changes as the cloth progresses. This involves the winding-roll speed and the thickness of each wrap[2] on the roll according to Equation [9] since, during each revolution, the radius increases by the thickness of one extra wrap of cloth. The rate of change of radius with respect to time is

$$\frac{dr}{dt} = \frac{\delta\omega}{2\pi} \quad [9]$$

It follows that

$$dt = 2\pi dr/\delta\omega \quad [9a]$$

The energy input of Equation [8] now becomes

$$W = \frac{2\pi}{\delta}\int_{r_1}^{r_2}\frac{P}{\omega}\,dr \quad [10]$$

In order to integrate Equation [10] we must express the speed of the winding roll ω in terms of its radius r. Since the peripheral speeds of the two rolls are always equal (the cloth speed), their rotational speeds are inversely proportional to their radii. Knowing this, we can modify Equation [1] as follows

$$\Omega = \omega\left(\frac{r}{r_b} + 1\right)$$

$$\omega = \frac{\Omega r_b}{r + r_b} \quad [11]$$

Equation [11] expresses the winding-roll speed in terms of the main-drive speed and the two roll radii. However, we still have to convert the radius of the unwinding roll into terms of the winding-roll radius. This additional relationship follows from a consideration of the total cross-sectional areas of the cloth wound on the two rolls. Since the amount of cloth in the batch does not change, the sum of the cross-sectional areas on the two

[2] It has been assumed that changes in tension do not influence the effective thickness of the cloth as it is wound on a roll. Although this is not strictly correct, the error thereby introduced is believed to be unimportant.

rolls is constant and equal to the cross-sectional area of the total batch when it is wound on one roll. This gives us

$$\pi(r_b^2 - r_1^2) + \pi(r^2 - r_1^2) = \pi(r_2^2 - r_1^2) \quad [12]$$

From Equation [12], we obtain the relationship for the unwinding-roll radius which we need, in terms of the fixed radii of the beam and the roll carrying the entire batch, and the instantaneous radius of the winding roll

$$r_b = \sqrt{r_1^2 + r_2^2 - r^2} \quad [13]$$

We can introduce Equations [7], [11], and [13] into Equation [10], and integrate to find the total energy input required to pass an entire batch from one roll to the other. Equation [14] thus gives the total energy input to the jig, the brake setting being left the same throughout the entire pass and the tension changing as it will

$$W = (\beta + 2f)(r_2 - r_1)\frac{2\pi}{\delta} \quad [14]$$

Equation [14] gives the energy input to the jig in foot-pounds. This must be divided by the motor and drive efficiency and by 2,654,000 to give the total kilowatthours input to the motor, from which the cost of the power can be computed.

Time per End

The power and energy requirements are best compared on the basis of equal time per end for the two types of jigs. The time required for a batch to pass completely from one beam to the other can be computed from equations derived as follows:

The cross-sectional area of cloth on the winding roll is

$$A = \pi(r^2 - r_1^2) \quad [15]$$

By integrating Equation [9], we arrive at the following general equation for the winding-roll radius, applicable to both tensionless and regular jigs

$$r = \frac{\delta}{2\pi}\int \omega dt + C \quad [16]$$

For a tensionless jig, on introducing the winding-roll speed of Equation [11], and the unwinding-roll radius of Equation [13], we can integrate Equation [16], arriving at

$$t = \frac{2\pi}{\delta\Omega}(r - \sqrt{r_1^2 + r_2^2 - r^2}) + C \quad [17]$$

This gives the time elapsed from the beginning of an end in terms of the instantaneous winding-roll radius r, its initial and final radii r_1 and r_2, and a constant of integration c.

The constant of integration is determined by considering conditions at the beginning of an end when the winding-roll radius is equal to the radius of the empty beam and the time elapsed is zero. We can thus introduce into Equation [17], the values $t = 0$ and $r = r_1$. Then solving for C, the constant of integration, we find that

$$C = r_2 - r_1$$

Equation [17] now takes its complete form

$$t = \frac{2\pi}{\delta\Omega}(r + r_2 - r_1 - \sqrt{r_1^2 + r_2^2 - r^2}) \quad [18]$$

When the total time per end, U, has passed, the entire batch has been wound upon the winding roll. Its radius is now r_2. On substituting these two symbols into Equation [18], we have the desired formula for the time required for a complete end with a tensionless jig

$$U = \frac{4\pi}{\delta\Omega}(r_2 - r_1) \quad [19]$$

Regular Jig

The regular jig has advantages in low cost, ease and economy in operation and maintenance. It is simple, it has high tension capacity with moderate-size motor and brakes, and its power consumption is low. Although its cloth speed changes widely from beginning to end of each pass, in practice, this is probably of little actual importance. Most of the dyeing is said to take place while the cloth is padded up on the rolls, and changes in the time actually spent in passing through the bath do not have much effect upon the levelness of dyeing.

The machine being so simple, its mechanical analysis is also simple.

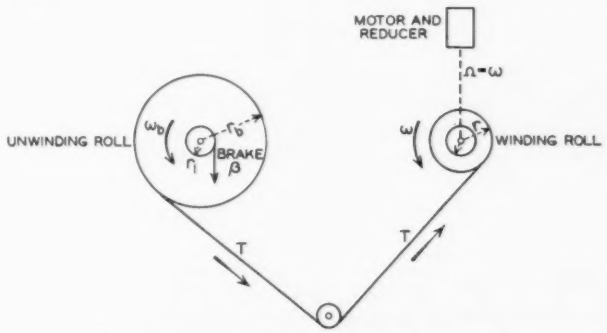

Fig. 2 Schematic Diagram of Regular Jig
(Brake and drive for reverse direction not shown.)

In a regular jig, Fig. 2, the tension in the cloth is that which is necessary to turn the unwinding roll against the friction and the brake torque

$$T = \frac{\beta + f}{r_b} \quad [20]$$

The cloth speed always being the same as the peripheral speed of the rolls, we can write

$$\text{Cloth speed} = r\omega = r\Omega \quad [21]$$

Here the main-drive speed and the winding-roll speed are always equal, all of the gear reduction being assumed to be associated with the motor.

The total power consumed is that absorbed by the brake and miscellaneous friction in the unwinding roll plus the friction in the winding roll. Multiply these torques by their respective roll speeds and add

$$P = (\beta + f)\omega_b + f\omega \quad [22]$$

Since the surface-roll speeds are always equal to the cloth speed and to each other

$$r\omega = r_b\omega_b$$

$$\omega_b = r\omega/r_b \quad [23]$$

Substituting Equation [23] in Equation [22], and noting from Fig. 2 that the winding roll has been assumed to be directly connected to the main drive shaft ($\omega = \Omega$), we now arrive at the power equation

$$P = \frac{\Omega}{r_b}[\beta r + f(r + r_b)] \quad [24]$$

On the assumption that the operator succeeds in adjusting the brake on a regular jig so that the tension is maintained constant throughout the entire pass, the general energy integral develops according to Equation [25]. This equation represents the total mechanical energy consumed per end by a regular jig

$$W = \int_{r=r_1}^{r=r_2} P\,dt$$

$$W = \frac{2\pi}{\delta}\left[f(r_2 - r_1) + \frac{T}{2}(r_2^2 - r_1^2)\right] \quad [25]$$

Time per End

The time required for a complete end in a regular jig can be computed from the general Equation [16] by a procedure similar to that used for a tensionless jig. For a regular jig, however, the winding-roll speed is constant ($\omega = \Omega$). On this basis, the integration of Equation [16] is simple

$$t = \frac{2\pi}{\delta\Omega}(r - r_1) \quad [26]$$

Again, substituting the symbols representing conditions at the completion of an end ($t = U$, $r = r_2$), we quickly find that the time required per end for an ordinary jig is

$$U = \frac{2\pi}{\delta\Omega}(r_2 - r_1) \quad [27]$$

On comparing Equations [19] and [27], the formulas for times per end for tensionless and regular jigs, we note that the first appears to be twice the second. This simply means that if we want a tensionless and a regular jig to handle a certain-size batch in the same time we must make the driving speed Ω, of the tensionless jig twice that of the regular jig. This observation is, of course, based upon the conventions relating to gear ratios which have been set up in Figs. 1 and 2.

With suitable modifications, all these formulas apply equally well to any other gearing arrangement.

Summarizing, comparisons between tensionless and regular jigs can be based upon the foregoing equations, as follows:

Characteristic	Equation no. Tensionless	Equation no. Regular
Tension of cloth	[5]	[20]
Speed of cloth	[5a]	[21]
Time per end	[19]	[27]
Power	[7]	[24]
Energy consumed per end	[14]	[25]

Numerical Examples

In order to visualize the significance of the foregoing equations, jigs have been selected which have beam diameters of 6 in. The batch of cloth being handled makes a roll 30 in. in diam when rolled on one beam. Thus, $r = 3$ in., $r_2 = 15$ in.

In order to simplify the computations and to make the results as general as possible, a group of conventional units has been adopted. They are listed in the nomenclature at the beginning of the paper. For purposes of tension comparison, for example, the cloth tension when the two rolls are of equal diameter has arbitrarily been termed one "force unit," *fu*. When the rolls are equal in size, their radius is

$$r_b = r = 10.81 \text{ in.}$$

computed from Equation [13].

The total frictional torque comprising bearing friction, liquid forces on the cloth passing through the bath, etc., has been assumed to be 0.1, its unit being the product of force units multiplied by inches ($fu \times$ in.). This amount of frictional torque is assumed to be associated with each roll.

The brake torque required to create unit cloth tension under the conditions assumed can be computed from Equations [5] and [13] for a tensionless jig, its value being $\beta = 21.62$.

For a regular jig, the brake torque is computed from Equation [20], giving $\beta = Tr_b - f = 10.71$.

The mechanical power input to a regular jig is defined as one power unit *pu*, when the tension is one force unit and the roll sizes are equal. Thus, the sum of the brake torque on the unwinding roll plus the friction torque on both rolls, multiplied by the roll speed (the same for both) equals unity

$$(\beta + 2f)\Omega = 1$$

Substituting the previously established values for the brake torque and the friction, we find that the main-drive speed for a regular jig must be $\Omega = 0.0917$.

Since it is logical to compare two types of jigs upon the basis of equal total time per end, we note by comparing Equations [19] and [27] that the main-drive speed for a tensionless jig must be twice that for a regular jig. Consequently, for a tensionless jig, $\Omega = 0.1834$.

Cloth Tension

Now we can substitute the foregoing values in the formulas which have been established, arriving at numerical formulas for the cloth tension in terms of the winding-roll radius. Thus, from Equations [5] and [13] we arrive at the following expression for the cloth tension in a tensionless jig

$$T = \frac{21.6}{r + \sqrt{234 - r^2}}$$

Similarly, for a regular jig, the cloth tension is computed from Equations [20] and [13] to be

$$T = \frac{10.8}{\sqrt{234 - r^2}}$$

Curves representing these formulas are plotted in Fig. 3.

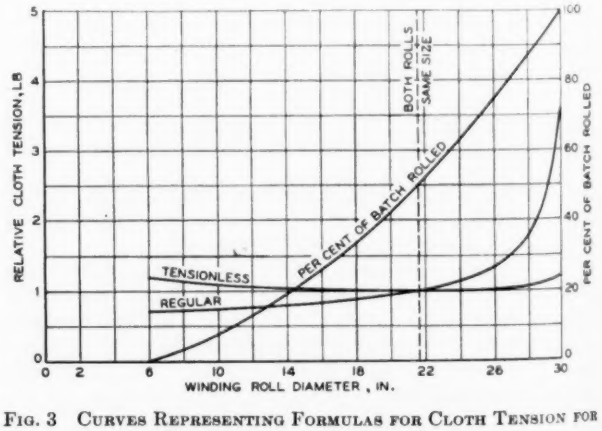

Fig. 3 Curves Representing Formulas for Cloth Tension for Tensionless and Regular Jigs

This illustration shows how rapidly the tension on a regular jig would rise toward the finish of an end if the operator did not loosen the brake. It is evident that no operator can be expected to achieve very uniform tension by periodic brake adjustments. If let alone, the tension would change over a range of nearly 5 to 1; and an operator is expected to keep the tension always the same!

A tensionless jig under the computed conditions keeps the tension always within a total range of only 1.2 to 1.

Cloth Speed

The speed of the cloth is always equal to the peripheral speed of the winding roll. Consequently, for a tensionless jig from Equation [5a] we can write

$$\text{Cloth speed} = r\omega = \frac{0.183\, r\sqrt{234 - r^2}}{r + \sqrt{234 - r^2}}$$

Similarly, for a regular jig, the cloth-speed equation is

$$\text{Cloth speed} = r\omega = r\Omega = 0.092\, r$$

The cloth speeds of various roll diameters are shown in Fig. 4.

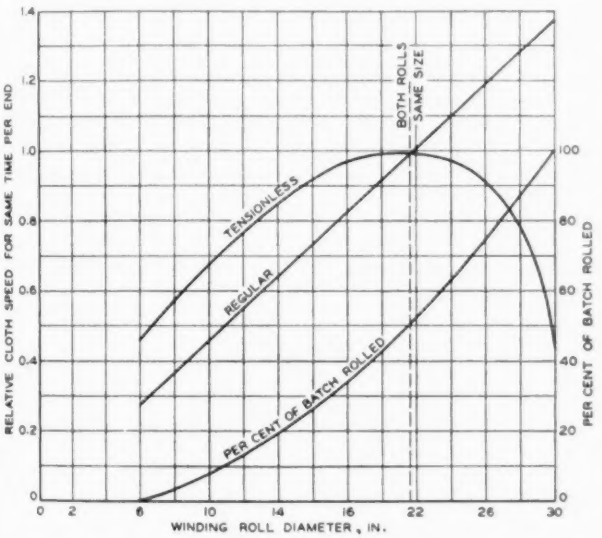

FIG. 4 CLOTH SPEEDS FOR VARIOUS-DIAMETER ROLLS

Evidently, the speed of cloth in a tensionless jig can change during an end through a range of more than 2 to 1. However, a regular jig is worse. Its cloth speed shifts over a range of 5 to 1. This would be an important disadvantage if it were not for the fact that most of the exhaust is said to take place while the cloth is padded up on the rolls, and not while it is actually passing through the bath.

The curves of Fig. 4 were computed for equal-size batches and equal total times required for an end.

Time per End

The total time required for a complete end has, for comparison, been set the same for both tensionless and regular jigs. Thus, from either Equation [19] or Equation [27] we find that $U = 821$. These units of time are neither seconds nor minutes, but instead, certain arbitrary conventional time intervals which involve the conventions which have been established for other units. For the cloth thickness there has been used the dimension $\delta = 1$ cloth thickness unit, *tu*.

Power

From Equations [7] and [13], the following formula for the mechanical power input to a tensionless jig results

$$P = \frac{0.183}{r + \sqrt{234 - r^2}}\left[21.6\, r + 0.1\,(r + \sqrt{234 - r^2})\right]$$

A corresponding formula for power input to a regular jig from Equations [24] and [13] is

$$P = \frac{0.092}{\sqrt{234 - r^2}}\left[10.7r + 0.1(r + \sqrt{234 - r^2})\right]$$

In practice, the operator of a regular jig attempts to keep his brake adjusted so that the cloth tension stays about the same. Otherwise it would increase too much toward the finish of each end. If he were to succeed in maintaining constant tension by adjusting the brake, the power would be substantially proportional to the winding-roll radius. A curve showing the power under these conditions of assumed constant tension accompanies those for the foregoing two equations in Fig. 5.

Here is illustrated the most striking difference between

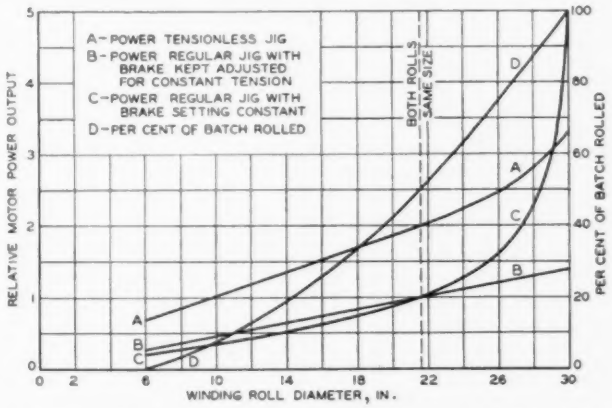

FIG. 5 POWER REQUIRED UNDER CONDITIONS OF ASSUMED CONSTANT TENSION

regular and tensionless jigs. At the time when one half the batch has been rolled (both rolls are the same size), the power required by a tensionless jig is twice that of a regular; and more than twice at other times. As more cloth is rolled, the operator of a regular jig keeps the power down by loosening the brake instead of allowing it to go up fast as the chart shows. With a tensionless jig he cannot do that without dropping off the tension. Consequently, the power for a tensionless jig goes on up at the end of the batch. That is why the brakes on a tensionless jig run so hot if high tension is set on the machine.

Energy Consumption—Cost of Power

The relative amounts of energy consumed per end for tensionless and regular jigs can be computed from Equations [14] and [25], respectively. On introducing our assumed dimensions, we obtain the following

Tensionless

$$W = (21.6 + 0.2)(15 - 3) \times \frac{2\pi}{1} = 1640 \text{ energy units}$$

Regular (constant tension)

$$W = \frac{2\pi}{1}\left[0.1(15 - 3) + \frac{1}{2}(225 - 9)\right] = 685 \text{ energy units}$$

Thus we find that, under the conditions of our numerical example, a tensionless jig requires 1640/685 = 2.4 times as much energy input for the same production output as a regular jig with correctly adjusted tension. Power costs are in substantially the same ratio.

In actual service, the beam and roll diameters are frequently different from those of the example. Corresponding numerical comparisons can quickly be computed for any other set of

conditions. Such further computations will also show that the tensionless jig is notably advantageous in constancy of cloth tension; but that the user pays for it, not only in higher initial cost for the machine, but also by limitations in tension capacity, by higher installed power demand, and by doubling his power bill for jig dyeing.

There evidently is a need for improvement in dye jigs of both types, to overcome their respective limitations.

Discussion

J. D. ROBERTSON.[3] Mr. Heinz's admirable paper gives a thorough mathematical analysis of the variation in cloth speed and cloth tension, among other operating characteristics, during the passage of a lot of cloth from one beam to the other, both on regular jigs and on so-called tensionless jigs.

According to formula [20] of his paper, the cloth tension on regular jigs varies inversely with the instantaneous radius of the unwinding roll. For any given number of yards in a batch and for a constant setting of the brakes, therefore, the larger the diameter of the beams used the smaller will be the variation in cloth tension from end to end of the batch. In the same way Mr. Heinz's formulas show that the variation in cloth speed is kept very low by using large beams.

It may be of interest, therefore, to consider a difficulty which arises when the comparatively simple modification of increasing the diameter of the beams of regular jigs is made for the purpose of securing approximately constant cloth speed and tension.

It is common experience that the larger the diameter of a roll of cloth on a jig beam the greater the tension required to keep it from "coning" or slipping endwise. This effect is independent of the diameter of the beams. When the character of the cloth being dyed does not permit heavy cloth tension large beams cannot be used because of this endwise slipping.

For any given cloth tension it can be shown that the greater the diameter of the roll, the less the radial pressure between the outside layer of cloth and the layer immediately under it. The writer believes from observation that the endwise slippage of cloth on a large-diameter roll of cloth occurs when the radial pressure between adjacent layers near the outside of the roll drops to the point where the water carried up on the cloth fails to be squeezed out between the outside layer of cloth and the layer of cloth under it.

At this stage the water is carried in between the layers of cloth near the outside of the roll until the additional cloth rolling on top of it continues to build up the pressure of water to the degree required to force its way out at one of the ends of the roll. This explanation can be checked by feeling the roll with the hand when it is running under those conditions. The roll feels very spongy because of the water pocketed between the layers of cloth. When the pressure on the water gets high enough it squirts out, most of it at one end, carrying the cloth with it. Probably what happens is that the selvages, stretching less than the rest of the cloth, hold the water in until the pressure is increased to a sufficient degree to move the selvage sidewise by the amount of its width. This tends to open the space between the layers of cloth, permitting the water to rush out, and making the cloth much looser than it was when the water was between the layers. The cloth rapidly moves endwise from this stage.

The foregoing explanation agrees with the observed fact that larger rolls can be run on regular jigs without coning by slowing them down. Less water is carried up with the cloth at the slow speed.

It may also explain why so-called tensionless jigs can handle larger rolls without coning than regular jigs for a given elapsed time per end.

The percentage increase of cloth speed as the winding roll diameter increases on a regular jig of ordinary (6 to 8 in.) beam diameter is very substantial, carrying considerably more water up as the roll gets larger. The cloth speed on a tensionless jig in comparison is practically constant.

[3] Plant Engineer, Mt. Hope Finishing Co., North Dighton, Mass. Mem. A.S.M.E.

AUTHOR'S CLOSURE

Causes of coning are numerous and difficult to isolate. Analysis of the radial pressure exerted by each lap of cloth as it winds onto a roll indicates that variations in this radial pressure might easily be partly responsible. The author would welcome correspondence from anyone whose observations tend either to confirm or disprove the inferences which are drawn.

The most interesting result of this analysis is the demonstration that there is almost certain to be a soft region toward the center of a roll wound by a regular jig. If the brake setting be left constant from beginning to end of a pass, the radial compression starts out high, declines to some minimum value at the mid-point of the pass, and thereafter rises rapidly again to a high compression at the finish. Correct adjustment of brakes by the operator can prevent the compression from going up again, but it is improbable that this is accomplished very satisfactorily in regular practice.

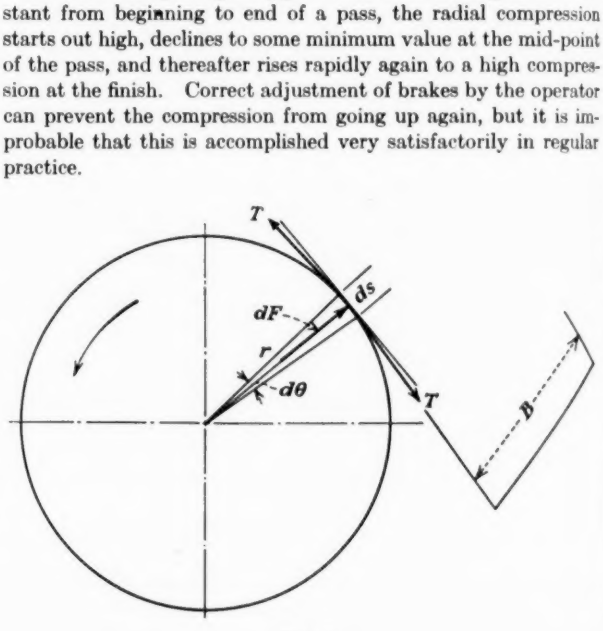

FIG. 6

With reference to Fig. 6, the normal force exerted by an incremental length of cloth ds is

$$dF = 2T \sin \frac{d\theta}{2} = 2T \frac{d\theta}{2} = T\,d\theta, \text{ lb} \quad [28]$$

The radial pressure over the area B in width and ds in length is

$$p = dF/Bds = Td\theta/Brd\theta = T/Br, \text{ lb per sq ft} \quad [29]$$

In a regular jig from Equations [20] and [13] the cloth tension at any instant with constant brake setting is the following

$$T = \frac{\beta + f}{\sqrt{(r_1^2 + r_2^2 - r^2)}}, \text{ lb} \quad [30]$$

Equation [29] consequently takes the following form

$$p = \frac{\beta + f}{Br\sqrt{(r_1^2 + r_2^2 - r^2)}}, \text{ lb per sq ft} \quad [31]$$

If we put into Equations [29] and [31] the same numbers as

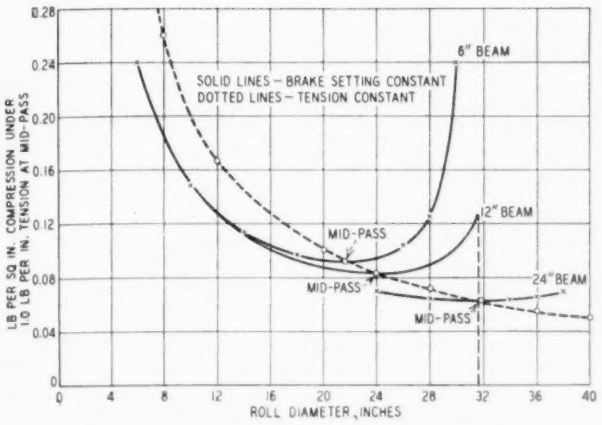

FIG. 7 ROLL COMPRESSION DURING WINDING

were previously used in numerical examples, we obtain curves which appear in Fig. 7. The three solid lines represent the compression created by each lap of cloth as it winds onto a roll from beginning to end of a pass for 6, 12, and 24-in. diameter beams, handling the same size batch of cloth. The brake setting in each case is left constant at such a value as to give the same tension at the mid-point of the batch for all beam sizes.

The dotted line shows the way in which the compression at the surface changes as a pass progresses if the tension in the cloth be always the same. Since this curve depends only upon the external radius of the roll at each instant, it is not influenced by the diameter of the beam within the roll. Consequently, the corresponding sections of this one curve represent conditions for all beam sizes.

The compression at any point within the roll (beneath the surface), of course, depends upon the cumulative effects of instantaneous compression at the surface as the roll builds up, shrinkage within the roll from squeezing out of water, gradual compression, and shrinkage of the fabric itself. These influences are not subject to any simple analysis. Their effects can only be judged by observation or tests in the field.

On examining the curves for the regular jigs, one wonders about the probable effect of faulty tension (ordinary manual control) upon the stability of a roll wound upon normal size beams. The curves show that if the brakes be left unadjusted after the mid-point in a pass, there is a very pronounced minimum compression in the vicinity of the mid-point. The compression rises very steeply thereafter unless the operator promptly and correctly loosens the brakes. As further winding goes on, a soft region is left in the roll. This region is continually subjected to higher and higher shear stresses as the roll radius increases, particularly if the tension be allowed to increase also. It is to be expected that high shear inside the roll might frequently cause slippage in the direction of tighter winding there. Any slippage at all is going to facilitate endwise slippage; and again coning may result.

Successful Mechanical Atomization of Fuel Oil Heavier Than Bunker C

By G. G. MARTINSON,[1] MARCUS HOOK, PA.

The purpose of this paper is to report the difficulties encountered and their successful solution when burning a heavy-petroleum cracking-still residue as a fuel in combination pulverized-coal and fuel-oil burners for the boilers of the American Viscose Company powerhouse at its Marcus Hook plant. Though the problems involved were comparatively simple, the development of a burner arrangement to achieve a solution and the results obtained may be of value to the designers and operators of boilers who are in search of both flexible and efficient combination firing equipment for pulverized coal and fuel oil in boiler plants.

EQUIPMENT of the boiler plant of the American Viscose Company at Marcus Hook consists of three boilers of C.E. type fin-tube waterwall-furnace construction, each having a maximum steam output of 150,000 lb per hr at 425 psi and 700 F total temperature. Fig. 1 shows a side view in cross section of one of these boilers. The furnaces, of the dry-bottom type, have a volume of 7000 cu ft and a waterwall surface of 2300 sq ft. Steam from the boilers is used to drive three 3000-kw turbogenerators and three 2000-kw turbogenerators. Some of the steam is extracted from the turbines at 175 psi and some at 20 psi for plant process duty.

Each boiler is equipped with four Lo-Pul-Co type C.E. combination burners for oil and pulverized-coal firing, the general arrangement being shown in Fig. 2. When firing pulverized coal, the fuel is mixed with tempered primary air at the pulverizers and delivered through the center pipe of the burner assembly, while secondary air is forced through the air preheater by a forced-draft fan and delivered to the burner assembly outside of the pulverized-coal pipe. Control of the secondary air is accomplished by regulating the register shown in Fig. 2 and the speed of the forced-draft fan. Primary-air fans are direct-connected to the bowl-mill motors and, therefore, when using oil as fuel for these furnaces, no primary air is delivered through the coal pipe, combustion depending entirely upon the mixture of the fuel oil and secondary air supplied in the manner described.

Control of the firing rate of each of these units is completely automatic for both types of firing equipment and, after setting the proper air-fuel ratio for the type of fuel used, the controls maintain this ratio automatically within close limits throughout the range of the controls. An increase in steam demand causes the controls to increase the air supplied to the burners before increasing the fuel supply and, with a decrease in load, the fuel supply is decreased before the air supply is reduced. This cycle of operations is very effective in preventing smoke when changes in load occur.

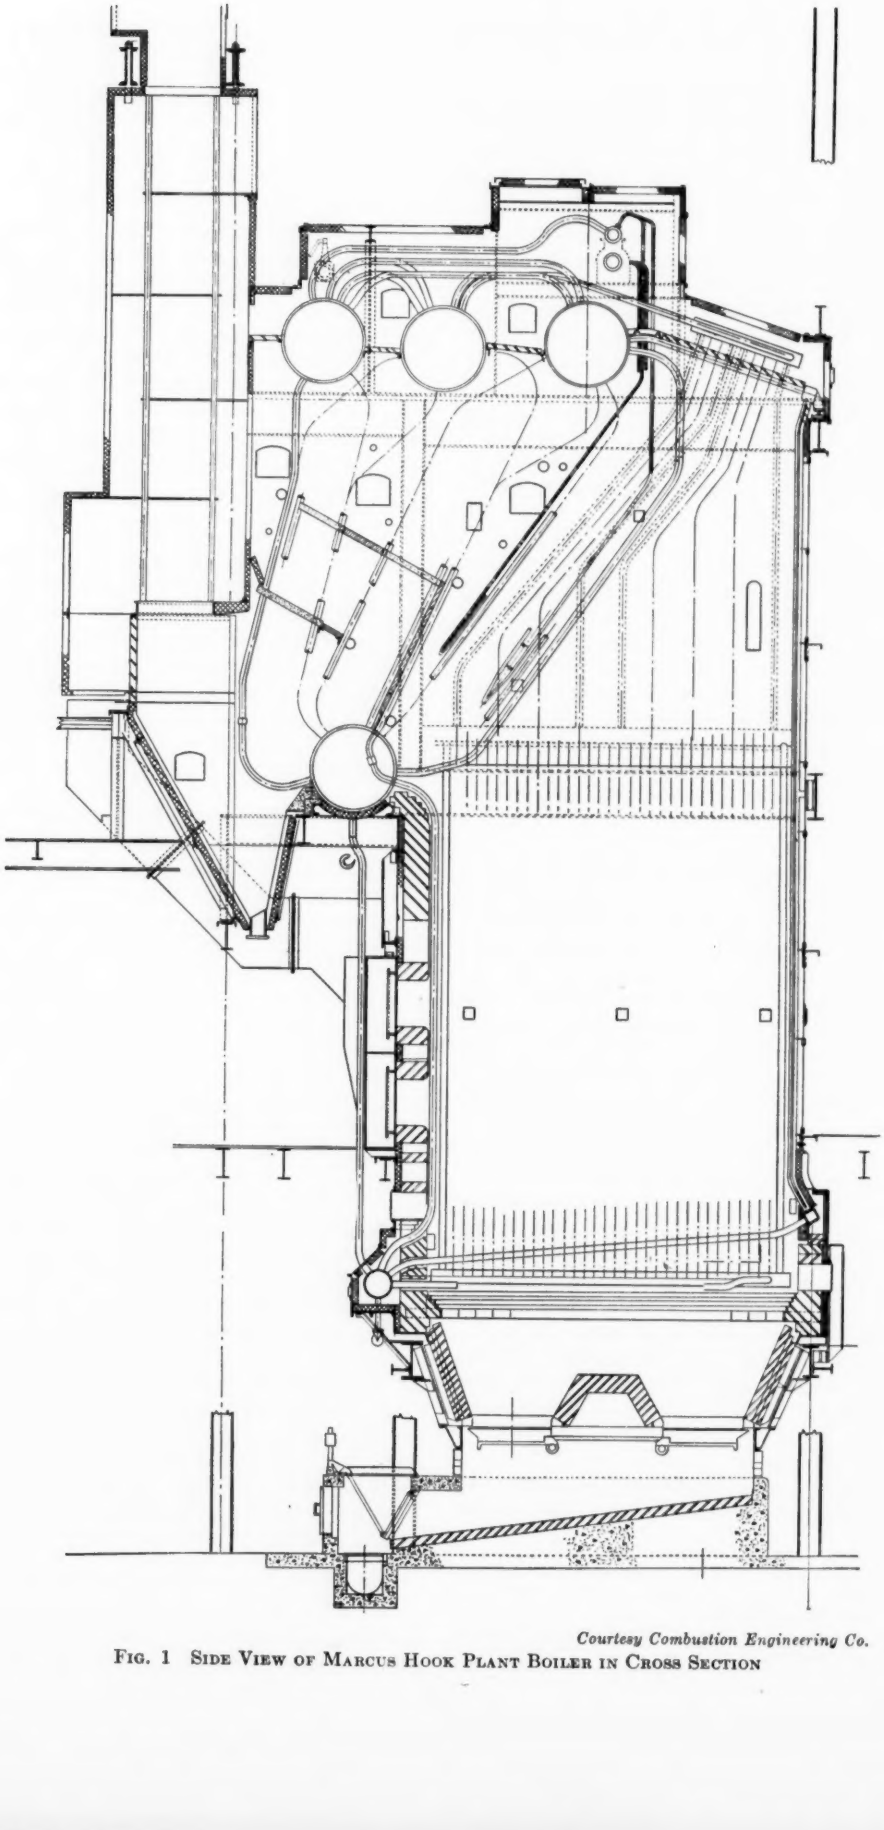
The proximity of the plants of the American Viscose Company and the Sinclair Refining Company made the direct delivery of heavy fuel oil by pipe line from the latter to the former a rather simple problem. Fig. 3 shows a flow diagram of the manner in which this heavy fuel oil is measured and delivered to the consumer's burners without the heat loss attendant upon other methods of fuel-oil delivery, such as tank-car and barge deliveries. The refinery delivers this heavy fuel oil to the supply tank shown in Fig. 3 at a temperature about equal to the optimum temperature at which the oil is most readily atomized. Therefore, in order to have the fuel oil at the correct temperature for atomization at the burners in the Viscose plant, it is only necessary for the consumer to supply the heat lost in the oil delivery line.

Difficulties Encountered in Oil Firing With Original Equipment

The original oil burners and burner assemblies gave unsatisfactory results because the atomized fuel oil and the air required for combustion were not properly mixed. This condition caused the atomized-oil streams to impinge upon the side-wall tubes of the furnace where the oil distilled and the residue formed a coke deposit which kept building up in size until the weight of the mass of coke overcame its adhesive powers and the entire mass fell onto the screen tubes across the bottom of the furnace. Some of these blocks of coke were heavy enough to bow the floor screen tubes slightly.

Fig. 2 shows the combination burner and air register in cross section with the normal angle of atomized-oil spray from the standard mechanical atomizer and illustrates the relative positions of the air and oil streams. In this illustration the oil burner is shown withdrawn to the greatest possible extent without impingement of the oil on the nozzle of the coal pipe. It can be readily noted that the flame in this position fails to fill the throat and, since the stream of air leaving the secondary-air passage is "barreling," there is little mixing of the air and fuel except at the outside of the oil-flame cone. Therefore, a considerable portion of the air introduced into the furnace in this manner is not efficiently utilized in combustion and, although excess air exists in the furnace, smoke and soot fill the firebox and boiler setting.

Steam atomizing oil burners with the tips drilled to give approximately the same included angle of flame cone as that produced by the mechanical atomizing burner tips were tried and produced only slightly better results than the mechanical atomizers. Experimental work was carried out with steam atomizing oil-burner tips with various drillings; it developed that a tip drilled to give a flame included angle of about 120 deg produced the best results. With this tip, the flame could be pulled back into the throat, without impinging on the coal-pipe nozzle, thereby forcing the air into the flame and resulting in good mixture of the fuel oil and the air required for combustion. The amount of steam consumed by the steam atomizers, while probably in line with the steam consumption of other modern steam atomizing oil burners, was considered to be an unnecessary loss. Therefore, a further solution to the problem, using mechanical atomizing oil-burner tips, was sought.



Design, Installation, and Operation of Fixed Air Register

Since the normal mechanical atomizing oil burner gives a flame cone with an included angle of about 75 to 85 deg, which experience with steam atomizing burner tips had proved to be too

narrow, it was deemed advisable to change the manner in which the air was introduced into the furnace in an effort to mix the combustion air properly with the fuel oil. Another important reason for the decision regarding the air introduction was the fact that firing conditions using pulverized coal as the fuel were very good and it was felt that a change in air introduction would have less effect upon coal-burning characteristics than a change in the coal nozzle. The coal nozzle could, of course, be shortened to the extent of permitting the oil burner to be withdrawn far enough to enable its normal flame included angle to fill the throat of the burner. However, this procedure would undoubtedly disrupt the coal-burning characteristics of the burner assembly.

To direct the air stream into the flame produced by the standard mechanical atomizing oil burner, an assembly of 24 fixed

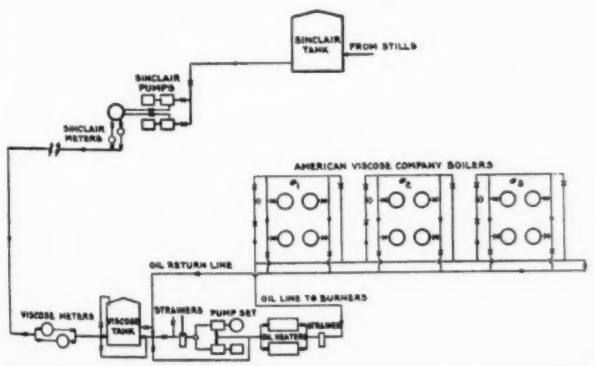

FIG. 3 DIAGRAM OF OIL FLOW FROM REFINERY TO CONSUMER'S BURNERS

vanes was made into a circular register, fitting between the coal nozzle and the refractory throat of the burner assembly, and placed at the furnace inlet of the secondary-air supply. Fig. 4, although it shows a cross section of the burner assembly fitted with a movable-vane register, indicates the position of the registers of both the fixed type and the movable-vane type which was developed later. The vanes of the fixed register were arbitrarily set at an angle of 45 deg to the face of the burner assembly as it was thought that this setting would be sufficiently accurate to determine definitely the feasibility of this method of mixing the air and fuel oil more effectively. The shroud around the outer ends of the vanes was formed to produce a constriction on the air stream by making the outlet diameter smaller than the inlet and, thereby, to assist in obtaining a good mixture of fuel oil and air.

Tests were made, using these fixed-vane registers under actual firing conditions, which indicated that the angle chosen for the vanes had been too great for any normal load on these furnaces. Under light loads, the fire had an excellent appearance, all of the fuel oil being consumed completely within a short distance of the burner tip but, as the load was increased and the fuel-oil and air quantities increased, the flame was torn apart and a "sunflower" appearance of the flame became very noticeable. There was a short solid flame for about 3 ft from the burner tip, then flame propagation was apparently too slow for the speed of the combined air-and-oil-stream mixture and no flame was apparent for the next 4 or 5 ft of travel, after which ignition again took place and combustion was completed.

One of the surprising features of the test was that the flame produced, even though of such unorthodox shape, was remarkably stable and gave no indications of "puffing" or "backfiring." Since the direction and rotation of the air by the fixed-vane register caused the flame to flare out into the sunflower shape, it is

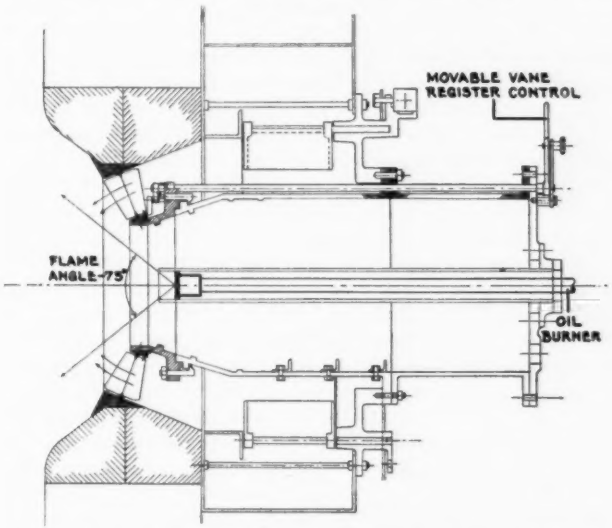

FIG. 4 MOVABLE-VANE AIR REGISTER FITTED TO ORIGINAL BURNER ASSEMBLY

obvious that there was no real length of flame extending into the furnace and most of the heat was concentrated on the front wall.

DEVELOPMENT OF MOVABLE-VANE AIR REGISTER AND ITS OPERATION

The logical procedure from this point was to develop a movable-vane register which could be controlled from the firing floor of the boiler room, varying the position of the vanes with changes in load sufficiently great to require their readjustment. The register shown in Fig. 4 was designed with movable vanes located in about the same position in the burner assembly as the fixed vanes had been in the previous test. Each of the movable vanes was connected to a control ring by a small lug welded to the corner of the vane and riding in a slot in the control ring. This control ring was connected, through suitable linkage, to a rod which extended through the front plate of the burner assembly, terminating in a handle by which the vanes could be adjusted while the burner was in operation and could also be locked in a given position.

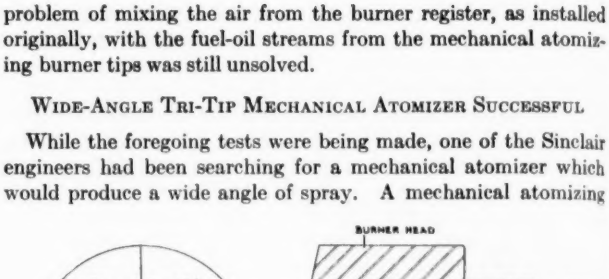
After the movable-vane air registers had been constructed and installed, a test was made to determine their characteristics using oil as the fuel and varying the load on the boiler within limits allowed by plant operations. Some difficulties were encountered

in the operation of the movable vanes of the register, chiefly due to the expansion of the 18-8 chrome-nickel alloy from which the vanes had been made. Greater clearances were given to the vanes and their bearing supports and no further problems arose from that source.

Further tests indicated that a position of the vanes, suitable for normal load swings, was about $^{2}/_{3}$ open at about 80 per cent maximum output of the boiler. Decreasing the load on the boiler more than approximately 15 per cent required the closing of the vanes of the register proportionately and vice versa. Firing conditions on oil were considered satisfactory as combustion was complete and the flame shape and length could be controlled by the adjustment of the movable-vane air registers.

The characteristics of the revamped burner assembly had not been determined with pulverized coal and tests were therefore started to investigate the firing conditions with that type of fuel. As previously mentioned, the secondary-air stream from the original burner assembly entered the furnace in approximately a hollow rotating cylinder form or "barrel." This air-stream shape had been disrupted and changed in both direction and shape by the addition of the movable-vane air register at the secondary-air outlet. Tests made with coal as the fuel and the movable-vane register in the air stream were generally unsatisfactory as the register in the wide-open position seemed to take any rotational effect out of the secondary air that had been imparted to it by the register of the original equipment, causing an unstable flame condition. If the movable vanes of the added air register were partially closed, the flame was also unstable and ignition was difficult to maintain.

A proposal was made that deflectors be installed in the pulverized-coal pipe to direct the pulverized coal and primary-air stream toward the secondary-air stream in a manner similar to the shape of the atomized-oil stream. It is believed that this would have overcome the unsatisfactory coal-burning characteristics of the movable-vane register, but the idea was tabled in favor of further consideration of the original equipment using mechanical atomizing oil burners of another make in place of the burners originally supplied.



Sinclair engineers had definitely established the fact that the heavy fuel oil supplied by the refinery could be efficiently burned as fuel in the Viscose plant, even though the furnaces were completely water-cooled and the resultant furnace temperatures were comparatively low.

In seeking an adequate solution, another manufacturer was permitted to demonstrate a different type of mechanical atomizer. This burner manufacturer had had considerable experience with mechanical atomization of fuel oil in marine boiler furnaces and it was felt that engineers of the company might suggest a solution to the problem based on previous experience. Tests were made under the direction of two engineers, using this company's mechanical atomizers in the original burner assemblies, both with and without additional deflectors placed on the oil-burner guide pipes. These deflectors could be moved in or out along the oil-burner guide pipes. However, changing the position of the deflectors seemed to have but little effect on the fires, since no primary air passes through the coal pipes on oil firing and the deflectors could have no effect on the secondary-air streams.

Because of the fact that the mechanical atomizers used were more or less of the conventional type with the usual included angle of flame cone of about 75 deg, the results obtained from tests of these burners were similar to those obtained on the original mechanical atomizers. When using the atomizers of the second manufacturer, it was impossible to get more than a slight mix between the fuel oil and air and, consequently, a very smoky unsatisfactory condition existed in the furnace. The basic problem of mixing the air from the burner register, as installed originally, with the fuel-oil streams from the mechanical atomizing burner tips was still unsolved.

Wide-Angle Tri-Tip Mechanical Atomizer Successful

While the foregoing tests were being made, one of the Sinclair engineers had been searching for a mechanical atomizer which would produce a wide angle of spray. A mechanical atomizing

Courtesy Coen Burner Co.

Fig. 5 Tri-Tip Mechanical Atomizing Oil-Burner Head

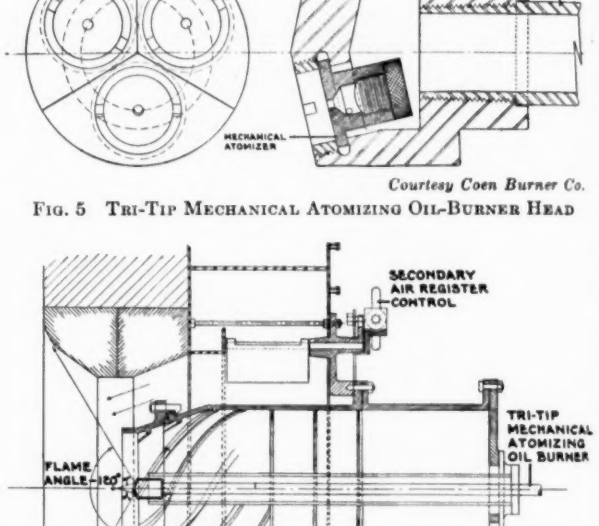


Fig. 6 Original Burner Assembly With Tri-Tip Mechanical Atomizing Oil Burner

burner tip was located which had been developed for steel-mill purposes. This tip consisted of three atomizers set in a single burner head in the manner shown in Fig. 5. The included angle of flame cone that would be produced by this arrangement was apparently about 120 deg. Judging from previous satisfactory results obtained with wide-angle steam atomizing tips, it was assumed that the wide-angle mechanical atomizer would be successful. Four of these burner heads were immediately ordered, each containing three atomizing tips of a size estimated as correct for the normal load conditions.

Preliminary tests of these burners upon their arrival indicated that they would be entirely satisfactory, except for size, as the included angle of spray was such as to produce the proper air-fuel-oil mixture. The atomizers of the original installation were too large for the load requirements, which resulted in a lower pressure on the fuel oil to the burners than that required to give the best atomization. However, the tests that had been made showed sufficient promise to warrant the purchase of additional burner heads of this type to complete the installation on all of the boilers.

Atomizers of several sizes were ordered, the range in size making it possible to have all four burners of the boiler furnace in operation producing a balanced firing condition and an even distribution of heat in the furnace. Normal changes in load are

easily taken care of by the range of the oil pressure to the burner, while the large changes, such as occasionally occur due to starting up or shutting down portions of the plant, can be taken care of in a few minutes by changing the atomizer tips.

In the operation of these burner tips, flame propagation begins within 1 or 2 in. of each of the atomizers but, 6 or 8 in. from the tip, the three streams lose their identity and become one large flame issuing from the burner throat. Because of the wide angle of the combined atomized-oil sprays from these burner tips, the burner can be withdrawn to a point where the fire completely fills the throat without danger of impingement of the oil spray on the coal nozzle of the burner assembly. Thus, the atomized-oil spray is forced into the secondary-air stream, as shown in Fig. 6, and complete combustion takes place with little excess air. Firing conditions are good and the complete operation of these furnaces on heavy fuel oil is entirely satisfactory.

These furnaces have been operated for more than 15 months using heavy oil as fuel, and the costs of steam and power produced during this operating period compare very favorably with those obtained while burning pulverized coal. Additional advantages, not included in the cost statement but important to the operator, are the ease of handling and over-all plant cleanliness of the oil-firing operation.

Automatic Control Satisfactory for Heavy Oil

Very few problems have arisen on the control system used in connection with the firing of heavy fuel oil. The controls vary the amount of fuel oil and air to the burners in response to load changes on the boiler, maintaining the fuel-oil-air ratio set on the master control throughout the range of the control. The fuel-air ratio is manually set for the best combustion on any particular load and the proper ratio is then maintained by the control. A pilot or measuring valve in the fuel-oil line to the boiler burners actuates suitable equipment to damp the action of the control valve in the same line and, thereby, smooths out the flow of oil to the burners. This pilot valve as originally installed was of the piston-type and the heavy-oil fuel had a tendency to stick the piston, making the control sluggish. To remedy this condition, a diaphragm-type valve was substituted.

Physical Properties of Fuel Oil

The heavy fuel oil mentioned in this paper is a residuum product of a petroleum-refinery-cracking process and, as such, the characteristics of the oil may vary slightly from time to time with changes in operation. Representative characteristics of this heavy fuel oil may be listed as follows:

Specific gravity	1.014	Flash point, F	250
B.S.&W., centrifuge, per cent	0.50	Sediment, per cent	0.05
Viscosity, Furol at 122 F	800–1400	Weight, lb per gal	8.45
Pour point, F	80	Btu per lb	18300

A temperature of approximately 275 F has been found satisfactory to reduce the viscosity of the oil to about 20 Furol, or 150 S.S.U. At this viscosity, the oil is readily atomized and its characteristics are such that the viscosity at the firing temperature is about the same, whether the Furol viscosity at 122 F is 800 or 1400. The carbon-hydrogen ratio is greater for the heavy fuel oil than it is for the lighter oils, consequently, the advantage of the heavy fuel lies not only in the additional heat obtained from the carbon but also in the proportionate reduction of loss from the formation of water vapor.

Discussion of Conditions and Results

In general, combination burner assemblies are of incorrect design for the efficient combustion of all the fuels included in the combination. The apparent practice, in the East, has been to design for pulverized-coal firing and to fit in accommodations for some other fuel, such as oil, in the easiest manner possible and with little regard for resultant operating conditions. The true combination burner assembly should handle all fuels intended for it in an equally efficient manner. Such an assembly cannot be designed without a complete knowledge of the characteristics of all the fuels and burner equipment proposed for a particular installation. Since this information may not be available to the designer and since there are many installations of improperly designed combination burner assemblies in operation at the present time, it would be advisable, where one of the fuels used is oil, for the designer or operator to investigate the possible advantages in using a multiple-tip mechanical atomizing oil burner in his original burner assembly.

The number of atomizers per burner head is not limited to three, nor is the included angle of spray from the tip limited to 120 deg. These conditions were found satisfactory for the installation reported in this paper, but another installation might require five or six atomizers, or more, per burner head and a much greater included angle of spray than the 120 deg used in the Viscose installation. It would appear possible, where faulty air distribution around the burner is inherent in the burner assembly, to improve over-all combustion by the selection of proper-sized atomizers and face angles to alleviate this condition to a considerable extent.

Satisfactory combustion of heavy fuel oils, using mechanical atomizing oil burners, can be readily accomplished when the proper equipment is available for heating, atomizing, and mixing the oil and combustion air. The additional cost of this equipment over that required for steam atomizing oil burners can usually be justified on steam saving alone.

Conclusion

The results obtained in this investigation and herein reported have definitely shown that it is not only possible, but practical and economical, to burn heavy petroleum oils in properly designed combination coal-and-oil burners, using mechanical atomization under automatic control, in completely water-cooled furnaces.

Acknowledgment

The advice of O. F. Campbell, R. J. Self, and E. W. Griscom of the Sinclair Refining Company is acknowledged in the successful completion of the investigation and the preparation of this paper. The author wishes to acknowledge, also, the willing cooperation of the American Viscose Company, the Combustion Engineering Company, the Coen Burner Company, and others for their assistance.

Discussion

J. M. Goldstein.[2] Briefly, the paper relates to the operating difficulties encountered in an oil-burning power plant using fuel oil heavier than bunker C. Here particular difficulty was experienced in the building up of coke deposits on the side-wall tubes of the furnace, as after a time these coke deposits fell to the bottom screen tubes. After experimenting with different burner tips and various methods of air introduction, the tri-tip head was used successfully to eliminate the coke deposits building up on the side-wall tubes.

In analyzing the type of oil spray that is obtained with the tri-tip head, it appears that the outside cone consists of a much finer spray than that on the inside of the cone; i.e., the oil particles nearest the center of the head from each tip will meet and the resultant oil particle will become larger and more difficult to

[2] Combustion Service Company, New York, N. Y.

burn completely. Close observation will show decidedly black streaks of unburned oil near the center of the oil fire, with the result that carbon deposits will accumulate on the upper tubes, and there will be excess heat losses due to unburned gaseous hydrocarbons. However, finer atomization on the outside of the flame cone will aid combustion nearest the side-wall tubes, and thus eliminate the difficulty due to coke deposits building up on these tubes.

The use of a specially designed atomizer head to produce a fine oil spray of the desired angle represents, however, only one important factor in obtaining clean, efficient combustion. In order to obtain satisfactory operating results in the burning of heavy fuel oil with mechanical atomizers, other important factors in addition to atomization are oil-air intermixture, combustion process, and combustion atmosphere.

In breaking up the oil into a very fine spray with the mechanical atomizer, the control of the process can be regulated to some extent by adjustment of the oil pressure and temperature. It is desirable that the oil particle, when projected in suspension, should not come in contact with either solid surfaces or other oil particles. However, in the case of some heavier bunker oils, atomization will be poor in spite of the fact that oil temperatures and pressures are adjusted over the entire operating range as recommended for the fuel and oil burner. Inherent characteristics of the fuel itself will affect the quality of atomization. Heavy bunker oils, which are residual fuels, are subject to change in content and characteristics from time to time, and require constant attention to maintain best operation.

A proper oil-air intermixture depends upon the quantity, direction, and velocity of the air supplied in relation to the oil spray. Each oil particle should be completely surrounded by air to promote oxidation of the hydrocarbons. Regulation of the oxidation process will control combustion so that it is neither too rapid nor too slow, thereby greatly diminishing the "cracking" or thermal decomposition of the oil particle.

When combustion takes place due to the oil-air intermixture, a combustion atmosphere is created in the furnace. Since the air used for combustion is subject to change due to temperature, humidity, and contamination, it follows that proper combustion is also a function of a proper quality of air supply.

The common practice of sampling fuel oils in a laboratory for analysis and burning characteristics has proved inadequate. For example, good ignition characteristics and balanced distillation are important factors affecting combustion. Then again, fuel oil, after leaving the refinery, is subject to contamination in transportation, storage, and handling, which also affects atomization and combustion.

Again referring to the paper, it is shown that the fuel oil is transported by pipe line from the refinery to the power plant with small loss in temperature; also that the boilers are of waterwall-furnace construction. These conditions are unusually favorable for oil burning, and are the exception rather than the rule. For instance, in most installations fuel oil is delivered either in tank trucks or barges and, as mentioned, becomes subject to contamination which in turn increases the difficulties in burning. In many cases, refractory material is used in combustion chambers, with and without facilities for cooling. The presence of noncombustibles in the oil, such as natural salts, chemicals used in the refinery operations, scale, and dirt will cause rapid deterioration of the refractory materials, particularly at high combustion-chamber temperature.

The mechanical atomization of heavy bunker oils is a problem which has confronted engineers in charge of every type of installation used for heating and processing. In many plants, high-pressure steam for steam atomization is not available, which automatically eliminates this method of solving combustion problems.

Methods must be provided to control within limits the variable factors which affect atomization and combustion. Recent tests with the use of a chemical oil conditioner to improve the atomization and combustion of light and heavy fuel oils have resulted in the solution of many common difficulties encountered in oil burning.

A recent troublesome installation, similar to the case cited, where carbon deposits formed in the furnace, was in an apartment building in New York City, where a rotary-type oil burner using bunker C oil had been installed in a low-pressure fire-tube boiler several years ago. The combustion chamber was built of standard firebrick, and was too short and too narrow for the size of the boiler. A dutch oven was recommended but not installed.

The oil fire impinged somewhat on the side walls but much more on the rear wall of the combustion chamber. During the several years that the burner was in operation, the quantity of carbon deposits which accumulated on the walls of the chamber and in the fire-tubes over a 30-day period was not excessive or bothersome. However, by the fall of 1939, the carbon deposits on the rear wall of the chamber became excessive and required removal every two hours when the burner was in operation. Oil temperature and pressure were changed, primary- and secondary-air adjustments were regulated, and even the oil supplier was changed, but the carbon deposits kept building up. The oil-burning system was reset for normal operation, using the same bunker oil, and "chemical conditioning" was applied. Now for the last several months, in spite of continued flame impingement on the walls, carbon deposits have been eliminated, and trouble-free, efficient operation has been maintained.

Another interesting case is the conversion of several coal-burning boilers to oil burning by a public-utility company. The bunker oil used is a by-product of the gas-making division of this company, and a standard-make mechanical-atomizing oil-burning system was installed and operated in accordance with the manufacturer's instructions. Difficulties encountered were high furnace temperature and melting of the refractory material in the combustion chamber at normal overloads. There was no flame impingement, fires were sparky, and there were complaints of smoke nuisance when a boiler was put on the line. Changes were made in the type of burner tips, design of the combustion chamber, air delivery, and quality of firebrick, but operation was only slightly improved. As a further remedy, this heavy-residuum bunker oil is now treated so that its specifications are equivalent to or better than a commercial bunker C fuel oil. Further experimentation is being carried on by the company engineers in cooperation with the equipment engineers to burn this residuum by-product successfully, without the necessity of this expensive treatment.

In view of the fact that in recent years revolutionary new catalytic processes have been developed in petroleum refining, and since bunker oils are thereby subject to change, it may prove difficult to design a mechanical atomizer which will function efficiently with all grades of bunker oils under all conditions. When mechanical changes fail to solve oil-burning problems, the chemical-conditioning method may prove economically sound and advantageous. The consumer of fuel oil and his staff should seek the cooperation of the oil supplier and equipment manufacturer, and in addition, the impartial advice of the combustion specialist.

R. C. Vroom.[3] The paper emphasizes the desirability of installing suitable combined burners initially, when it is possible that future requirements may make it necessary to burn a liquid or gaseous fuel instead of a pulverized fuel or vice versa. The writer feels, however, that the paper may have created an impre-

[3] Chief Engineer, Peabody Engineering Corporation. Mem. A.S.M.E.

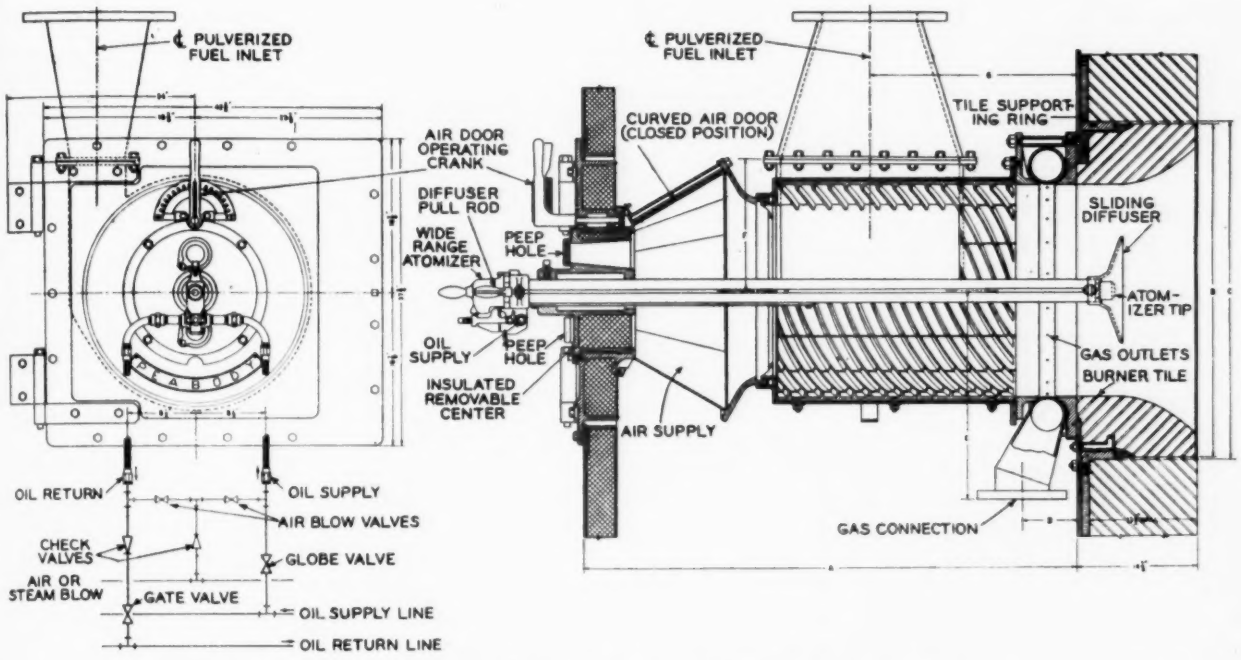

FIG. 7 COMBINATION BURNER DESIGNED TO BURN PULVERIZED FUEL, GAS, AND OIL

sion which surely was not intended, i.e., prior to the experimental program which the author describes, there were not available suitable combined burners, nor atomizers, of the mechanical type which could handle liquid fuels heavier than bunker C.

For nearly 15 years the company with which the writer is connected has been building combined burners for liquid, gaseous, and pulverized fuels varying in capacity from 15 to 150 million Btu per hr liberation each. They have been described in papers presented before the A.S.M.E. and a typical burner is illustrated in Fig. 7 of this discussion. These burners are designed to meet and do meet combustion guarantees which are in every respect competitive, and no difficulty is experienced in burning individually any of the fuels which the burner is designed to handle, nor in changing from one fuel to another without loss in steaming capacity. They are successfully firing, in many of the well-known steam plants in this country, in units varying in capacity from 20,000 to 500,000 lb of steam per hr each.

In connection with mechanical atomizers for heavy liquid fuels, the writer spent about 6 weeks in Louisiana 10 years ago running tests with such atomizers on all sorts of refinery-waste fuels. These included not only neutral fuels but acid and alkaline sludges, which are far from homogeneous, may contain various quantities of water, and tend to precipitate solids. As a result of these tests, mechanical atomizing liquid-fuel burners were installed in a new utility plant which was to use the waste fuels purchased from the refinery and in turn supply the refinery with process steam. In addition to the waste liquid fuels, it was necessary to burn petroleum coke from the refinery and also natural gas to make up the deficiency between the available waste fuels and the total fuel requirements.

The initial installation comprised four boilers, each to produce 350,000 lb of steam at 600 psi and 750 F temperature. Two of these boilers were equipped with 18 burners each, for liquid and gaseous fuels, and two with 15 such burners, and also two burners for handling the pulverized coke. More recent extensions have employed a smaller number of higher-capacity burners per boiler. There are several other plants which over a number of years have successfully employed mechanical atomizers for firing high-capacity boilers with such fuels, and also plants in which heavy residual fuels and tars with melting points of 300 F or over are being handled. In addition, of course, there are hundreds of combined burners in use where the liquid fuel is ordinarily bunker C.

T. H. WALKER.[4] The design of combination burners to fire pulverized coal and oil, or coal, oil, and gas has been given considerable study, since economic conditions or character of plant load often justify their use. As pointed out in this paper, such burners should handle all fuels equally well, i.e., without operating difficulties or smoke nuisance, and with combustion efficiencies corresponding to best practice for each fuel. Usually the change from one fuel to another must be made without shutting down the unit and sometimes two fuels must be burned together; therefore, no device can be added which will improve operation with one fuel at the expense of that with another.

It has been and to some extent still is the practice with oil-and-gas firing to use a number of small burners. This assists in the utilization of all the furnace volume, reduces the flame length, and to some extent simplifies the problem of introducing the correct amount of air at the proper place, since the flames tend to be mutually sustaining and the burners are close enough to each other so that a slight excess of air from one burner may tend to compensate for a deficiency in another. Also, wide-range operation can be obtained by shutting down some burners and operating others at approximately their design velocities.

Pulverized-fuel burners for the same steam delivery must be fewer and larger because no satisfactory means has yet been devised for splitting a coal-air mixture into many small streams at the same pressure and air-coal ratio; the use of many small mills would be complicated and expensive. Thus the individual burners must be capable of handling a wider load range. Thorough mixing of fuel and air as they enter the furnace, a minimum of excess air, and stability of ignition are essential. In combination burners these objectives must be accomplished with fuels of quite different physical characteristics, since the volume of coal-air mixture is greater than that of either oil or gas. The coal is

[4] Combustion Engineering Company, Inc.

carried to the burner by a quantity of air which often is a sizable proportion of that required for combustion and, hence, requires less secondary air. In burners of the type under discussion where furnace turbulence must be obtained by the use of a turbulent air stream, the fuels must be introduced concentrically, and the necessity for a rather large coal-air nozzle, as compared with the size of oil or gas burners, moves the latter further away from this turbulent air stream than would be the case in similar burners designed for oil or gas only.

With these considerations in mind, the solution which the author describes is interesting. The advantage of the tri-tip burner lies in its ability to provide a wide-angle spray which can be directed into the secondary-air stream, thus accomplishing more thorough mixing of fuel and air than the conventional single-jet atomizer.

Author's Closure

Mr. Goldstein's observations regarding the oil spray obtained with the tri-tip burner head apparently did not take into account the action of the turbulent-combustion air stream on the oil spray from this type burner head. An intimate mix is obtained between combustion air and the atomized fuel oil, as reported in the paper, and observation of the fires, from any of the furnace observation ports, reveals no black streaks of unburned oil in the center, or at any other portion of the flame. These boilers were recently shut down for internal inspection and no appreciable deposits were found in the furnaces or flue gas passages. This would appear to be a further indication of complete consumption of the carbon in the fuel oil. This writer's discussion also states that the waterwall-furnace construction of these boilers is unusually favorable for oil burning. It is felt that most authorities agree that fuel oil requires a higher furnace temperature for good combustion conditions than other fuels, i.e., pulverized coal or gas. Furthermore, furnaces designed primarily for fuel-oil firing usually contain more refractory, to maintain a higher temperature, than those furnaces designed primarily for pulverized coal. The furnace walls of the boilers which were described in the paper are almost completely covered with water-tubes and, due to the amount of heat absorbed by these tubes, the furnace temperatures are considered low.

Mr. Goldstein reports a few interesting cases of oil-firing difficulties but they seem to be concerned with lighter fuel oils and are therefore hardly comparable to the installation described in the paper.

Mr. Vroom's discussion is of great interest to the author. Combination burners for liquid, gaseous, and pulverized fuels, as he points out, have been on the market for many years. A great many of these combination burners, however, have left much to be desired when operating on one or more of the fuels for which they were designed. Revision of such an installation, to correct the undesirable condition, becomes a problem of that installation only; the solution found satisfactory in one instance might or might not be successful if applied in another case. There are combination burners in operation with undesirable firing conditions recognized by the operators but accepted by them as unalterable. Consequently, no effort is made to correct the difficulties.

In his discussion, Mr. Walker emphasizes many of the points which the author sought to bring out in the paper. The observations regarding general practice on burner spacing and placement, with his explanation of the reasons for such spacing and placement, tend to clarify the statement of the problem involved in the original installation.

The author wishes to thank all the discussers of the paper for their contributions to the general subject.

The Analogy Between Fluid Friction and Heat Transfer

Discussion of Paper[1] by Th. von Kármán

By BORIS A. BAKHMETEFF,[2] NEW YORK, N. Y.

IN HIS paper[1] Dr. von Kármán has focused light on a fundamental precept, the import of which lately may have become somewhat eclipsed.

The heat-transfer analogy was originally offered by Reynolds as a fascinating hypothesis to be probed and substantiated by observation and experiment. Quantitatively, the interpretation from the very first was in terms of momentum, the heat exchange due to turbulent convection being appraised at

$$q = \frac{c\tau\Theta}{U} \qquad [a]$$

This basic relation, equivalent to Equation [19][3] and leading directly to von Kármán's

$$C_H = C_f/2 \qquad [16]$$

was accepted in all subsequent interpretations and improvements without scrutiny, even if certain physical aspects cast doubt as to the validity of expressing the Reynolds analogy in that particular form. Indeed as Equation [a] applies to the heat exchange in the turbulent zone only, the symbol $\Theta = \Theta_\delta - \Theta_0$ should signify the difference between the temperature of the fluid Θ_0 and a certain temperature Θ_δ at the boundary between the turbulent core and the laminar region. Accordingly Θ in all cases must be less than the full temperature difference $\Theta_0 = \Theta_\infty - \Theta_0$ between the wall and the fluid. In fact one may properly introduce

$$\eta = \frac{\Theta_\delta - \Theta_0}{\Theta_\infty - \Theta_0} = \frac{\Theta}{\Theta_0} \qquad [b]$$

as a "reduction coefficient," featuring the "insulating effect" of the laminar zone.

The practical meaning is, that if Equation [a] were to express correctly the physical facts relating to turbulent heat transfer, as for example in a pipe, then the quantities of heat observed experimentally should under all circumstances be below the figures computed from Equation [a] with $\Theta = \Theta_b$. In other words, observed values should comply with

$$q = \eta \frac{c\tau\Theta_0}{U} \qquad [c]$$

where η is < 1.

Such, however, is not the case. Since the early experiments by Stanton and Pannell,[4] it has been known that, for air and gases for which the Prandtl number $\sigma = \mu\, c/k$ is < 1, measured heat values are in excess of q, computed from Equation [a] with $\Theta = \Theta_b$. Accordingly, the over-all experimental values of the heat-transfer number C_H in Equation [5] exceed $C_f/2$. Mathematically, this discrepancy has been repaired by G. I. Taylor, Prandtl, and von Kármán, who complemented the original Reynolds disclosure by accounting supposedly for the effect of the near-to-the-wall laminar film, across which the transfer of heat is by conduction. To elucidate, one may refer to the prototype Taylor Equation [21], written in the form

$$\left.\begin{aligned} q &= \frac{c\tau\Theta_0}{U}\left[\frac{1}{1 + U_\delta/U\,(\sigma - 1)}\right] \\ C_H &= C_f/2\left[\frac{1}{1 + U_\delta/U\,(\sigma - 1)}\right] \end{aligned}\right\} \qquad [d]$$

Indeed for $\sigma < 1$, the bracket value becomes larger than unity, a feature which, because of the presence in the structure of the group $(\sigma - 1)$, is equally shared by Prandtl's Equation [22] and von Kármán's Equation [34] expressions.

The physical implications devolve from comparing Equation [d] with Equation [c]. The bracket groups are obviously equivalent to the reduction coefficient η, which for $\sigma < 1$ becomes thus larger than unity, meaning that a correction term, ostensibly intended to account for the insulating effect of the laminar zone, results in increasing the heat flow numerically beyond the highest limit which could possibly be achieved in accordance with Equation [a] if the whole of Θ_0 were contributing to turbulent convection. Obviously, the source of the discrepancy must lie in the very form of the basic relation of Equation [a], which seems to understate the actual intensity of the heat transfer due to turbulence.

The writer finds, that the inconsistencies are easily removed if instead of using the "momentum," one were to interpret the Reynolds analogy in terms of "energy."[5] In such a case the second of von Kármán's Equations [5] could be appropriately expressed by the ratio

$$C_H = \frac{q}{\rho c U\Theta} = \frac{\text{Energy lost per unit wall surface}}{\text{Energy of flow per unit cross-section area}} \qquad [e]$$

Using for the numerator Equation [10] in a text[6] by the writer, we obtain

$$C_H = \frac{q}{\rho c U\Theta} = \frac{U\tau}{\rho U U^2/2}$$

from which there follows

$$q = 2\,\frac{c\tau\Theta}{U} \qquad [f]$$

$$C_H = C_f$$

By comparison with Equation [a] and Equation [16], the heat transfer derived from interpreting the Reynolds analogy in terms of energy, is twice as large as when using momentum. Physically, there is no reason why the analogy between heat transfer and friction should not be considered in energy terms. In fact convective heat transfer is a process of diffusion, and the

[3] Numbers in brackets refer to equations in the original von Kármán paper.[1]

[4] "The Mechanical Properties of Fluids," a collective work, Blackie & Son, Ltd., London, 1925, p. 174.

[5] This method of presentation was first disclosed by the writer in his lectures at Columbia University in 1932–1933.

[6] "The Mechanics of Turbulent Flow," by B. A. Bakhmeteff, Princeton University Press, 1936, p. 4.

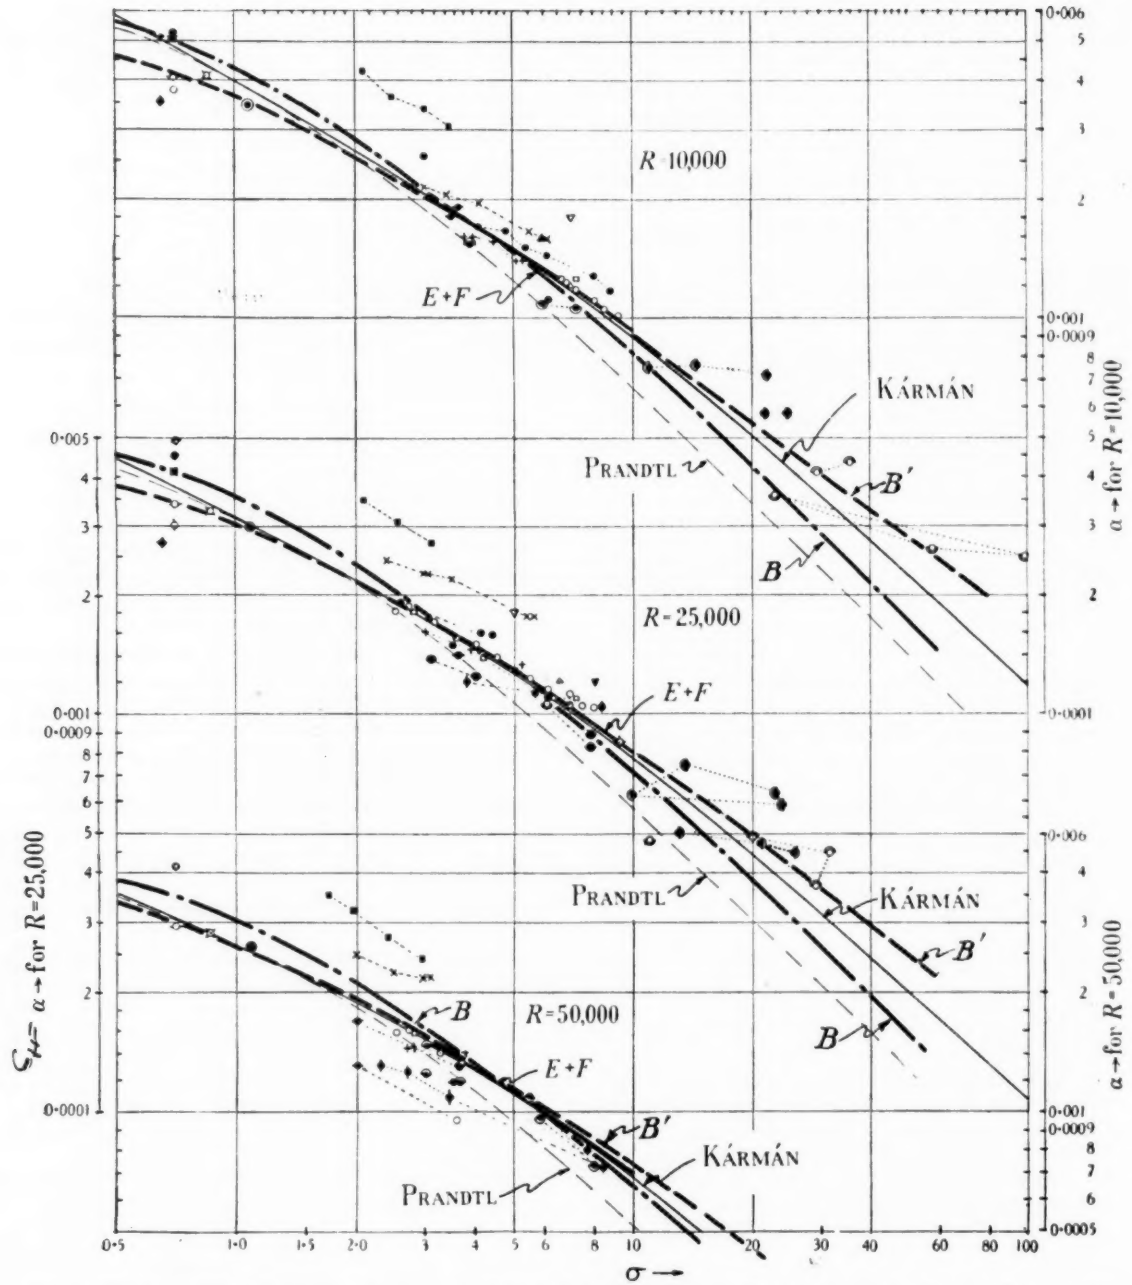

FIG. 1 HEAT-TRANSFER NUMBER IN PIPES, FIG. 4 OF VON KÁRMÁN PAPER,[1] WITH ADDITION OF CURVES REPRESENTING EQUATIONS [h] AND [j]

rate of the latter is appropriately reflected by energy loss.

To arrive at final expression of an equation of the type of Equations [22] and [34] one proceeds by equating the turbulent heat exchange $q = 2c\tau(\Theta\delta - \Theta_h)/U = \eta(2c\tau\Theta_0/U)$ based on Equation [f], with the conduction across the laminar film $q = k(\Theta_w - \Theta\delta)/\delta = (1-\eta)(\Theta_0 k/\delta)$, in which δ is the thickness of the insulating layer, equivalently expressed through $\delta = \mu U_\delta/\tau$. This determines the reduction coefficient as

$$\eta = \frac{1}{1 + 2\sigma U_\delta/U} \qquad \text{[g]}$$

and then with Equations [f] and [c]

$$\left.\begin{aligned} q = \eta 2\,\frac{c\tau\Theta_0}{U} &= \frac{2c\tau\Theta_0}{U}\left[\frac{1}{1 + 2\sigma U_\delta/U}\right] \\ C_H = \eta C_f &= C_f\left[\frac{1}{1 + 2\sigma U_\delta/U}\right] \end{aligned}\right\} \qquad \text{[h]}$$

Assuming finally with von Kármán that, in terms of the dimensionless distance parameter y^* Equation [25], the $U\delta/U$ ratio may be expressed through

$$U_\delta/U = N\sqrt{C_f/2} \qquad \text{[i]}$$

with N a numerical constant, one obtains for η the convenient form of

$$\eta = \frac{1}{1 + N\sigma\sqrt{2C_f}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [j]$$

In first approximation, one single value of N can be assumed to qualify conditions within the whole range of σ and R, the particular number lying ostensibly somewhere near the point, where in Figs. 51 and 53 of Bakhmeteff's text,[6] the u/u_* curves leave the laminar outline. Accordingly in Fig. 1 of this discussion, complementing von Kármán's Fig. 4,[1] the curves, marked B, represent Equations $[h]$ and $[j]$ with N = constant = 7. The practical accord with the experimental points, notwithstanding the crudeness of the assumptions, is quite satisfactory. It does seem, however, that with the increase of σ, the N value, which features the size of the conduction laminar zone, should somewhat decrease. The possible variation could be appraised by a simple exponential expression $N = N_0/\sigma^m$. This possible improvement is introduced into the curves, designated as B', taking N_0 = constant = 9.5, and $m = 0.2$, so that in Equation $[j]$ $N\sigma = 9.5\ \sigma^{0.8}$.

In all computations, the Blasius values of $\lambda = 4C_f$ for smooth pipes were used.

The insulating effect of the laminar film is especially evidenced by the comparative outlines of the η curves which are plotted in Fig. 2 of this discussion. Obviously with σ approaching zero, the insulating effect vanishes, and C_H tends to its limiting value C_f.

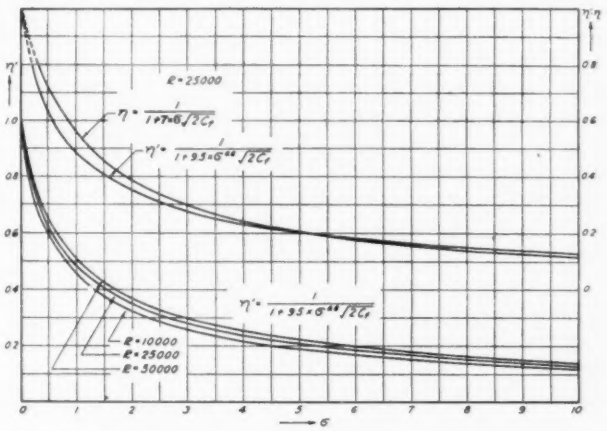

FIG. 2 INSULATING EFFECT OF LAMINAR FLOW EVIDENCED BY COMPARATIVE OUTLINES OF η CURVES

Pump Discharge Valves on the Colorado River Aqueduct

By R. M. PEABODY,[1] LOS ANGELES, CALIF.

This paper outlines the arrangement and physical equipment of the five pumping plants installed on the Colorado River Aqueduct. Studies and estimates indicated that for these aqueduct plants a common delivery pipe with a valve at each pump was more economical than separate delivery lines. Rotating-plug-type pump valves were finally selected for shutoff service at all plants. With proper control of the rate of closure they can be made to limit the pressure rise to a moderate percentage in systems comparable to those of the Metropolitan Water District. Constructed by two manufacturers for application at different plants, the valves, while varying somewhat in detail, give practically the same operating result. Model tests were conducted by the manufacturers and by the hydraulic laboratory at the California Institute of Technology. Details of the design, construction, and operation of the valves, as well as the test results, are included in the paper.

THE Colorado River Aqueduct extends from the Colorado River across the entire width of California and is to supply water for domestic and industrial purposes to the highly developed areas of the south coastal basin of Southern California. The main aqueduct is 242 miles in length. The greater part lies across a barren desert country at a higher elevation than the Colorado River. To cross this elevated region a succession of pumping plants, five in number, are required with a total lift of 1617 ft. The designed capacity of the aqueduct is 1600 cfs. Power for pumping, which for the ultimate development will be about 300,000 kw, is obtained from the power plant at Boulder Dam about 150 miles north of the point of diversion on the Colorado River. Fig. 1 shows the location and the profile of the portion of the aqueduct which includes the pumping plants.

Pumping Plants

Each pumping plant will ultimately contain nine pumping units of 200 sec-ft capacity each, which will allow one spare unit. Three such units are installed in each plant initially and others will be added from time to time as the demand for water increases. Table 1 gives the principal engineering data for each of the plants.

The five pumping plants are almost identical in general design. There are differences in detail made necessary by the variation in head and by the different intake and discharge conditions at the site of each plant. The pumps are all of the single-stage, single-suction, vertical-shaft, volute type, without guide vanes or diffusers. The pumps are set below the minimum inlet water levels, not only to avoid the necessity of priming apparatus, but to give sufficient positive inlet pressure to insure operation at minimum head and maximum discharge without cavitation. The ultimate nine pumps of each plant will be connected, in groups of three, to three main 10-ft diameter, steel delivery pipes.

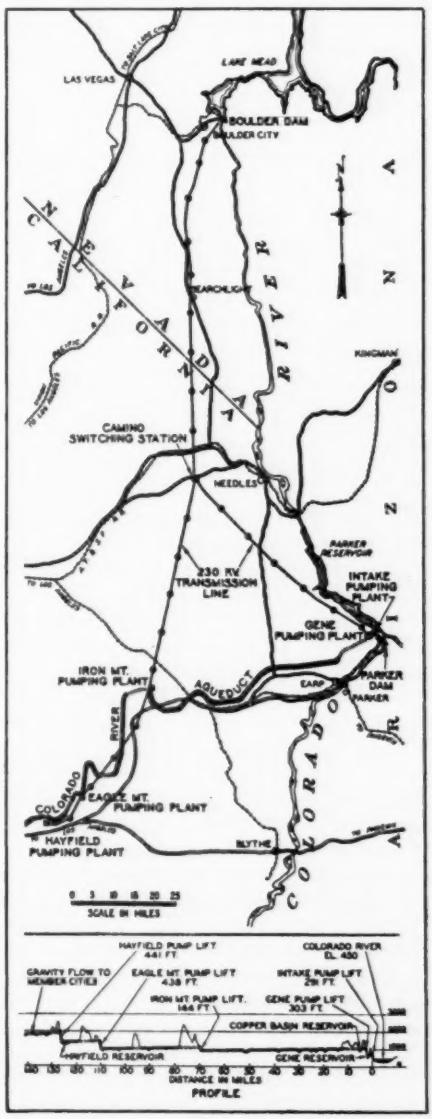

FIG. 1 MAP OF POWER SYSTEM FOR COLORADO RIVER AQUEDUCT AND PROFILE OF SECTION WHICH INCLUDES PUMPING PLANTS

Discharge pipes 6 ft in diameter from each pump converge through a three-branch manifold or wye to the main delivery pipe at a short distance from the plant. The delivery lines at three of the plants, Intake, Gene, and Eagle Mountain, connect at the upper end through surge chambers to pressure conduit or pressure tunnels and reservoirs. At the other two plants, Iron Mountain

NOTE: The average submergence of the pump center line below the inlet water level is as follows for the various plants: Intake, 14 ft; Gene, 17 ft; Iron Mt., 15 ft; Eagle Mt., 20 ft; Hayfield, 37 ft.

and Hayfield, the delivery lines connect through simple transition structures to gravity-flow tunnels. A headgate is installed at the upper end of each delivery line so that any main pipe line can be unwatered independently and without draining the reservoir.

It is not considered desirable to sacrifice efficiency by operating the pumps with throttled discharge. The flow in the aqueduct will therefore be in multiples of about 200 sec-ft, the unit pumping capacity. Due to variation in reservoir and canal water levels, the pumps at consecutive plants may operate at heads above or below the design point with a consequent variation in discharge. The reservoirs at Gene draw, Copper basin, Hayfield, and Cajalco are sufficient to hold the entire capacity of the aqueduct between these reservoirs and the next pumping plant upstream. At these plants, variation in pump discharge may be compensated for by starting and stopping one or more pumps at comparatively long intervals, and in power outages of long duration no water will be wasted from the aqueduct. The available regulatory storage at Iron Mountain and at the inlet of Eagle Mountain is small (about 100 acre-feet at each plant) so that starting and stopping of one pump at each of these plants may be necessary at shorter intervals to maintain a balanced discharge. These small reservoirs will provide rejection storage for power outages up to 30 or 45 min duration and, for unanticipated longer outages, spillways provide for wasting the excess flow.

Figs. 2 and 3 show the general arrangement of the Intake plant and appurtenant structures. Fig. 4 shows a cross section of the Intake plant in more detail and is typical of all the plants, except for the arrangement of the pump inlet. In all of the other plants, the inlet is through a branch from a 16-ft-diameter steel manifold. There is a butterfly valve instead of a slide gate to close off the pump inlet.

With the adopted arrangement of three pumps discharging into a common delivery pipe, valves at the outlet of each pump are necessary. Another possible arrangement, which was studied and abandoned because of greater cost, was to have separate delivery lines from each pump all the way to the upper reservoir or conduit with no discharge valves at the pumps, but with a device at the upper end of each pipe line to prevent backflow from the reservoir. With such an arrangement, should a pump be taken out of service, either intentionally or as a result of emergency shutdown, the water would run back through the pump until the delivery pipe was empty. The pump would of course reverse its rotation under these conditions. Studies and estimates showed conclusively that for the aqueduct plants the common delivery pipe with a valve at each pump was more economical than separate delivery lines.

Discharge Valves

The large size of the pumps and the high discharge velocities called for careful consideration of the various available types of valves, which include plain swing-check valves, combinations of check valves, and pressure- or mechanically operated relief valves, butterfly valves, gate valves, needle and plunger valves, and plug-type valves or cocks. On account of the high velocity at the pump discharge, reaching 24 fps at maximum flow, loss of head is an important consideration. Butterfly valves, needle and plunger valves, and certain types of plain gate valves all create a certain amount of obstruction or disturbance in the flow, with more or less head loss. However, two types of valves, the ring-follower gate valve and the rotating-plug-type valve, could be so constructed that at full opening they would offer no more resistance to flow than an equal length of straight or tapered circular pipe. In both types, when fully open, the water passages through the valve body and the valve disk or plug are circular and of uniformly increasing diameter from the pump-discharge flange to the connection of the valve to the delivery pipe.

Of even greater importance than the type of valve is the operating and control mechanism. Considerable power is necessary to operate high-pressure valves of this size, particularly for the rapid valve movement on emergency closure. Electric power is not suitable since failure of power supply would leave the valves inoperative at the very time when emergency operation is necessary. Hydraulic operation, using the delivery-line water pressure, is not wholly desirable, partly because of the variation in the pressure source during closure and even more so because of

the possibility of incrustation and corrosion of the small control valve parts and the resulting irregularity or failure in operation. The most reliable power source, although the most expensive, appeared to be hydraulic cylinders, using oil from air-pressure-accumulator tanks similar to those commonly used for supplying power to actuator-type governors for hydraulic turbines.

Specifications were issued for both ring-follower gate valves and rotating-plug-type valves. Hydraulic-cylinder operation was required using oil pressure. The control mechanism was specified to be flexible enough to give the slow valve travel desired for normal opening and closing, as well as an adjustable fast travel for emergency closure. The bids received showed a lower cost for the rotating-plug-type valves in all plants and contracts for this type were awarded to the S. Morgan Smith Company for the valves at the Intake, Gene, and Iron Mountain plants, and to the Pelton Water Wheel Company for the valves at the Eagle Mountain and Hayfield plants. The hydraulic-cylinder operators for the Eagle Mountain and Hayfield valves were made by the Chapman Valve Company for the Pelton Water Wheel Company. Controls for all valves were made for

both principal contractors by the Woodward Governor Company.

The general design of the valves made by the two companies is similar, except for the operating mechanism. In all valves, with the plug in the fully open position, the water passage is circular in cross section, increasing in diameter from the pump to the delivery pipe. The total angle of the taper is about 8 deg. The valve thus forms an extension of the pump diffuser and helps to regain the velocity head at the pump discharge. Close to the periphery of the water passage on both the valve plug and valve body are noncorrosive seats, which are of monel metal on the S. Morgan Smith valves and bronze on the Pelton valves. The plugs are conical and, in both the open and closed position, the plug is pushed down into the valve body so that the seats are in contact. To open or close a valve, the entire plug is first raised sufficiently to separate the seats, then rotated 90 deg, and finally pushed down again to reseat. On the sides of the plug are seats corresponding to those around the water passages. There is thus full seat contact in both the open and closed positions. Fig. 5 is a shop erection view of one of the S. Morgan Smith valves which shows the opening and closing seats on the plug. Fig. 6 is an

assembled view of one of the Pelton valves. Figs. 7 and 8 show cross sections of the two valves and their operating mechanism.

The valves are all hydraulic-cylinder-operated with oil at 300 lb per sq in. working pressure. The principal difference between the S. Morgan Smith valves and the Pelton valves is in the mechanical arrangement by which the straight-line motion of the hydraulic piston is made to raise, rotate, and then lower the plug.

On the Pelton valves, the operating cylinder is separate from the housing containing the mechanism for rotating the plug. A guided crosshead on the piston rod operates a rotator arm and a lifting nut which are attached to the valve stem. For the first few inches of crosshead travel, the rotator arm is prevented from rotating. Through a linkage the crosshead turns the nut on the threaded portion of the stem in a direction to lift the valve stem and plug. After the crosshead has traveled far enough to lift the plug completely free, the rotator arm is released and a pin on the crosshead enters a slot in the rotator arm. Further travel of the piston rotates the entire assembly of rotator arm, lifting nut, valve stem, and plug. After the required 90-deg rotation, the rotator arm strikes a stop which prevents further angular motion;

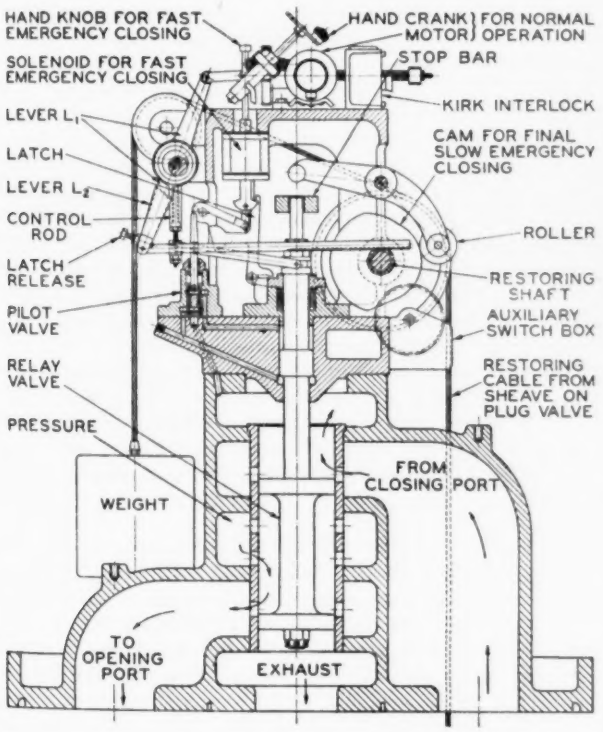

Fig. 9 Cross Section of Control Mechanism Used on All Valves; Woodward Governor Company

the pin on the crosshead comes out of the slot in the rotator arm; and further travel of the piston turns the nut in a direction to lower the valve stem and reseat the plug. The crosshead, rotator arm, and lifting nut operate in a bath of lubricant.

On the S. Morgan Smith valve, the lifting, rotating, and reseating motions are accomplished through an interacting combination of racks and gear segments. The piston acts directly on a rack which has three separate rows of teeth, each row matching with a separate gear sector. The first few inches of piston travel cause rotation of the lifting gear sector. The lifting sector is keyed to a screw which rotates freely on the valve stem but is threaded into a nut which is keyed to the reseating gear sector. During this portion of the stroke, the rotating sector and the reseating sector are both prevented from turning by special teeth which slide on flat surfaces on the rack. When the stem has lifted the required amount, all three gear sectors are engaged by the rack teeth and rotated 90 deg. The rotating sector and the lifting sector then come out of mesh with the rack and are prevented from rotating further by stops in the housing. The reseating sector is still in mesh, however, and the relative motion between the nut and the screw forces the nut downward and

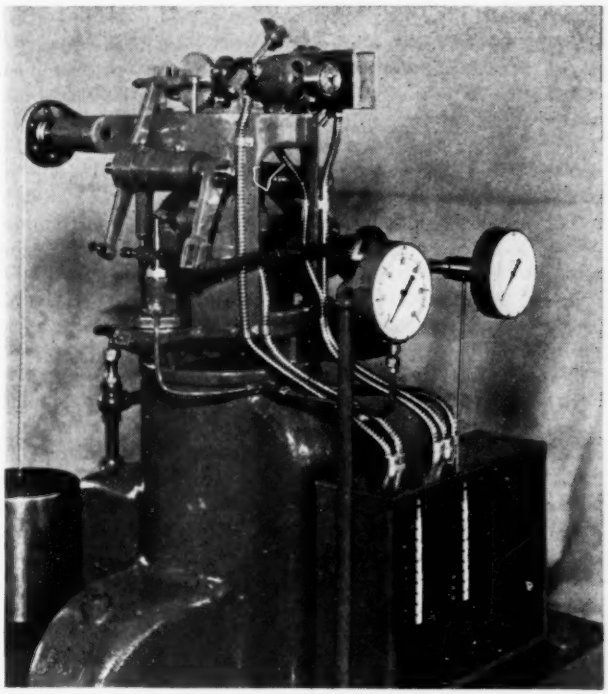

Fig. 10 Assembly of Control Valve, Cover Removed; Woodward Governor Company

reseats the plug. Adjusting screws limit the rack travel for both seating and reseating and can be adjusted to give the proper seat contact.

The principal parts of all the valves are steel castings fully annealed. Shop hydrostatic tests were made on all valves at a pressure approximately two and one-half times the maximum static head. The operating cylinders were tested at 450 lb per sq in. oil pressure. The specifications required the operating mechanism to have sufficient capacity to unseat the valve against an unbalanced pressure of 120 per cent of the maximum static head, assuming a friction coefficient of 0.50 for the seats, and a pressure of 250 lb per sq in. in the operating cylinder.

Control Mechanism

The source of oil pressure for valve operation is an air-pressure-accumulator tank, with return-oil sump tank and pump, very similar to the oil-pressure sets used for actuator-type governors for hydraulic turbines. The proper oil level and pressure are maintained in these tanks automatically. There is an independent pressure set for each valve. The control mechanism, furnished by the Woodward Governor Company for all valves, operates the valves slowly for normal starting and shutting down a pump. On failure of power to a pump motor, this mechanism closes the valve very rapidly to about 5 per cent of the effective opening and then very slowly to full closure. The time of the fast part of the stroke can be varied from about $1^1/_2$ sec to 5 or 6

sec. The point on the stroke where the motion changes from fast to slow can be varied. The slow-closing part of the stroke can be adjusted to any time up to about 60 sec. For normal opening and closing, the time of the full stroke is 40 to 60 sec and the rate is nearly uniform.

Before starting a pump, the inlet valve is fully opened and, since all the pumps are set well below the inlet-water level, the pump casing is completely filled. The discharge valve is closed and normally the discharge pipe above the valve is completely filled. The motor is started, brought up to speed, and synchronized, the pump operating at practically shutoff head. An 8-in. by-pass with a check valve on each of the main plug valves permits sufficient water to be pumped to prevent overheating the water in the pump casing. The by-pass is also used to fill the delivery line if it is empty when the pump is started. The main plug valve is then opened slowly. When taking a pump out of service, the discharge valve is first slowly closed, the motor circuit breaker opened, and the unit decelerates to rest.

Fig. 9 shows a cross-sectional view of the control mechanism. Fig. 10 shows the control valve with the cabinet removed. The relay valve for applying oil pressure to operate the hydraulic cylinder, the pilot valve, the floating lever (in this case a double eccentric), and the control rod are similar in construction and operation to the corresponding parts in a water-wheel governor. The control rod corresponds to the speed rod of the flyballs.

Referring to Fig. 9, the control rod is actuated by a double eccentric. The control rod is journaled on the hub of the outer eccentric and the outer eccentric is journaled on the inner eccentric. The outer eccentric is integral with the lever L_1 and is turned thereby. The lever is operated by the back-geared motor, through gearing and a screw. The inner eccentric is integral with the central shaft, which is turned by the restoring lever, L_2. To the end of lever L_2 is attached a rack bar which meshes with a gear on the restoring shaft. This shaft is connected to the vertical shaft of the main pump discharge valve by a cable and sheaves, the cable and sheaves all being enclosed. Thus lever L_2 moves with and its position corresponds to the angular position of the cone valve plug. The cable is kept taut by a heavy weight. With the levers L_1 and L_2 in line with each other, the control-rod length is adjusted to hold the relay valve in its central position with the relay ports closed. If lever L_1 is moved out of line with L_2, the control rod will be moved up or down, causing the relay valve to be moved down or up and admit oil to the main-valve operating cylinder. The main valve plug then rotates and, through the cable connection, the restoring shaft, and the rack, brings lever L_2 in line again with L_1, moving the pilot valve in a direction to cause the relay valve plunger to close the relay ports and stop the movement of the plug. If L_1 continues to move, then the main valve plug and lever L_2 will continue to move at the same rate.

In Figs. 9 and 10, the levers are shown in the position they assume after the main valve has been fully opened. To close the valve in a normal slow-closing operation, the control motor is started in the direction to cause the upper end of lever L_1 to move to the left, which will cause the main valve plug to unseat and rotate in the closing direction, and lever L_2 to move toward a position in line with L_1. When lever L_1 has been moved to its extreme left position, the main valve plug will have rotated to its fully closed position. A little overtravel of the lever L_1, causes the piston of the hydraulic cylinder to continue on and seat the plug. The control-valve motor is provided with a friction governor to secure a constant speed irrespective of the voltage. The governor is adjusted to give full plug rotation in about 40 sec.

To open the valve the motor is operated in the opposite direction.

In case of motor or current failure, the valve may be operated by the small hand crank shown close to the motor. This is geared for a number of turns calculated to make it convenient to operate at about the same speed as motor operation gives.

Limit switches operated by the motor screw open the motor circuit when the screw has traveled its full movement in either direction.

For emergency closing, the main-valve plug is closed rapidly by energizing the 125-volt, d-c solenoid or by raising the solenoid core by means of the hand knob. As the core is raised, it acts, through the link and lever shown in Fig. 9, to depress the pilot valve. A spring in the control rod permits it to do so. The pilot valve then causes the relay valve to rise, closing the plug rapidly, at a rate determined by the setting of the stop bar, which limits the amount the relay valve can open.

When the solenoid core is raised, the latch shown falls into place and holds it up. Then the plug cannot be moved to open until the latch is released. This will occur when the lever L_1 has been moved to the closed plug position and the lower extension of lever L_1 strikes the latch.

When the plug has been closed rapidly to a predetermined position, the cam, shown on the restoring shaft, engages a roller on the right-hand end of a rocker arm shown just above the cam. The other end of the rocker arm is thereupon depressed and forces the relay valve down to a port opening which will cause the final closing of the plug to be made at the desired slow rate.

The principal adjustments on the control mechanism are as follows: (1) The rate of normal opening or closing can be varied by the governor on the d-c motor; (2) the initial rapid-closing rate can be varied by raising or lowering the stop bar, which limits the travel of the relay valve; (3) the position of the main-valve plug, at which the emergency-closing rate changes from fast to slow, can be varied by rotating the cam with reference to the restoring shaft; (4) the final slow-closing rate can be varied by replacing the roller which is lifted by the cam and using another roller of slightly larger or smaller diameter. Once made these adjustments are locked and are not readily changed.

The entire control mechanism is enclosed in a dustproof cabinet. The top cover of the cabinet is hinged and provided with a lock. When this cover is raised it gives access to the hand control for normal and emergency operation. For access to the adjustments, there are two side openings with dustproof covers, bolted in place from the inside.

Operation

Control of the main-pump motors and of the pump discharge valves is centralized in a control room adjacent to the pumping plant. Normally, the sequence of operations in starting and stopping a pumping unit is automatic. In starting up, the operator throws a switch on the control board which applies full voltage to the main motor. As the speed approaches synchronism, a relay operates to apply field current and the motor pulls into step. Closing the field breaker initiates the opening of the pump discharge valve. For normally shutting down a unit, the operator turns the control switch in the closing direction, which starts the pump discharge valve closing slowly. When the valve plug has rotated past the cutoff position so that the pump discharge is entirely through the 8-in. by-pass, the motor is tripped off by a switch actuated from a cam on the control-mechanism restoring shaft.

On emergency closure, the motor is tripped off and rapid closure of the valve is started at the same time. There is an emergency shutdown switch on the control board in the operator's room, so that the operator can trip the unit off in this manner whenever necessary. Emergency trip of the valve and motor is also initiated by any one of the following abnormal conditions: (1) Failure of lubricating-oil supply to pump or motor bearings.

(2) failure of water supply to the motor coolers; (3) operation of motor overload or differential relays; (4) operation of transformer differential relays; (5) accidental opening of motor or high-voltage circuit breakers; (6) phase or line-to-ground faults on transmission system.

Laboratory Tests

Extensive tests on small gate valves and plug valves and on scale models of the pump discharge valves were made by both of the firms that manufactured the valves and by the Metropolitan Water District. These tests were made in order to estimate closely the power required to operate the valves under the assumed maximum-flow conditions, and to determine the loss in head through the valves at various openings. Tests by the manufacturers were made in their own laboratories. The District's tests were made in the hydraulic-testing laboratory at the California Institute of Technology.[2]

It is not within the scope of this paper to describe in detail the work done in the various laboratories. Preliminary testing by the District was conducted on a 6-in., quarter-turn, S. Morgan Smith plug cock with a circular water passage of uniform diameter and on a 6-in., ring-follower, Yuba gate valve. Tests were confined to determining the loss of head at various openings and rates of flow. Tests by the valve manufacturers were made on scale models of the actual valves as they were to be constructed. The model valves were about one seventh the linear dimensions of the full-sized prototypes. The manufacturers' tests were primarily for determining the torque required to rotate the valve plugs at various openings and rates of flow. However, since the laboratory facilities also permitted head-loss measurements, these were taken for the same openings and rates of flow as the torque. The independent tests made by the S. Morgan Smith Company and the Pelton Water Wheel Company were in reasonably close agreement both as to torque and head loss.

The torque tests showed conclusively that, with the operating mechanism designed to have power enough to unseat the plug under the maximum unbalanced head required by the specifications, there was more than ample torque to rotate the plug and control its rate of rotation at any angular position and under the severest flow conditions reasonably expected, even considering the possibility of free reverse discharge through a ruptured pump casing.

The model valve, made by the Pelton Water Wheel Company and used by that company in the determination of torque and head loss, was afterward made available to the District. Further head-loss tests were carried out on this model in the District's laboratory at the California Institute of Technology. Prior to these tests, seat rings were added to the model in order to make it conform as nearly as possible in dimensional relations with its prototype. However, in the unseated position after lifting the plug and in that portion of plug rotation between cutoff and the full quarter turn, it was not practicable to make the clearances such that the clearance dimensions were in the same ratio to the prototype as the main water-passage dimensions. Consequently, the water that flows past and around the model valve plug, when it is lifted and rotated to the position where the water passage through the plug no longer opens directly into the water passage through the valve body, is not a correct measure of the flow through the corresponding clearances in the full-size valve. Since this so-called leakage could not be segregated and accurately measured and, even if it could be measured, would not represent the correct leakage in the prototype, it was decided to neglect it in water-hammer calculations and to assume that the flow through the valve is entirely shut off when the plug is rotated to the cutoff position. This assumption is on the side of safety, since abruptly cutting off the final flow results in a higher calculated pressure rise.

For both the Pelton and S. Morgan Smith valves, the cutoff position is about 70 deg from the full-open position. During the remainder of the 90 deg of total rotation, the plug is lifted off its seat and there is a considerable flow around the plug and through the clearance between the plug and body seats until the reseating operation has brought the seats into full contact. The effect of neglecting this flow is to make the calculated pressure rise considerably greater than the actual observed pressure rise.

In the first loss-of-head tests made by the District, as well as in similar tests made by the manufacturers, the model valve was placed in a straight run of pipe and the net head loss due to the valve only was measured. Pressures, measured directly downstream of the valve at partial openings, showed a considerable drop, due to the high velocity. Therefore, the net head loss was measured from a point just upstream of the valve to a point sufficiently far downstream (about six pipe diameters) so that recovery of velocity head was no longer observed. In the prototype installation, however, the valve is placed directly at the pump discharge. In reverse flow, the jet from the partially opened valve enters the pump casing before the jet velocity has been fully converted into pressure head. A setup was made in the laboratory to simulate the actual installation. The model valve was placed directly at the discharge of a model pump, the complete head and torque characteristics of which had been determined previously for a wide range of normal and reverse rotation, and direct and reverse flow. From this series of experiments, it was found that the head loss in the valve, as affecting reverse flow through the pump at both normal and reverse rotation, was somewhat less than the head loss when the valve was tested in a straight run of pipe.

The experiments showed that the head loss through the valve can be expressed with sufficient accuracy by the equation

$$H_v = KV^2/2g \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

where H_v is the head loss in the valve, in feet; V is the velocity through the valve plug at the center of the plug in feet per second; and K is a coefficient which is a function of the valve opening and is determined experimentally.

Fig. 11 shows the values of K, determined by these experiments for the Intake and Gene valves and plotted as a function of the angle of the plug in degrees from the full-open position. It should be noted that K approaches infinity as the plug is turned to the cutoff position.

Control of Water Hammer

In order to meet the construction program, it was necessary to design and construct the pump-delivery pipe lines before all of the valve investigations had been completed. Preliminary water-hammer studies were based upon the first experiments on 6-in., uniform-diameter plug and gate valves and upon pump characteristics taken from a pump, having a specific speed somewhat near that of the full-sized pumps, but not in any sense a scale model. These studies showed that the most severe combination of abnormal operations reasonably to be expected was for the motor to be tripped off, the valve not starting to close, until full reverse flow had developed and then closing for its full stroke at a very rapid rate without any retardation near the end of the stroke. It was assumed that this condition would occur on only one pump in any group of three, the valves on the other two pumps operating normally. The resulting maximum pressure rise was calculated to be about 50 per cent for the two highest-head plants, Eagle Mountain and Hayfield; about 75 per cent for

[2] "The Hydraulic Machinery Laboratory at the California Institute of Technology," by R. T. Knapp, Trans. A.S.M.E., vol. 58, Nov., 1936, p. 663.

the Intake and Gene plants; and about 125 per cent for the lowest-head plant, Iron Mountain. The pipe lines were designed for the maximum total heads given by these overpressures, using a maximum stress of 20,000 lb per sq in. in the 10-ft-diameter pipe and 15,000 lb per sq in. in the 6-ft pipes leading from the pumps and in the manifold connecting the 6-ft pipes to the 10-ft pipe.

Water hammer in the pump-delivery lines is a transient condition occurring within a very short period of time. It results

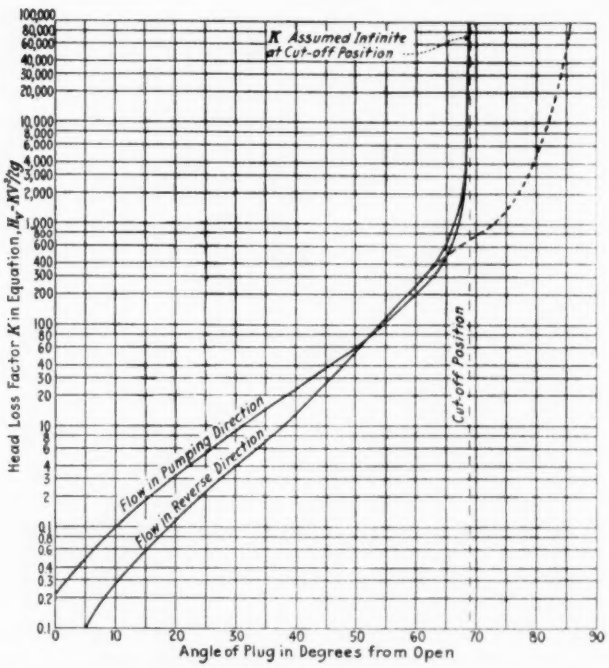

FIG. 11 HEAD-LOSS COEFFICIENT K, PLOTTED AS A FUNCTION OF VALVE OPENING

from rapid variations of the velocity. The slower the changes in velocity, the less the pressure variation. The characteristics of the pipe line, the head loss through the valve as it closes, the variation of pump discharge and torque with changing head and speed, and the combined flywheel effect of the pump and motor, all affect the velocity in the pipe line and hence the magnitude of the pressure variation. The water-hammer pressure produced by an emergency shutdown of a pump is thus the result of interaction between the pump and motor, the pipe line, and the shut-off valve. Analysis to predict water-hammer pressure must take into account the characteristics of all these elements of the pumping system.[3] The motor, pump, and pipe-line characteristics, once selected, are fixed, so that the timing of the valve stroke is the only available means of regulating the velocity changes in the pipe.

The valve timing for emergency closure is adjusted so that closure is very rapid for about 59 deg of plug rotation, reducing the effective valve area to about 5 per cent in about 3 sec. During this period, the pump is rapidly decelerating, the velocity in the pipe line drops, and the pipe-line pressure drops. As shown by the K diagram in Fig. 11, the throttling effect for the first part of the stroke is small. The pressure drop during this period is dependent almost entirely on the pump characteristics, the motor flywheel effect, the length of the pipe line, and the initial velocity. The valve has comparatively little influence since, by the time the valve closes to an appreciable throttling effect, the velocity is low whether forward or reverse. Somewhat before the time the valve reaches the end of the rapid part of its stroke, the pressure beyond the valve has begun to build up due to reflection from the upper end of the pipe line. The speed of the pump in the meantime has dropped to a point where the head developed by the speed of rotation is less than the opposing pressure. The flow reverses, although the pump is still rotating in the pumping direction. The reverse flow through the pump acts as a relief for the overpressure which tends to develop in the pipe line. The very slow final closure of the valve prevents any large pressure rise in shutting off the reverse flow. By adjusting the final slow-closing time, it is found possible to make complete closure before reverse rotation of the pump, and yet without producing overpressure of any considerable magnitude. Fig. 12 shows the valve timing used at the Intake and Gene plants.

Analyses were made for a number of different emergency conditions, such as delayed tripping of the valve until full reverse flow is developed, abnormal initial speed drop of the motor due to electrical trouble, emergency valve closure without tripping off the motor, and other possible abnormal operations. In all cases the calculated maximum pressure rise was well below the maximum

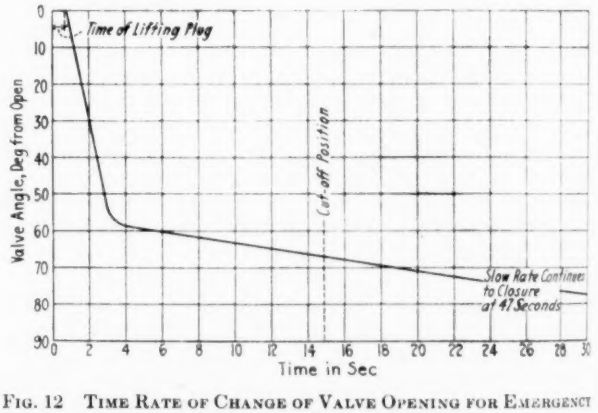

FIG. 12 TIME RATE OF CHANGE OF VALVE OPENING FOR EMERGENCY CLOSURE AT GENE PLANT
(Timing shown is very close to the actual valve timing recorded simultaneously with the test curves in Figs. 13 and 14.)

which the pipe lines and other apparatus are designed to withstand, although it was found that in some cases the pump would reverse rotation and attain considerable speed in the reverse direction.

COMPARISON OF CALCULATIONS WITH FIELD TESTS

At the date of writing (February, 1939), the first two pumping plants, Intake and Gene, had been placed in operation, and a number of observations had been made on the water hammer produced by several different types of emergency shutdowns. Comparison of the observed pressure rise with previous calculations shows that in every case the observed pressure rise is less than that calculated. Figs. 13 and 14 show the comparison for one and three pumps tripped off at the Gene plant, where there is the longest delivery line. One reason for the difference between the observed and calculated results is undoubtedly the assumption made in the calculation that the flow is abruptly cut off when the plug is rotated to cutoff position. Reference to Fig. 12 shows the K curve approaching infinity at cutoff. Probably the K curve in that region is more nearly that shown by the dotted line, indicating that the flow just before cutoff is more than was assumed and that flow continues and is gradually shut off between cutoff position and full rotation.

[3] "Typical Analysis of Water Hammer in a Pumping Plant of the Colorado River Aqueduct," by R. M. Peabody, Trans. A.S.M.E., vol. 61, Feb., 1939, p. 117.

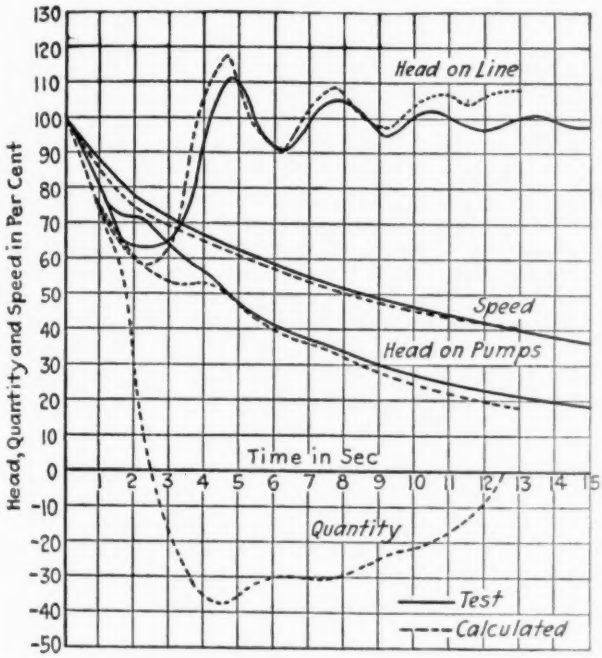

FIG. 13 COMPARISON OF MEASURED PRESSURE AND SPEED VARIATION WITH CALCULATIONS AT THE GENE PLANT; EMERGENCY SHUTDOWN OF ONE PUMP; NO OTHER PUMPS OPERATING

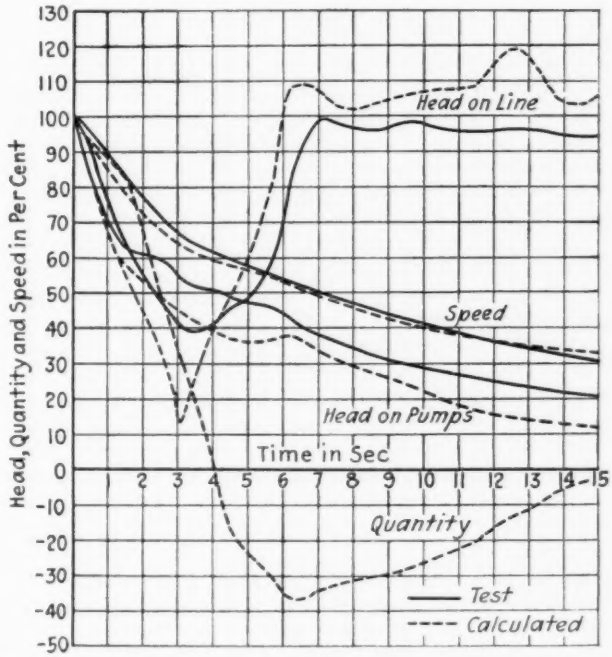

FIG. 14 COMPARISON OF MEASURED PRESSURE AND SPEED VARIATION WITH CALCULATIONS AT THE GENE PLANT; EMERGENCY SHUTDOWN OF THREE PUMPS SIMULTANEOUSLY

It is known from observation that considerable reverse flow continues after cutoff but it has not been possible to measure it. The closing time of the three valves was purposely made slightly different so that all the valves do not fully close at the same instant. This tends to reduce further the pressure rise when two or three pumps are tripped off simultaneously. A careful study of the speed drop at the very start of the transient, which the scale of Figs. 13 and 14 is too small to bring out, shows that, in the first small interval after the start of the transient, the drop in speed is less than given by calculation. This would tend to reduce the initial pressure drop and consequently the subsequent pressure rise. After the first half second or so, the observed and calculated speed drops check fairly well. This indicates a larger flywheel effect at the very start. A suggested explanation is that the rotational inertia of the water in the casing surrounding the impeller tends to increase the total inertia of the pump and motor, and that this effect diminishes rapidly with reduced discharge.

In Fig. 13 the single pump shutdown was made from the emergency switch in the control room. The three-pump shutdown was made by opening the 230-kv circuit breaker close to the plant. The most severe pressure rise observed was when a single pumping unit, no other units operating, was tripped by opening the circuit breaker at the Boulder power plant, with 237 miles of energized 230-kv transmission line between that breaker and the pumping unit. In this case the motor had to act momentarily as a heavily loaded generator supplying charging current to the line. The effect was a rapid drop in the speed of the motor in the short interval before the reverse power relays could act to open the motor circuit breaker and clear the motor from the line. With several motors operating in parallel, each would contribute only a part of the charging current and the speed drop would be less rapid.

Line-to-ground and phase-to-phase short circuits were applied to the transmission system at different distances from the plant, but the resulting pressure rise was less than in the case above cited.

When one pump was tripped off, while either one or both of the other pumps in the plant continued to run, the pressure rise was found to be less than when the pump was tripped while the other two pumps were shut down. This was to be expected since with several pumps running the return-pressure wave, resulting from shutting down a single pump, is relieved through the operating pumps.

Pressure variation in the pumps and pipe line was measured by a fast-motion, strip-chart pressure recorder. The records of valve movement were taken on a fast-motion recorder. Speed variations were observed on a high-speed recording voltmeter, which showed the variation in the voltage of a magneto-tachometer driven from the motor shaft.

CONCLUSION

Rotating-plug-type valves are well adapted for shutoff valves on large pumps. With proper control of the rate of closure they can be made to limit the pressure rise to a moderate percentage in systems comparable to those of the Metropolitan Water District. A marked advantage of this type of valve, which is lifted off its seat while rotating, is that the entire flow is not abruptly shut off when the main water passage is rotated past the cutoff point. The final flow is thus extinguished gradually which tends to cushion the maximum pressure rise.

The magnitude of the pressure rise to be expected can be predicted by well-established methods of calculation, provided that the characteristics of the elements making up the pumping system are known.

All work on the Colorado River Aqueduct is under the direction of F. E. Weymouth, general manager and chief engineer of The Metropolitan Water District of Southern California. The design and construction of the pumping plants are under the direction of J. M. Gaylord, chief electrical engineer.

Discussion

ROBERT W. ANGUS.[4] The writer wishes to commend the author for making available some of the data and results used in connection with the water-hammer study on this very extensive pumping problem. The magnitude of the project is such as to justify experimental investigations of the characteristics of the pumps and also of the valves used, and information is thus available in a somewhat unknown field.

The paper is really part of the one by the same author,[3] where the method of working out the water-hammer pressures is given in some detail. For a proper study of this nature, a complete set of characteristic curves of the pump is necessary, covering the action of the machine (1) as a pump, (2) running forward but with the water running downward through it, (3) running under zero torque with the water passing downward, and (4) operating as a turbine with both water and impeller running in reversed directions. The excellent work[2] of R. T. Knapp, to which the author refers, has given data on a pump in such a complete form that its action on water hammer may be studied. It is hoped that similar information will be made available on a number of other pumps.

Presumably, the valve referred to in the author's earlier paper[3] is similar to that in the present one; in any event, the characteristics of the two are of the same form, and the data in the papers supplement one another. In Fig. 11 of the present paper, the losses in the valve for different plug positions are shown, the loss naturally varying with the direction of flow. The head-loss coefficient K will vary with the reference velocity, which has here been taken as that at the center of the plug, whereas it would seem to be more consistent to use one of the end velocities. For partial openings the plug will not be filled with water and the meaning of the velocity there is obscure; the author apparently means by it the quotient of the discharge divided by the area of circular opening at the center of the plug.

The writer has made a number of experiments[5] on a 3-in. cone valve with a cylindrical opening and, while it is not possible to compare the coefficients on this small valve with those on such a large tapering valve, yet there is in general a very good agreement, particularly for the large openings. In the small valve the cone was not lifted off its seat in any position, and hence the smaller openings would be less in agreement.

Fig. 12 shows that in the Gene plant, for the pipe line of which the value of $2L/a$ is given as 1.533 sec in Table 1, the plug has been turned through about 58 deg in about 3 sec or, if allowance is made for the time of lifting the plug, the latter has been turned through about 58/69 or 85.5 per cent of its total closing movement in about 2.3 sec or 1.5 times $2L/a$ sec, which is very quick. The remaining 14.5 per cent of the movement has been made in about 12 sec and Fig. 14 shows that this causes no pressure trouble when the water is running at full velocity in the delivery line. This further illustrates the point mentioned by the writer in the paper[2] already referred to. Many statements have been made that valves in long pipe lines must be closed very slowly to avoid water hammer, whereas the author shows that a closure in 15 sec causes no appreciable pressure rise.

Provided that it is not less than perhaps 10 times the period of the pipe, the total time of closure of a valve is of far less importance than the way in which the closure is effected. For many types of valves it is scarcely possible to effect the first 70 per cent or so of the closure fast enough to cause any trouble, but the final part of the operation must usually be done with great care and with proper consideration of the characteristics of the valve being used. Great differences exist among valves, in regard to their method of control, and some would cause trouble under similar operating conditions to those herein mentioned. However, the valve described in the paper has good features, and the author has done a real service to the profession in giving information about it in such detail.

The writer feels that the control valve shown in Figs. 9 and 10 would be very expensive and quite impossible for any but the very large plants. There may, however, be ways of effecting a similar movement of the cone in a simpler way and, if so, the writer would like information about them. The writer also thinks that some details of the recording devices used in producing the curves of Figs. 12, 13, and 14 would be of much help to those working on water-hammer problems, and hopes the author will add this information to his paper.

A. HOLLANDER.[6] This paper is a worthy complement to the author's former paper,[3] disclosing the method of analysis and the means of reducing the pressure rise in a large pumping system. It shows that a relatively inexpensive rotating-cone valve, which continues the diffusion of the pump-discharge taper without any additional loss under normal operating conditions, is the only direct regulating means required for such a system. The indirect means are a constant-pressure oil supply and the Woodward actuator-type governor. This is the first application of this turbine governor in a pumping plant, where it serves as a pilot valve for the oil-pressure-operated cone valve. The very complete model experiments included the combined pump-and-valve behavior under transient conditions. In reference to these, the writer would like to ask whether both directions of rotation from open to closed were explored, as they would undoubtedly give different results for reverse flow, due to the different entrances into the volute.

It is interesting to note that the valve coefficient K (should be designated as φ)[7] is increasing from open (0 deg) to closed (68 deg) with an inflection point at around 55 deg. If this coefficient is referred to the gate area actually open, $H_v = \frac{A \text{ gate}}{A} c \frac{v^2}{2g}$ (it should be corrected to read this way in the first paper),[3] then the coefficient c shows a maximum at about 38 deg from open.[8] The two coefficients with the areas at different openings and time rate of opening give a complete picture of the valve effect.

The writer would suggest that in the time-history diagrams[9] the term "quantity" be changed to "flow" or "flow rate" as this is what it means. Furthermore, it should be understood, that this flow, as a function of time, refers only to the flow at the point where the pressure is measured, i.e., to the sections next to the valve, "head on line" at the pipe-line side, and "head on pump" at the pump side of it. For these sections, the flow being proportional with the velocity, a velocity-time diagram in percentage becomes identical with the flow-time curves and therefore could be designated as a velocity-wave curve at these points, in the same manner as the head curves are actually pressure-wave curves at the same sections. For better understanding of the phenomenon, this would be helpful, as the differential of the velocity-time curve gives the acceleration of flow.

The very excellent graphical solution[10] of Professor Bergeron

reproducing the numerical data in a diagram would help further to illustrate the phenomenon step by step.

The author calls attention to the very short but powerful electrical-braking effect of the motor, during the time interval between the opening of the energized circuit at a far-away point and the opening of the control that takes the motor off the line. The importance of this effect in this case is clearly shown and calls for inclusion of this factor in analyzing similar problems.

The publications describing the great project of the aqueduct of the Metropolitan Water District of Southern California, including the author's two papers, show that they blazed new trails in many fields and by giving all details made notable contributions to the art of designing and building of great waterworks.

RAY S. QUICK.[11] The author and his associates are to be congratulated upon the excellent test results secured in the control of pressure surge and reverse flow in the discharge lines of the pumping plants on the Colorado River Aqueduct of the Metropolitan Water District of Southern California. The prediction of the surge with respect to valve timing shows a satisfactory agreement with the test results and confirms the engineering principles developed and used in the calculations.

The pumps for the Intake and Gene Plants were manufactured in the San Francisco works of The Pelton Water Wheel Company in collaboration with the Byron Jackson Company. The discharge valves for the Eagle Mountain and Hayfield Pumping Plants were manufactured jointly by The Pelton Water Wheel Company in San Francisco and by the Chapman Valve Manufacturing Company, the cover and operating mechanism having been designed and furnished by Chapman. When it is realized that the completed valve, illustrated in Figs. 6 and 8 of the paper, has an approximate weight of 50,000 lb, the problems of manufacture and handling will be appreciated.

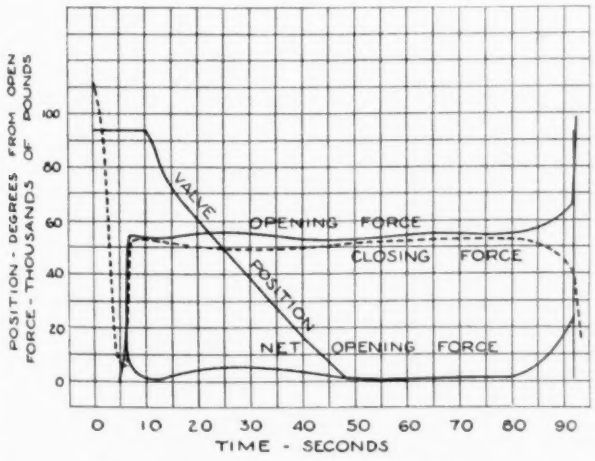

FIG. 15 NORMAL OPENING CYCLE OF VALVE
(Hydraulic cone valve, 40½ in. by 53⅞ in.; Eagle Mountain pumping plant.)

It may be of interest to consider further the performance of the discharge valves as tested at the Eagle Mountain Pumping Plant where the degree of control of pressure surge and reverse flow was equally satisfactory to that at Gene as reported by the author. Three sets of curves, Figs. 15, 16, and 17, are submitted to show the history of the valve action with respect to time for the conditions of normal opening, normal shutdown, and emergency shutdown, respectively. Opening, as illustrated in Fig. 15,

[11] Chief Engineer, The Pelton Water Wheel Company, San Francisco, Calif. Mem. A.S.M.E.

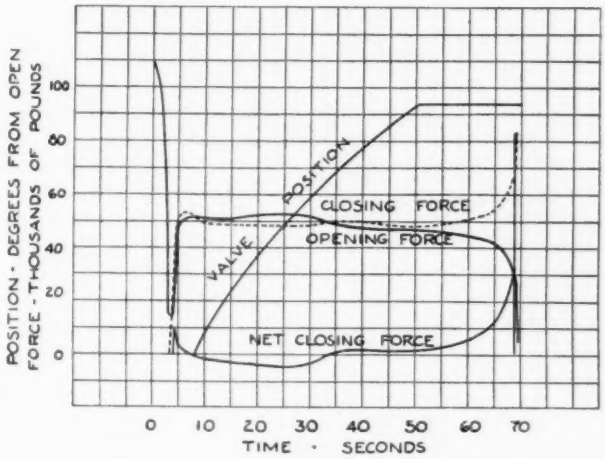

FIG. 16 NORMAL CLOSING CYCLE OF VALVE
(Same as Fig. 15.)

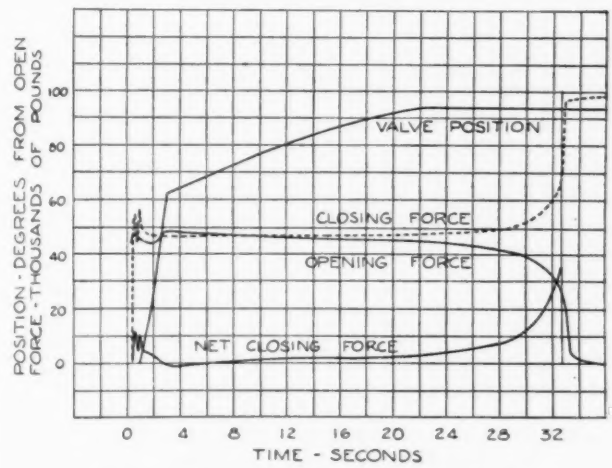

FIG. 17 EMERGENCY CLOSING CYCLE OF VALVE
(Same as Fig. 15.)

takes place only under normal conditions, with the pump running and with pressures substantially equalized on both sides of the valve. Since the rate of opening is controlled by the actuator unit developed and furnished by the Woodward Governor Company, with timed motor control, the forces on the operating mechanism are moderate and there is little or no pressure disturbances. Likewise, normal closing, as shown in Fig. 16, involves forces of moderate magnitude and little or no pressure disturbance, as here again the control motor is used to produce a steady rate of movement. These two cycles of normal opening and normal closing are used under operating conditions as there is no occasion to bring about emergency closure, except in case of power failure or other abnormal operating condition, requiring rapid shutdown.

The performance, shown in Fig. 17, illustrates the condition of emergency closure. It is interesting to note that, even under these conditions, the forces upon the operating piston are moderate and the reserve available at full pressure leaves a factor of safety of a very satisfactory amount. The greatest force is developed when wedging the plug into the seat in the closed position, as here it is desired to have a watertight closure. In the open position, the plug is very lightly wedged, in order that a wide margin of operat-

ing force may be available for emergency closure. When it is considered that the available force in the operating cylinder is about 115,000 lb, the factor of safety even for wedging is on the order of 3.

Laboratory tests conducted on the model cone valve showed the presence of a definite closing torque with hydraulic flow through the partially closed valve. This closing torque, however, is of relatively small magnitude. A study of the figures confirms this evidence and demonstrates that the greatest load on the operating mechanism occurs in the act of wedging the plug into the seat.

During the tests covered by the foregoing figures, the normal pressure in the discharge line was about 196 lb per sq in. On power interruption, the dip in pressure reached a minimum average of 162 and a maximum average of 207 lb per sq in. Thus the rise in pressure was only 5.5 per cent above the pumping head. These tests are well within desired limits and demonstrate conclusively the effective control of surge.

Cavitation of Hydraulic-Turbine Runners

By R. E. B. SHARP,[1] PHILADELPHIA, PA.

This paper contains a brief analytical discussion of runner cavitation. The I. P. Morris cavitation equipment is described, and results with this apparatus are compared with those of the Holtwood laboratory. A calibration gage in the development stage is also described. Stroboscopic apparatus for photographing runners during operation under cavitating conditions is illustrated, and various photographs above and below the sigma break are reproduced and discussed. A comparison of the index test of a prototype with a model at the same value of sigma is submitted.

THE sigma break of any hydraulic-turbine runner is considered as the value of sigma at which the performance characteristics begin to undergo a change due to cavitation. This value increases with the specific speed of the runner, i.e., the greater the specific speed, the greater, in general, must be the allowance for pressure drop $H_b - H_s$ on the back of the blades in the usual Thoma formula (1).[2]

Sigma $= \dfrac{H_b - H_s}{H}$ with H_b as the height of the water barometer and H_s the vertical distance from the center line of the runner; or more strictly, from the local point of lowest pressure on the blade, to the tailwater elevation. The reason for this increasing value of $H_b - H_s$ with increasing specific speeds is due to several factors, namely, the greater pressure differential necessary on the two sides of the blades, the greater absolute velocity, and greater relative velocity at discharge.

In order to present an approximate comparative picture of the increase in differential blade pressure with increasing specific speed, Fig. 1 and Table 1 have been prepared. Runners of three different speeds have been arbitrarily selected, these values being 50, 80, and 135; the two former speeds falling within the usual range of Francis-type runners, and the latter of propeller runners. The proportions and velocities selected correspond with usual practice, and the method employed at arriving at the approximate pressure differential is based on the efficiencies being normal, without excessive losses. Inflow and outflow diagrams are indicated, these being taken in all cases for the sake of simplicity at the runner throat or periphery with the flow axial, i.e., without radial component. In every instance both the runner diameter and the head acting are considered as 1 ft.

The basic-energy relation as set forth by the Eulerian theorem is

$$u_1 Vu_1 - u_2 Vu_2 = gHe \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

where u_1 and u_2 = velocity of rotation in feet per second at inflow and outflow, respectively; Vu_1 and Vu_2 = components of the absolute velocity V_1 and V_2 in the direction of rotation; g = acceleration due to gravity; H = head; and e = hydraulic efficiency. With $u_1 = u_2 = u$ and $H = 1$

$$Vu_1 - Vu_2 = \frac{ge}{u} \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

Where $HP = \dfrac{WQe}{550}$, multiplying Equation [2] by $\dfrac{WQu}{g \times 550}$, we have

$$\frac{WQe}{550} = \frac{WQu}{g \times 550}(Vu_1 - Vu_2) = \frac{2\pi FRN}{550} \text{ with } N = \frac{RPM}{60}$$

$$= \frac{u}{\pi D}, D = 1 \text{ ft}, R = \frac{D}{2}, W = 62.4, F = \frac{WQ}{g}(Vu_1 - Vu_2)$$

= tangential force acting on blades at radius R.

Consider as Q the discharge through an annulus of Δr radial depth. Then the area on which F is acting per blade is $L \times \Delta r$, Fig. 1 and Table 1. The force F, however, is the tangential component of F_1 which for this comparison is considered as acting on the angle θ with the tangential, this angle being such that the direction of the force F_1 bisects the angle between v_1 and v_2.

The various steps are indicated in Table 1. Item 21 represents the area plotted between L_a and h_d, the differential blade pressure in feet, projected in the direction of rotation in the annulus Δr to produce each of the specific speeds under consideration. In Fig. 1, these areas are shown at the right-hand portion of the figure. Admittedly the shapes are inaccurate, but the areas serve to indicate the intensity of differential pressure to produce the three specific speeds selected. The minimum pressure is plotted as sigma H, these values in each case being about those usually encountered. Sigma H is made up of the terms, $\dfrac{Vm^2}{2g} \times$ draft-tube efficiency plus the term $K_c H$ (2). The expression $\dfrac{Vm^2}{2g} \times ed$ represents the pressure drop due to head regain in the draft tube. The term $K_c H$ represents the local pressure drop on the blades.

The portion of the blade pressure lower than that corresponding with tailwater level or zero on the head scale is a much greater proportion of the total for the propeller-type runner than for the Francis type of lower specific speeds. A region of relatively low pressure has been shown for the backs of the blades at inflow. This is to some extent the result of actual observation of cavitation (for the propeller type) as discussed later, and is also in line with measured values for airfoils. This same tendency, as indicated by pitting, apparently exists to a minor extent on Francis-type runners. The greater preponderance of positive differential pressure in the Francis runners (above 0) with a relatively small amount below the 0 line is the reason for the difficulty of determining by test, with lower specific speeds, the definite location of the sigma break. In other words, loss of head due to cavitation on the backs of the blades has a relatively small effect on the force causing rotation. The intensity of the differential pressure could, of course, be reduced for the propeller runner by increasing the blade length, but to do so would so increase the friction loss that, with the high relative velocities existing, the value of ϕ at which maximum efficiency occurs would be reduced.

Pitot-tube traverses taken just below a propeller-type runner at a steep blade angle demonstrate that the axial velocities are materially lower at the wall of the tube than further inward and indicate the increasingly severe conditions as regards cavitation for some distance in from the periphery of propeller-type runners when operating at the steeper blade angles. This condition has been taken into account in the diagrams of the propeller-type

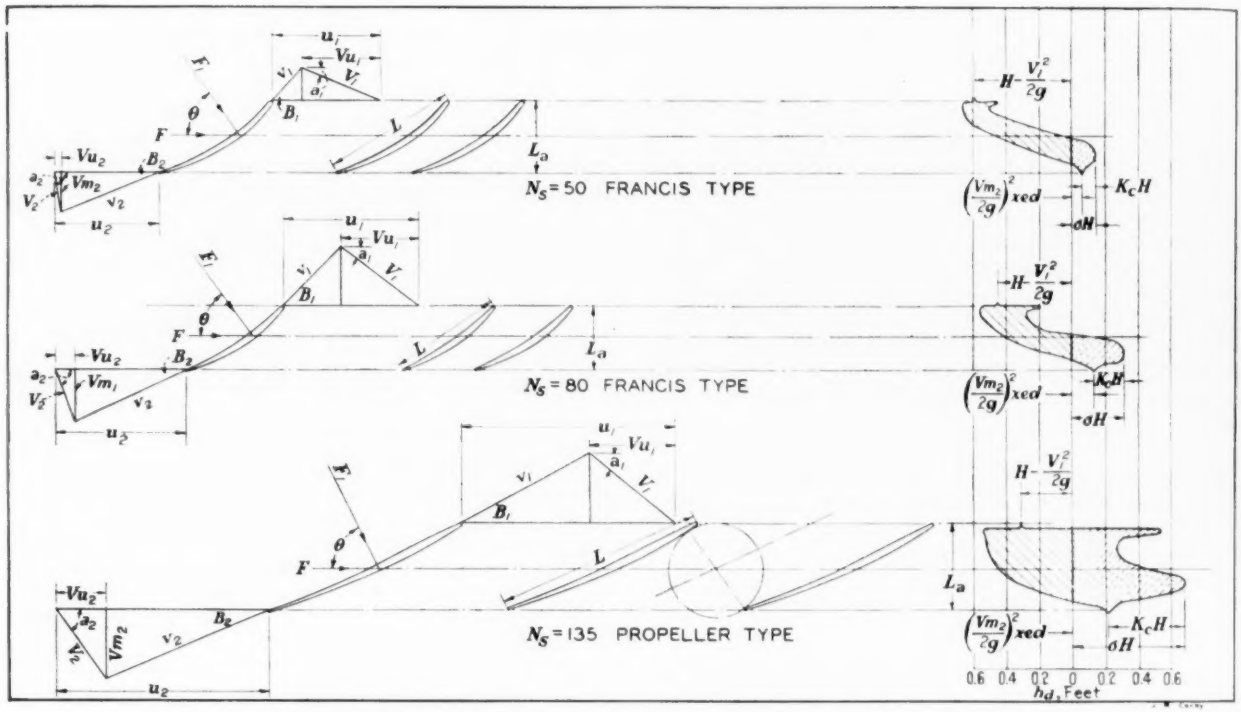

FIG. 1 SHOWING INCREASE IN DIFFERENTIAL BLADE PRESSURE WITH INCREASE IN SPECIFIC SPEED

runner in Fig. 1; that is, the value of Vm_2 in that figure is less than that corresponding with the average flow for this runner. Traverses taken at lower blade angles show that this condition of relatively low velocity at the wall of the tube dies out for lower flows. On this account, and in consideration of other test data, the flow for the two lower specific speeds in Fig. 1 has been considered as uniform across the runner discharge in arriving at the differential areas shown.

The increased cavitation tendency of runners of higher specific speed is also aggravated by the increased relative velocity. The pressure existing at any point on the blade where water tends to leave the surface is a function of the square of the relative velocity. Fig. 1 indicates by the comparative values of v_1 and v_2 for the different specific speeds how much greater this sensitivity is with the increased specific speeds, with resulting need for finishing of the blades true to contour.

That portion of each area, in Fig. 1, representing intensity of differential blade pressure which is below 0 on the head scale in the figure, is a function of Vm_2 and v_2. These values, as has been pointed out, increase with specific speed; and in addition, the ratio of the maximum to the average values of Vm_2 and v_2 undergoes an increase. As a consequence, certain portions of the blade may have a value of sigma H appreciably greater than the sigma H as determined by the change in performance characteristics. This is true even with runners having sharp and well-defined sigma-break curves.

It is not economically practicable to have the margin between the sigma break and the plant sigma sufficient to insure the absence of cavitation on the entire blade surface on this account. It is, therefore, becoming common practice to preweld portions of the runner blades with stainless steel where the operating head is above about 50 ft, in addition to providing a margin between the sigma break and the plant sigma (3).

Fig. 2 is a view of a turbine-runner blade before being welded. It will be noted that the portion prepared for welding extends along the entire periphery with a greater portion near the inflow

TABLE 1 DATA ON RUNNERS USED TO COMPARE INCREASE IN DIFFERENTIAL BLADE PRESSURE WITH INCREASE IN SPECIFIC SPEED

edge, and also near the outflow edge. In addition, a strip of rolled stainless steel is welded to the periphery of the blade, the need for which is discussed later. The portion of the blade which is to be prewelded is cast with a depression about 1/4 in. deep, and stainless steel containing essentially 18 per cent chromium, 8 per cent nickel, and with the carbon limited to about 0.08 per cent (3), is welded as indicated, precautions being taken to prevent distortion of the blade during this process.

FIG. 2 TURBINE-RUNNER BLADE BEFORE BEING PREWELDED

CAVITATION LABORATORY

The need for the convenient and prompt determination of the cavitation characteristics of model propeller runners resulted in the construction of the I. P. Morris cavitation equipment (5) in 1938, at Eddystone, Pa., Fig. 3. This involves essentially a closed circulating system with a service pump located about 8 ft below the floor, thus permitting relatively high values of H_s in the turbine draft tube without having as high values at the pump. A calibrated venturi meter measures the discharge. The tests are run under heads up to 35 ft. This equipment is designed primarily for tests of propeller runners of 11 in. throat diam, although it is possible in the case of Francis-type runners to increase this dimension. It is also designed for the cavitation testing of pumps. Variations of sigma are obtained by changing the pressure throughout the system (see Appendix for engineering data and equipment pertaining to cavitation equipment).

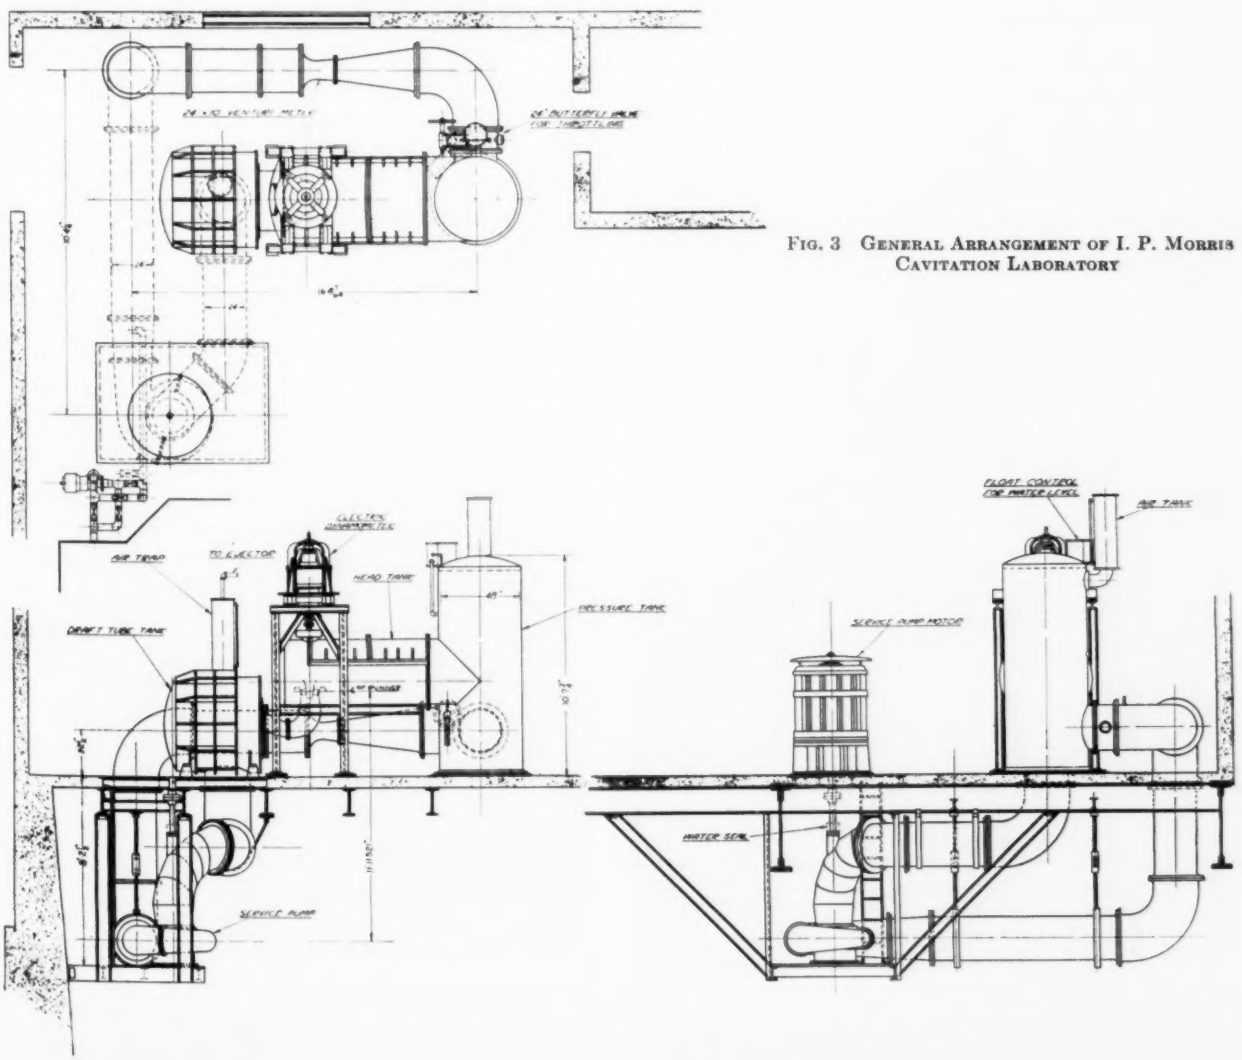

FIG. 3 GENERAL ARRANGEMENT OF I. P. MORRIS CAVITATION LABORATORY

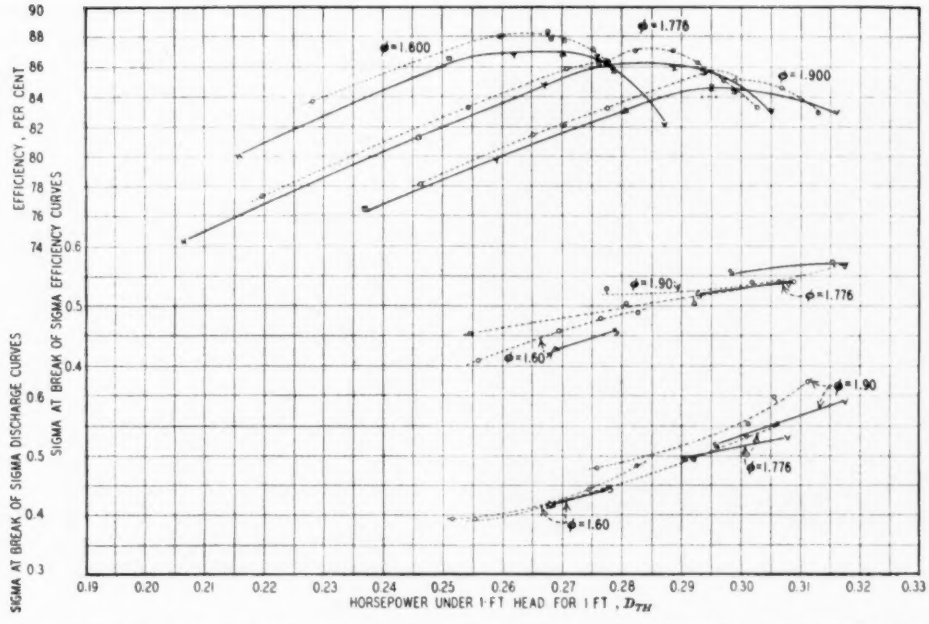

FIG. 4 COMPARISON OF I. P. MORRIS LABORATORY 11-IN. RUNNER MODEL WITH HOLTWOOD LABORATORY 16-IN. PROTOTYPE

This equipment was designed to permit the air to be separated from the water as much as possible, with the recognition that an undue air content would affect the sigma-break values (3, 4). The vertical pressure tank permits the air to rise to the top where it may be drawn off. However, it was later found advisable to add the air trap in the suction tank, and this has been the most effective means of air elimination since most of the air separation takes place in the draft tube. Particular attention has been paid to the possibility of air leaks in the suction tank and at the stuffing box to the service pump, where a water seal has been provided.

To calibrate this equipment as to efficiencies obtained and as to sigma-break values, a comparison was made with the Holtwood laboratory of the Safe Harbor Water Power Corporation by constructing and testing an exactly homologous but smaller (11-in. runner diam) model, for comparison with the Holtwood test of a 16-in. similar model. This particular 11-in. model is used as a standard at the I. P. Morris laboratory for check tests from time to time. Fig. 4 shows the results of a recent (March, 1940) test as compared with the Holtwood test made during June, 1935. The lower efficiencies at Eddystone are consistent with the smaller runner diameter, and the power and shape of the performance curves check closely.

The lower portion of Fig. 4 shows the comparison of sigma breaks for three values of ϕ. The upper set of curves is based on the break in efficiency and the lower set on quantity. While there is somewhat of a difference at 1.9ϕ, particularly on the quantity basis, the remaining curves check fairly well. At least, there is no systematic tendency for the 11-in. Eddystone results to show a higher sigma break due to air content. The tests were made at heads from 27 to 30 ft at Eddystone and under heads of 40 to 60 ft at Holtwood. It has subsequently been found necessary to keep above the 25-ft head at Eddystone to avoid an increase in sigma break due to air content. It is probable that this lower limit could be reduced if this were a noncirculating system.

In an effort to provide a means for determining whether or not or to what extent cavitation exists in a given turbine without recourse to measurement of change of characteristics, the device shown in Fig. 5 has been tried, with partial success. This device as tried out up to this time has been installed in the throat ring of

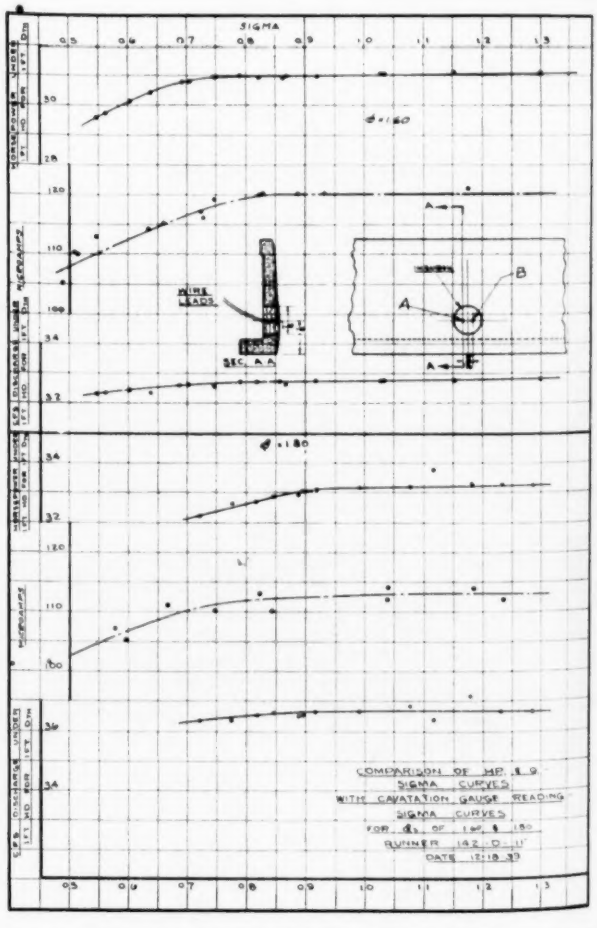

FIG. 5 COMPARISON OF SIGMA-BREAK CURVES WITH CAVITATION-GAGE READING

(Sigma curves for ϕ = 1.60 and 1.80.)

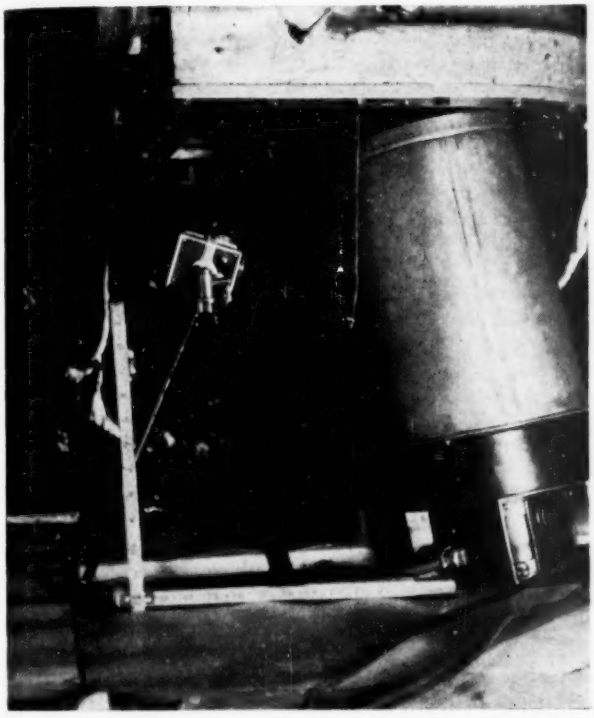

FIG. 6 STROBOSCOPIC EQUIPMENT FOR STUDYING CAVITATION

the turbine. The functioning of the device is based on the change in resistance between the points A and B to an electric current, when operating in cavitation-free water as compared to water with cavitation present. The change in current, in comparison with the measured change in characteristics is indicated in this figure. For $\phi = 1.61$, it may be noted that the change in resistance takes place at about the same value of sigma as that at which the power developed and discharge start to change; whereas, at the higher value of ϕ (1.805), the performance characteristics undergo a change somewhat prior to the change in resistance. A gage of this sort may have possibilities in view of the ease in obtaining readings at any time during the operation of the turbine.

PHOTOGRAPHIC RECORD OF RUNNER TESTS

With a view of having the report of each runner tested include photographs of the location and progress of cavitation for decreasing values of sigma, at different values of ϕ stroboscopic equipment, as indicated in Fig. 6, has been provided in connection with the I. P. Morris cavitation equipment. This too is yet in a state of development.

The elbow portion of the draft tube has been provided with an opening covered with "Plexiglass" which conforms with the curved portion of the tube. Below this is a flat glass opening, the space between these parts being filled with water during operation to eliminate distortion of vision. An Edgerton stroboscope is located on one side of a partition below this opening, with the other side of the partition used for visual study or for photography.

The stroboscope is wired to a commutator geared to the turbine

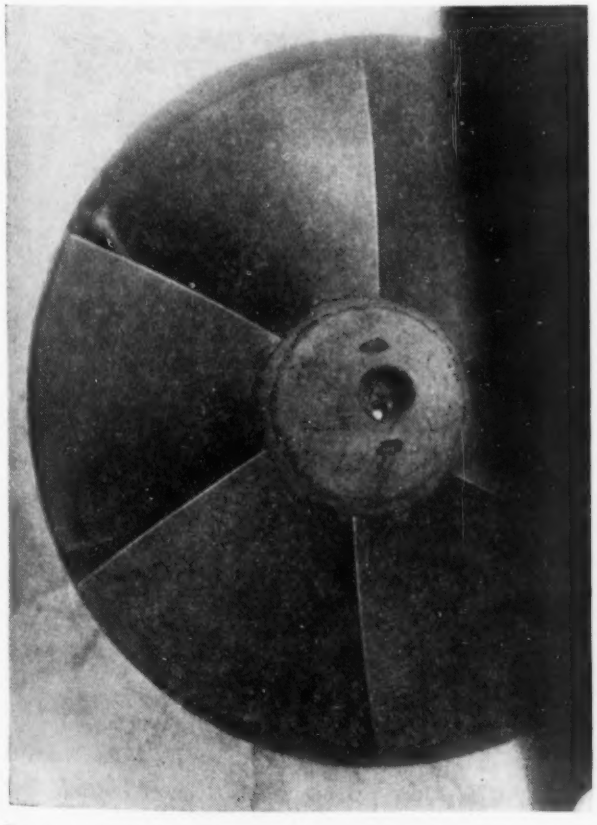

FIG. 7 STROBOSCOPIC VIEW OF PROPELLER-TYPE RUNNER (MODEL 128) WITH FIXED BLADES

(Test No. 617; water temperature = 68 F; head = 32.32 ft; h_s = —0.94 ft; $0.8H_v$ = 5.15; sigma = 1.055; HP_1 = 0.272; Q_1 = 2.76; efficiency = 86.8 per cent; ϕ = 1.60; break at sigma = 0.44.)

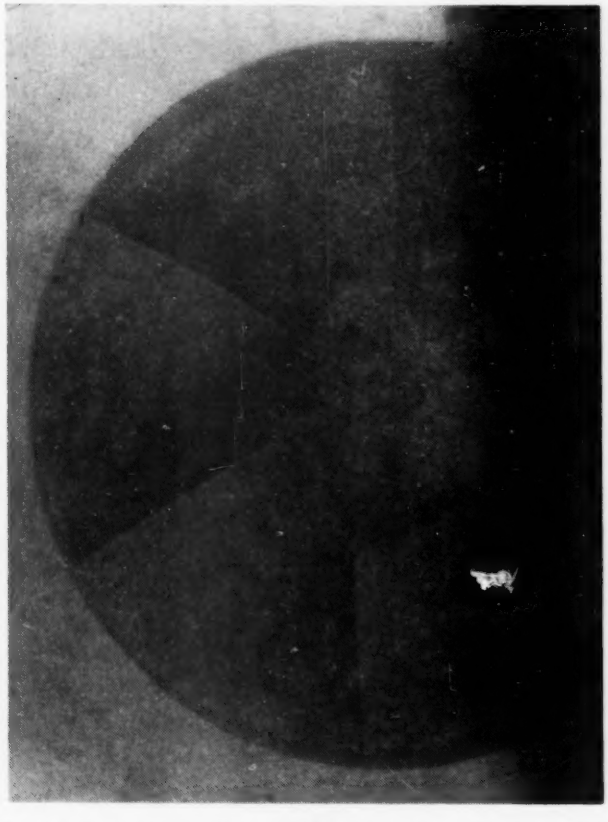

FIG. 8 STROBOSCOPIC VIEW OF PROPELLER-TYPE RUNNER WITH FIXED BLADES WHEN OPERATING JUST ABOVE SIGMA BREAK

(Test No. 617; water temperatures = 68 F; head = 32.22 ft; H_s = +16.21 ft; $0.8\,H_v$ = 5.10; sigma = 0.525; HP_1 = 0.271; Q_1 = 2.75; efficiency = 87 per cent; ϕ = 1.60; break at sigma = 0.44.)

shaft and normally flashes once at each revolution, thus giving a view of each separate blade rather than a composite effect. Time exposures have been found necessary, even with the most sensitive film available, due to the limited amount of light possible for photography. An alternate method has been used sometimes whereby photographs with single flashes were taken, requiring a special condenser for increasing intensity. A lens is provided above the stroboscope to confine light rays as much as possible to the runner blades. The photographs taken with sigma values well above the break, i.e., with relatively high pressures in the draft tube, have been quite successful. However, as the sigma is lowered with consequent reduced draft-tube pressure, the water below the runner becomes cloudy due to air coming out of solution, with resulting interference to the photography. Unfortunately, the photographs reproduced in this paper were taken during the winter months, and it was not practicable to raise the water temperature and thus reduce the amount of air in solution. It is expected that photographs taken during the summer months with water temperatures as high as 85 F will show better results.

Figs. 7 and 8 are stroboscopic views of a propeller-type model runner 128 with fixed blades and with the periphery of the blades turned cylindrical to give minimum clearance throughout their entire length inside of the cylindrical throat ring.

Both photographs were made at ϕ = approximately 1.60. Although best efficiency is at $\phi = 1.55$, it will be noted from Fig. 7 that cavitation starts at the intake edges on the backs of the blades near the periphery, at sigma values considerably higher than the break. This condition is doubtless aggravated at $\phi = 1.55$ where efficiency is maximum. The obvious suggestion for the correction of this condition is to design the blades with a steeper angle of intake where the cavitation takes place. This steeper angle results in excessive blade curvature, and reduces the efficiency and power at higher values of ϕ, which is quite undesirable, particularly where heads below normal are encountered. The efficiency performance of this runner, the unusually low and sharp sigma break, and the occurrence of cavitation at this point on many other runners leads to the belief that this may be a normal condition. This is also the point of minimum pressure on efficient airfoils (8).

Fig. 8 gives a very indistinct idea, due to air separation, of conditions as the sigma break is approached. With the sigma break at 0.44, Fig. 8 indicates the cavitation extending along the blade but still with a greater amount at inflow than at outflow. Some cavitation has appeared near the hub. It may be noted that in neither of these illustrations is there any indication of cavitation at the periphery due to flow through the clearance spaces. This is in sharp contrast with conditions indicated later with Kaplan-type runners, where the clearance at most of the periphery is necessarily greater.

Due to the manner in which the water clouds in these photographs, preventing a clear view of extensive cavitating conditions, it is planned to redesign the equipment in the I. P. Morris laboratory by lowering the turbine so that, by having a portion of the throat ring and upper draft tube transparent, the light can be introduced in a radial direction from the side, with observations and photographs made from adjacent points. This will permit observations of the face side of the blades, with a much shorter distance for the light to travel. The photographs show, however,

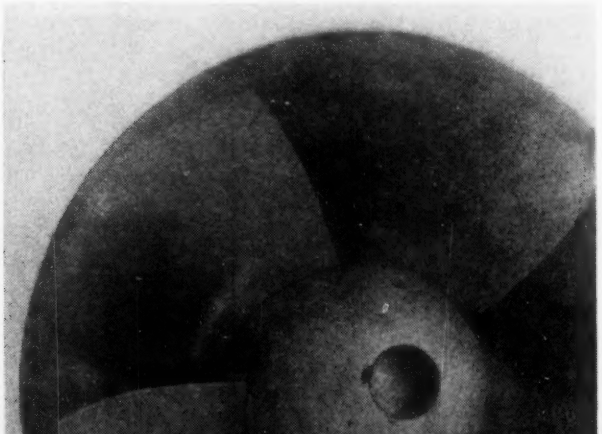

FIG. 9 KAPLAN-TYPE MODEL RUNNER 142-D OPERATING AT SIGMA BREAK

(Test No. 616-II; water temperature = 60 F; head = 30.67 ft; $H_s = +8.11$ ft; $0.8\,H_s = 8.27$; sigma = 0.815; $HP_1 = 0.33$; $Q_1 = 3.53$; efficiency = 82.3 per cent; $\phi = 1.60$; break at sigma = 0.81.)

FIG. 10 KAPLAN-TYPE MODEL RUNNER 142-D OPERATING AT HIGHER SPEED AND BEYOND SIGMA BREAK

(Test No. 616; water temperature = 65 F; head = 29.5 ft; $H_s = +4.16$ ft; sigma = 0.972; $0.8\,H_s = 10.55$; $HP_1 = 0.361$; $Q_1 = 4.06$; efficiency = 78.6 per cent; $\phi = 1.80$; break at sigma = 1.05.)

(Test No. 618; water temperature = 63 F; head = 29.74 ft; H_s = —6.04 ft; sigma = 1.307; HP_1 = 0.359; Q_1 = 3.97; efficiency = 79.8 per cent; ϕ = 1.60; break at sigma = 1.30.)

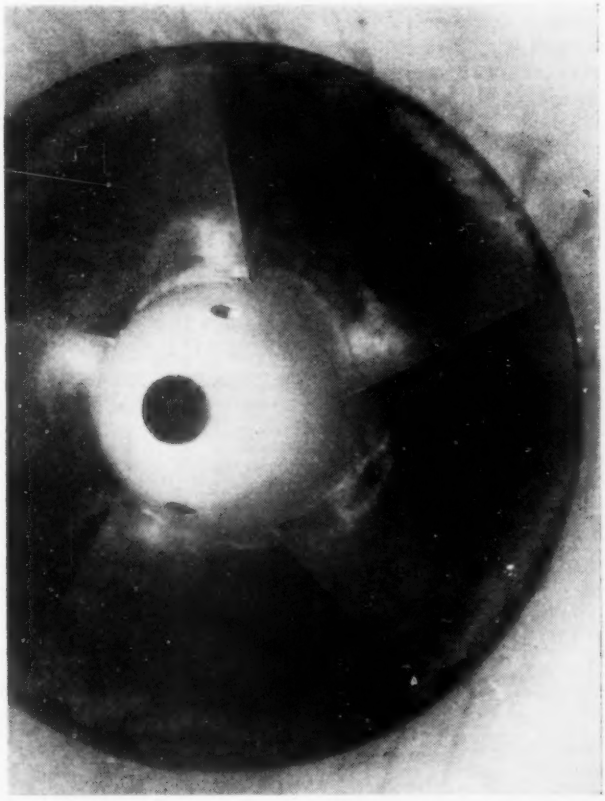

FIG. 12 KAPLAN-TYPE RUNNER MODEL 148, OPERATING FAR BEYOND SIGMA BREAK

(Test No. 618; water temperature 63 F; head = 30.5 ft; H_s = +8.06 ft; sigma = 0.817; HP_1 = 0.330; Q_1 = 3.80; efficiency = 76.6 per cent; ϕ = 1.60; break at sigma = 1.30.)

where cavitation is initiated and this is important as indicating the location of faults in design, or the desired location for prewelding.

Fig. 9 is a view of model No. 142-D which is of the Kaplan type with spherical throat ring. The value ϕ being 1.60 is slightly above that at best efficiency. Sigma is 0.814, the break occurring at 0.81. Cavitation is occurring at the periphery, at the intake, and through the clearance space just upstream and downstream from the blade axis where clearance is a minimum. Cavitation near the hub indicates rather too abrupt blade curvature, about at the blade axis.

At ϕ = 1.8, Fig. 10, sigma 0.972, break 1.05, the disturbance at the hub is accentuated, with indications of outward radial component of flow due to the higher whirl component Vu_2. The cavitation in the clearance space is also aggravated with streamers extending some distance beyond the ends of the blades. Punishment of the throat ring at the blade discharge is indicated. This latter condition exists to a lesser degree at this ϕ (1.8) well above the sigma break.

Figs. 11 and 12 show model No. 148 at ϕ = 1.60 with sigma = 1.307, 0.817, respectively, where the sigma break is at 1.3. The marked increase in cavitation at the hub will be noted. The entire series of photographs taken of this runner at ϕ = 1.4, 1.6, and 1.8 shows an interesting feature, namely, that cavitation at the periphery develops prior to the break in sigma, particularly at low ϕ values. Cavitation near the hub tends to develop later and, at least on this runner, it is the cavitation at this point rather than at the periphery which affects the performance by reducing the output and efficiency. It, therefore, appears that this is the portion of this runner which should be altered for improvement. In general, these studies show the importance of the blade design near the hub, also the need for smoother hub surface between the blades. Cavitation near the hub, however, seldom if ever results in pitting of the prototype due to the low relative velocity v, or more improbably, to the voids at this point on the runner not collapsing on the runner-blade surface.

Model No. 148 was made exactly similar to a former model with the exception that the blade axis was moved further downstream on the blade. The same blade pattern and templates were used, but with a shift in the axis. This change has had the effect of improving the efficiency and sigma break. The effect of this change is to reduce the clearance between the throat ring and the outflow portion of the blade, and the change is consistent with the improvement found with a properly designed spherical throat ring as compared to a cylindrical throat ring.

It is believed that the proper interpretation of stroboscopic photographs of runners is a valuable means of eliminating faults in design. The relation between the progressive change in cavitation with decreasing sigma to the change in performance can be used in deciding on the changes to be made for expected improvement. However, a liberal number of photographs showing the progressive changes are essential. By constructing the blades of a tough, ductile bronze, the same ones may be used for a large number of different blade shapes. Plaster of Paris forms may be kept as a record for each change made. Accurate templates are, of course, necessary for each change, to insure all blades being uniform for each test made.

In connection with the disturbance in the clearance space, Fig.

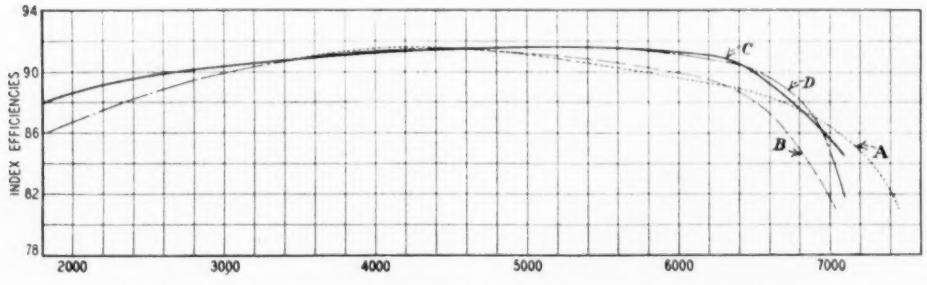

FIG. 14 COMPARISON OF SIGMA BREAK ON MODEL WITH THAT ON PROTOTYPE

(*A* = 16-in. model tested with high sigma; *B* = 11-in. model tested with sigma same as prototype; *C* = 109.5-in. prototype unit No. 1; *D* = 109.5-in. prototype unit No. 2.)

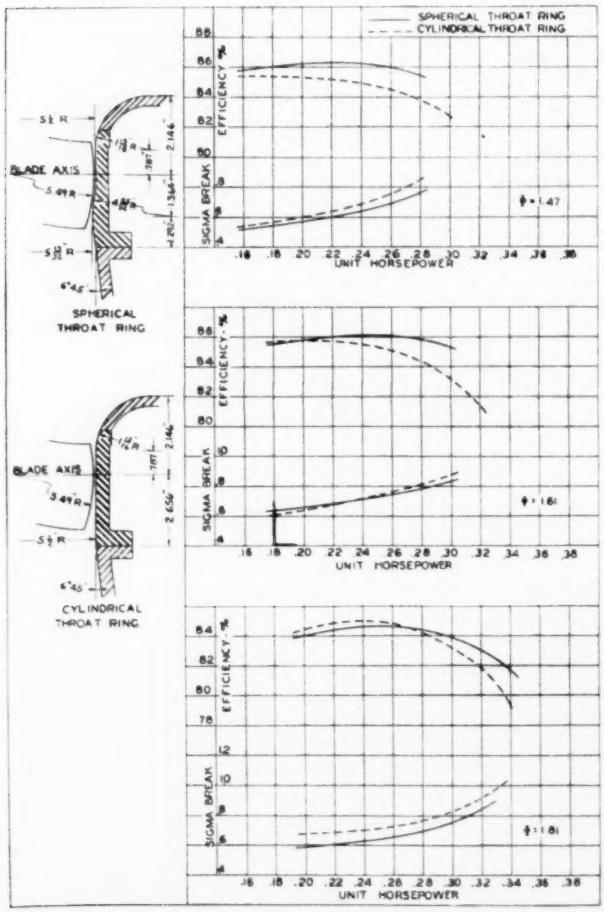

FIG. 13 CURVES SHOWING RELATIVE CAVITATION AND EFFICIENCY PERFORMANCE OF KAPLAN-TYPE RUNNERS WITH SPHERICAL THROAT RING AND STRAIGHT CYLINDRICAL THROAT RING, RESPECTIVELY

13 is introduced to show the relative performance (6, 7) as to efficiency and cavitation of a Kaplan-type runner (*a*) with spherical throat ring the same as used previously, and (*b*) with straight cylindrical throat ring. The former results in less clearance space disturbance but puts a greater burden on the draft tube due to the smaller minimum diameter of the throat ring. The latter is important when it is remembered that draft-tube losses vary with the fourth power thereof. The improved results with the smaller clearance space emphasize the importance of the spherical shape, if properly designed.

SIGMA BREAK ON MODEL AND PROTOTYPE

Fig. 14 is presented as an example of the relation between sigma break on the model and on the prototype. In this instance the model is homologous to the prototype throughout, including intake, casing, and draft tube. The prototype was not tested as to efficiency but the power was recorded accurately, and an index test was made by taking readings of Winter-Kennedy piezometers in the casing and stay ring. The maximum efficiencies shown are those stepped from the 16-in. model runner to a diameter of 109.5 in. by the Moody formula (10). Those of the 11-in. model have been arbitrarily stepped up to give the same maximum value as have those of the prototype.

The 16-in-model test was made at high sigma values, and is, therefore, not affected by cavitation. The 11-in-model test was made at the same sigma as the prototype. Some increase in prototype power is noted over the 11-in. model, with fair agreement in the form of the curves.

The flash photograph of runner No. 148, taken with a special condenser which is necessary to increase the intensity of the light to permit such a photograph, is shown in Fig. 15. This is at blade

FIG. 15 FLASH PHOTOGRAPH OF MODEL RUNNER NO. 148 SHOWING SPIRAL VORTEX

position No. 3 with $\phi = 1.595$, $HP_1 = 1.722$, $Q_1 = 1.82$, efficiency = 86.0, and $\sigma = 0.648$. Sigma break under this condition occurs at 0.4.

This vortex, it will be noted, appears to form in the hole in the center of the hub and is rotating with the runner. A time exposure taken under this condition would merely show a blurred effect even with the stroboscope, due to the rotation of the spiral vortex not being in synchronism with that of the runner. As the σ was reduced to a value nearer the break, this vortex disappeared. The gate opening at which this photograph was taken is such that this would represent an actual operating condition at this value of ϕ when the load on the turbine is reduced to slightly more than half of the normal value.

Acknowledgment is made of the helpful suggestions of L. F. Moody in the preparation of this paper, of the assistance of R. B. Willi, and of K. W. Beattie in connection with the photographs and test data included.

Appendix

I. P. MORRIS CAVITATION LABORATORY

General Data and Equipment

Diameter of runners tested: 11 in.

Head on turbine: 25 to 35 ft.

Variation of sigma: Accomplished by changing pressure in system upstream from turbine from below atmospheric to 20 psi above atmospheric.

Water supply: Closed circulating system with cold water connection automatically added from city main as make-up, and to regulate temperature. Volume of water in system about 500 cu ft.

Service pump: Designed for 25 cfs at 35-ft head; driven by 125-hp slip-ring motor, 220 v, 580 rpm rated speed. Possible speed regulation to one-half normal in eleven steps.

Water measurement: 24-in. by 10-in. venturi meter; calibrated by Professor Pardoe at the University of Pennsylvania.

Dynamometer: Specially built, using 40-hp 1200-rpm d-c motor reinforced for higher speeds. Dynamometer carried by cradle mounted on ball bearings. Torque measured by a Fairbanks beam scale connected through flexible steel tape to dynamometer frame. Electrical output dissipated in heat.

Pressure tank: 48 in. diam, 10 ft high, with supplementary air tank at top. Water level in this tank automatically controlled by float valve.

Head tank: 48 in. diam with float bottom, 7 ft 6 in. long.

Draft-tube discharge tank: 54 in. diam, 4 ft long, with trap for collection and drawing off air.

Gages and instruments: Head and water measurement pot-type mercury gages; rpm dial revolution counter, with electric release controlled by clock; atmospheric-pressure mercury barometer checked at intervals from weather bureau; instrument for measurement of air content in water, as developed at Massachusetts Institute of Technology.

Stroboscope: "Strobulux" controlled by "Strobotac," type 648-A, manufactured by General Radio Corporation.

Combined Tension-Torsion Tests on a 0.35 Per Cent Carbon Steel

By E. A. DAVIS,[1] SO. PHILADELPHIA, PA.

This paper contains the results of a group of combined tension-torsion tests on both cylindrical and notched bars. The author has tried to keep in mind the close relation between this type of test and the problem of bolting. The test results show the amount of reduction in the ultimate tensile strength when a torque is applied in combination with the tension load. They also show a similar reduction in the torsional strength when a tensile load is added.

IN general practice, it frequently occurs that some members of a structure or machine carry loads in both tension and torsion simultaneously. It is pretty well known or it may be logically deduced that the addition of a torque to a bar already stressed in tension will reduce the tensile load-carrying capacity of the bar. The amount that the tensile strength will be reduced, however, is not so well known, and engineers in general have tried to avoid this type of loading wherever either the tension or the torsional stress is likely to be high.

A typical example of this combined tension-and-torsion loading is a bolt which has been tightened by a wrench. As the nut is being drawn up, the twisting moment of the wrench is applied to the bolt and there is a danger that the bolt may be strained in torsion to the extent that it will not support its load in tension. Because of this danger, methods have been developed for reducing this twisting moment in the tightening of large bolts. It is quite common practice in the assembly of large bolted parts to expand the bolts by heating to such an extent that the nuts can be turned up just enough to give the bolts their proper working stress when the bolts are at the same temperature as their surroundings.

In some large alternating-current generators, the rotors are made up of several forged disks which are bolted together with long axial bolts. These bolts are drawn up to a given load by a "bolt puller" and the nuts are tightened by hand.

Unfortunately not all bolts can be tightened in this manner and often it is necessary to draw them up with a wrench. With this in mind, the present investigation was carried out in an effort to determine just what effect a superimposed load in one direction has on the strength of a bar carrying a second load in another direction. In order to do this, several sets of combined tension-torsion tests were made. In one set, various fixed amounts of tensile load were superimposed upon constant-strain-rate tests in torsion. This set contained one pure torsion test (zero tension). In another set, fixed amounts of torque were maintained while the bars were pulled at a constant strain rate in tension. In this instance, one of the tests was a pure tension test (zero torque). Another test was run in which the strain rates in both tension and torsion were kept constant. Since these tests are closely related to the problem of bolting, it was felt that the effect of notches and threads should be investigated in conjunction with these combined stress tests. Consequently, some of the foregoing tests were repeated on bars containing circumferential notches.

Theoretical Considerations

Probably the best approach to an understanding of the combined tension-torsion test would be to express the test results in terms of shearing stress and strain on some preferred set of planes in the material. For theoretical reasons, the best results would likely be obtained if the octahedral planes were chosen for making this analysis. These planes are the faces of a regular octahedron which is oriented so that its apexes point in the directions of the principal stresses. A. Nádai (1)[2] has made such an analysis of a combined tension-torsion test on a plastic material having a uniform yield stress $\sigma = \sigma_0 =$ constant. The stress distribution under combined tension and torsion in a round bar is reproduced in Fig. 1, in which it is assumed that the material flows plastically over the entire cross section of the bar.

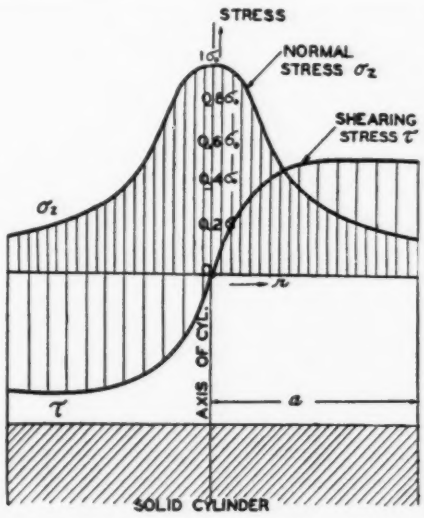

Fig. 1 Stress Distribution Under Plastic Flow in Cylindrical Bar Subjected to Combined Action of Axial Load and Twisting Moment

The distribution of the shearing stresses τ and of the normal stresses σ acting in the axial direction are plotted separately against the radius of the bar. It is to be noted that in the axis of the bar, a state of pure tension exists so that at $r = 0$ the stress in the axial direction is equal to σ_0, the yield stress of the metal in pure tension. Under these conditions, the tensile stress is confined mostly to the inner fibers, while the torque stress is carried by the outside fibers.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

When one tries to apply a similar analysis to a solid round bar of a material which exhibits the property of strain-hardening, certain difficulties arise which make an analysis complicated. With a solid bar in torsion the stress-strain diagram is not directly obtained. The shearing-stress (τ) versus the shearing-strain (γ) diagram is obtained from the moment (M) versus angle of twist (θ) curve by the following relations (2)

$$\tau = \frac{1}{2\pi a^3}\left(\theta\frac{dM}{d\theta} + 3M\right)$$

$$\gamma = a\theta$$

This stress and strain refer to the outside fibers of a bar of radius a. The expression for τ involves the slope of the moment-angle curve and this may lead to difficulty in determining the shearing-stress distribution in a test where the applied moment is held constant.

When tension and torsion are to be compared, another difficulty arises from the fact that the expressions for the strains become

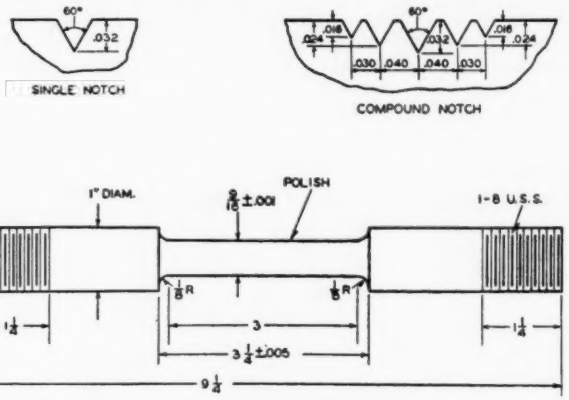

FIG. 2 TENSION-TORSION SPECIMEN

complicated if the strains are large. This is especially true for the strains in the octahedral planes. Also, when a bar extends axially, the diameter decreases in order to satisfy the condition that the volume remain constant. Furthermore, since the shearing stress on the outside fibers depends upon the third power of the radius, a change in the stress will occur even though the applied moment is constant. Because of these conditions, the test results in this paper are given as diagrams in which the tensile stress is plotted as a function of the axial strain and the moment of the applied torque as a function of the angle of twist. The tensile stress that is plotted and referred to throughout the paper is that based upon the original area of the bar $\left(\sigma = \frac{P}{A_0}\right)$.

The tension-torsion test is an example of a state of combined stress, a field in which a considerable amount of work has recently been done. The aim of most of this work has been to check the general conditions under which the ductile metals yield plastically. Among the investigations of this nature which have been made, those by Lode (3) and by Schmidt (4) in Germany; by Taylor and Quinney (5) and by Cook (6) in England; and by Ros and Eichinger (7) in Switzerland may be of interest. A survey of the results of most of these tests was made by Nádai (8).

The author in a former paper (9) attempted to show the relation between tension and torsion tests on a solid bar of copper by expressing the results of both in terms of the shearing stresses and strains on the octahedral planes.

The agreement was good in the region where the strains were small but, for strains greater than those corresponding to about 15 per cent elongation in tension, the curves for the different tests separated somewhat.

The present group of tests differs from most of the previous combined stress tests in that the stress-strain diagrams were obtained up to the point of rupture, while the others were concerned chiefly with the region in initial yielding. Also, in these tests the equipment was so arranged that either the tension or the torsion load could be held constant while the other was allowed to vary to suit the conditions imposed by a constant strain rate.

MATERIALS AND TEST SPECIMENS

In choosing a material for these combined tension-torsion tests, it was felt that certain characteristics would be desirable. If the results were to throw any light on the bolting problem the material should be similar to that generally used in bolts. It should be tough and not excessively ductile; however, a very strong steel would require that the dimensions of the test bar be small due to the limited capacity of the testing machine. Furthermore, the elongation associated with the yield-point region should not be too great, for this phenomenon is not observed to any appreciable extent in the alloy steels commonly used in large bolts. As a compromise among these requirements, a medium-carbon steel (0.35 C) was selected for the tests. With this material a bar with a $^9/_{16}$-in-diam test section could be used in the available equipment.

A sketch of the test specimen is shown in Fig. 2. The 1-in-diam heads were used in order that reasonable torque could be applied through the threaded ends without too greatly tightening the threads in the grips. It was realized that, if the axial extension and the angle of twist were to be obtained for strains up to the ultimate strength, the extensometer would have to be clamped on the shoulders of the bar. This has the weakness that the active gage length is somewhat unknown. For purposes of comparison, however, the actual gage length does not need to be known exactly. In these tests, it has been assumed that the gage length in each case was 3.1 in.

It was felt that it would be desirable to compare the results of tests on bars containing notches and threads with those of the cylindrical bars. Two types of notches, a single and a compound notch as shown in Fig. 2, were designed. The compound notch was included in order to determine whether or not an adjoining notch had any tendency to relieve the stress concentration in the main notch.

As a supplement to the combined stress tests on notched bars, it was decided to make up two mild-steel specimens, as shown in Fig. 3, and to stress them just to the point where yielding starts and then to show up the flow lines by the Fry etching method. The bars were $1^1/_2$ in. in diameter in the central section. One bar had about $1^1/_2$ in. of V threads, 8 threads per in., while the other had a single notch of the same dimensions as the V threads. These tests should show whether or not the flow in a deeply notched bar of mild steel will be confined to the plane at the bottom of the notch where fracture will eventually occur or to what extent it penetrates into the heavier sections of the bar.

TESTING EQUIPMENT

Some years ago at the Westinghouse Research Laboratories on the suggestion of A. Nádai special equipment was designed for running constant-strain-rate tests either in tension or torsion or in a combination of both.[3] The machine is illustrated in Fig. 4. The tensile load was measured on the regular Amsler dial while the torsion load was determined by measuring the deflection of two springs attached to the upper head of the machine. An electrical contact device was used on the dial of the Amsler

[3] For this purpose a 10-ton Amsler testing machine was reconstructed by W. O. Richmond and B. Cametti.

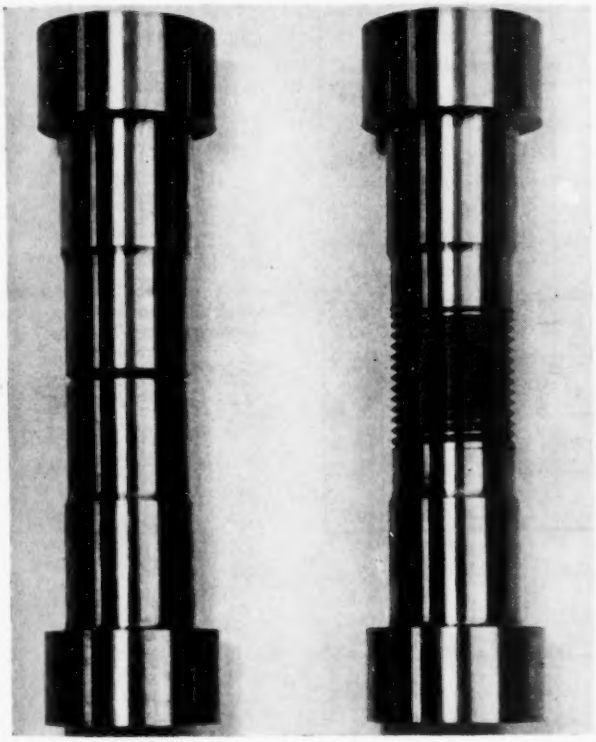

FIG. 3 TEST SPECIMENS FOR SHOWING WHERE INITIAL YIELDING WILL OCCUR

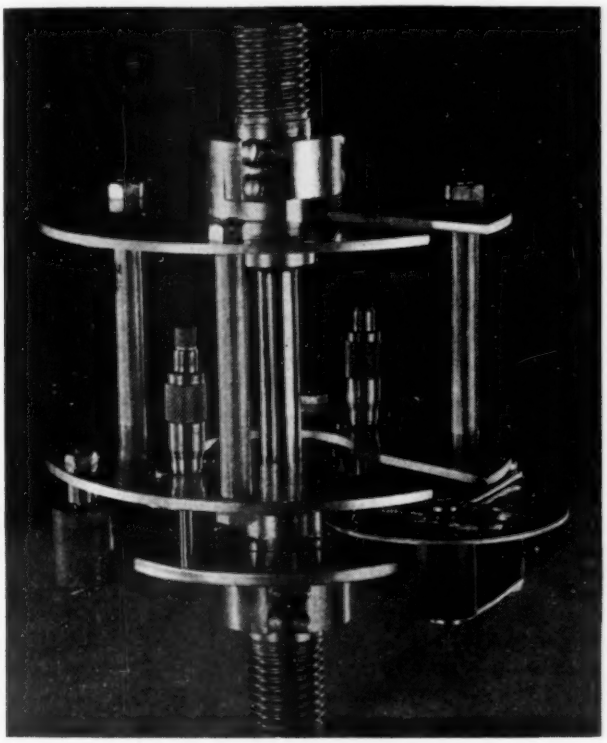

FIG. 5 TENSION-TORSION EXTENSOMETER

load indicator to maintain a constant tension when desired. A similar contact device was arranged on the torsion springs so that a constant torque could be obtained.

The strains were measured by means of the specially designed extensometer shown in Fig. 5. As has already been mentioned, the extensometer was clamped on the shoulders of the test specimen. The extensometer consisted chiefly of a frame which was clamped to the upper shoulder and a plane disk which was clamped to the lower shoulder. The axial strain was determined by two micrometer heads clamped to the frame in such a manner that they could measure the separation between the frame and the plane disk. The angle of twist was measured by a roller attached to the frame which rolled on the periphery of the disk.

TEST RESULTS

Before any combined stress tests were run, the material was tested in pure tension and pure torsion. The pure tension test is curve *J* in Fig. 6. The ultimate strength was 83,000 psi and the elongation at rupture was 27.3 per cent. In the pure torsion test, curve *G* in Fig. 7, the breaking torque was 237 lb-ft and the maximum angle of twist was 584 deg.

In addition to the pure tension test, Fig. 6 shows the constant axial strain-rate curves for bars upon which constant torques of 60, 118, and 199 lb-ft were superimposed. The value of the axial strain and the angle of twist at rupture are listed at the end of each curve. It can be seen readily that the amount of axial strain is considerably reduced when a high torque is applied to the bar. The ultimate tensile strength is also reduced. A torque of 60 lb-ft (one fourth of the breaking torque in pure torsion) reduced the ultimate strength only about 5 per cent, but a torque of 199 lb-ft (five sixths of the breaking torque) reduced the ultimate strength over 40 per cent.

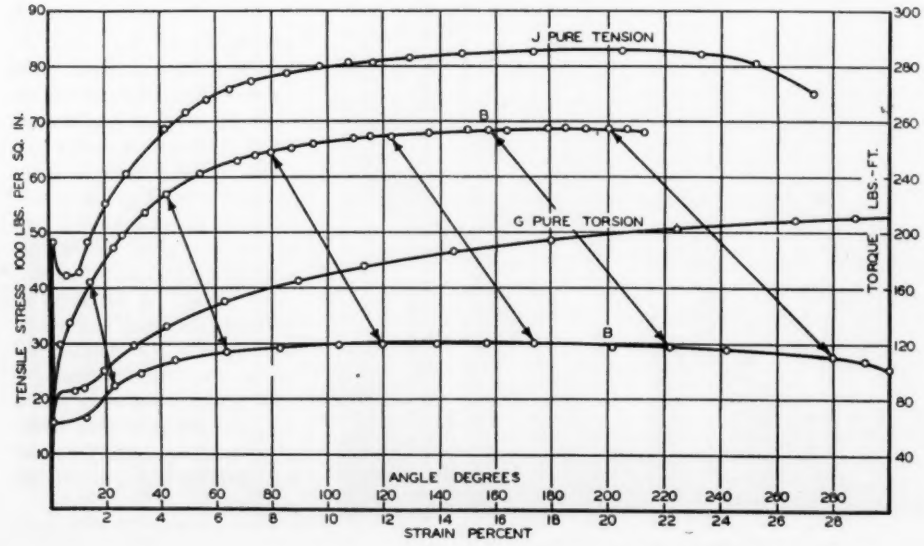

FIG. 8 COMBINED STRESS TESTS; CONSTANT RATE TENSION PLUS CONSTANT RATE TORSION

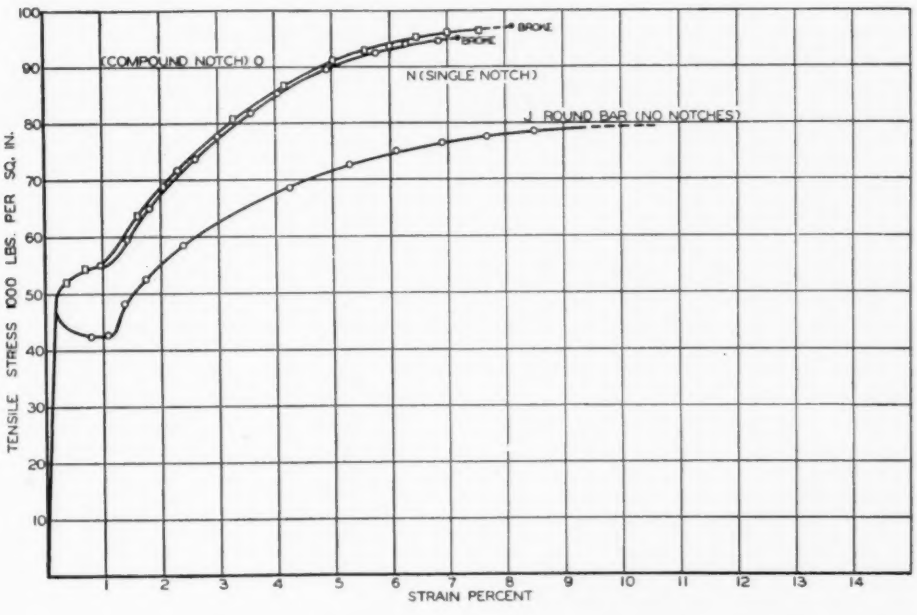

FIG. 9 TENSION TEST ON NOTCHED BARS

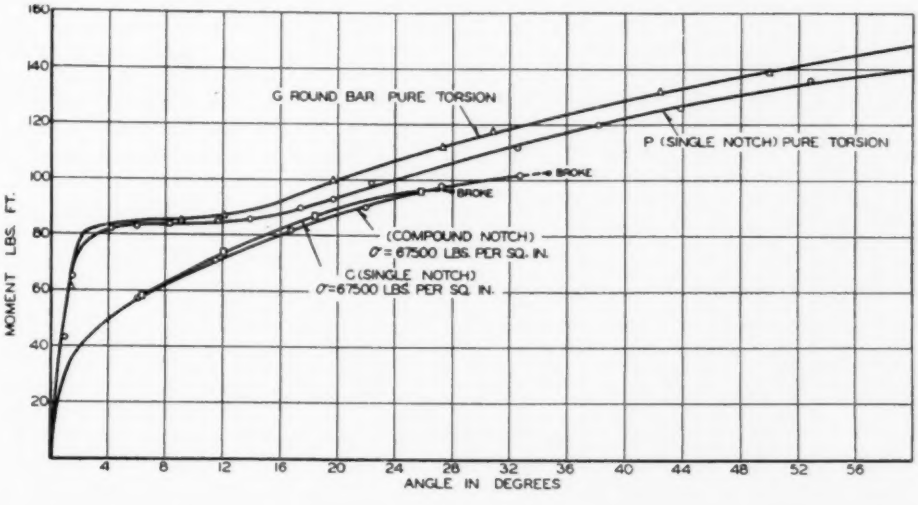

FIG. 10 TORSION TESTS ON NOTCHED BARS

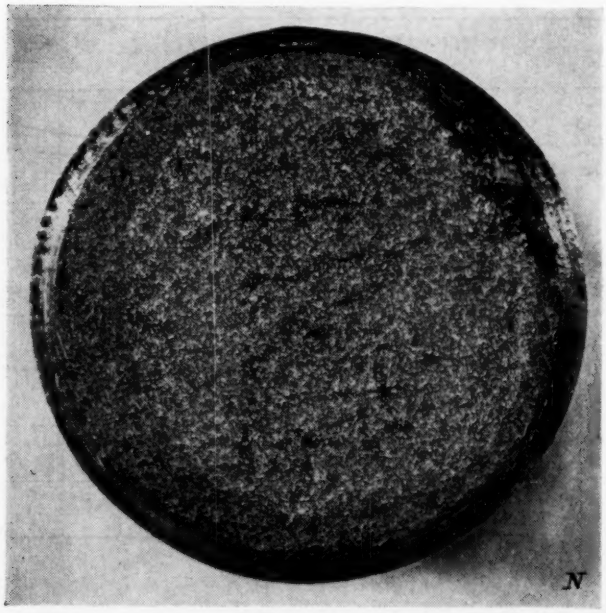
Fig. 7 shows the results of the tests which were run with a constant strain rate in torsion. Curve *G* is the pure torsion test. Curves *L*, *H*, and *D* are torsion tests with superimposed tensile stresses of 61,400, 68,500, and 75,000 psi, respectively. In these tests the tensile loads were fairly high. All were above the yield point in pure tension so that the curves do not show any discontinuity in torsion, such as curve *G* shows. The amount of axial strain did not vary much in these three combined stress tests but the angle of twist at rupture was reduced from 584 deg for the pure torsion test to 161 deg for the bar which also carried a tensile stress of 75,000 psi. Curve *C* shows the results of a test similar to curve *H*. Bar *C* had a single circumferential notch $^1/_{32}$ in. deep at the middle of the gage length. The constant tensile stress based on the area at the bottom of the notch was 68,500 psi. The apparent increase in strength over curve *H* is due partly to the fact that the notch prevents the bar from reducing in diameter and partly to the fact that the actual unit strains in the notch are much greater than shown by the diagram which is based on a 3.1-in. gage length.

In addition to the combined stress tests already mentioned, one test was run with a constant strain rate in both tension and torsion. Curve *B* in Fig. 8 shows this test compared with the pure tension and the pure torsion test. In this figure, the tensile stress and strain coordinates refer to the two upper curves, while the torque and angle coordinates refer to the two lower curves. Bar *B* was being tested in tension and torsion at the same time, hence, there are two curves labeled *B*. The arrows connect points on the two curves which occurred at the same time. For example when bar *B* had a tensile stress of 64,000 psi and an axial strain of 8 per cent, it also was subjected to a torque of 120 lb-ft and had twisted 120 deg in a 3.1-in. gage length.

At this point, an interesting observation can be made concerning the combined tension-torsion tests. In a pure torsion test, such as curve *G* in Fig. 7, the moment-angle diagram has a positive slope until the fracture occurs, and the bar carries its maximum torque just the instant before it fails. In the combined stress tests, where the tensile stress was fairly high, the torque reached a maximum quite some time before failure. This can be seen in curves *H* and *D* in Fig. 7 and in curve *B* in Fig. 8. This may possibly be due to the fact that the diameter of the bar becomes considerably reduced when it is stretched in tension, thus increasing the shear stress without increasing the applied moment.

The results of the tests on notched bars are shown in Figs. 9 and 10. Pure tension tests on the single and the compound notch are compared with that of the cylindrical bar in Fig. 9. Although the bar having the compound notch showed the greatest strength, the difference was but slight. The stress relieving due to the adjoining notches was almost negligible. The notched bars appear to be stronger than the cylindrical bar for the reason already mentioned. Fig. 10 shows the torsion tests on notched bars. Curve *P* is for a single notched bar and can be compared with the pure torsion test (curve *G*). It should be pointed out that these diagrams are moment-angle diagrams and not shear stress-strain diagrams. That explains why the moment curve for the notched bar is lower than the curve for the cylindrical bar. If we should plot the actual stress-strain diagrams, we would probably find that the curve for the notched bar would be higher. Curve *C* from Fig. 7 is replotted here for comparison with curve *M* which is the result of a compound notch tested under the same conditions as the single notched bar *C*. Both had a tensile stress of 67,500 psi superimposed. Here again there is very little difference between the two types of notches.



It is quite interesting to note the various types of fracture which occurred in these combined stress tests. Two pure tension fractures are shown in Fig. 11. Bar *J* is the cylindrical bar, while bar *N* had a single circumferential notch. The fracture of bar *J* is a typical tension fracture. In bar *N* two regions in the fracture are discernible. It appears that the bar cracked inward from the root of the notch for some distance and then the bar suddenly pulled apart. The notch prevented any reduction of area and the ruptured surface has the appearance of a brittle fracture.

Bar *G* in Fig. 12 shows how the pure torsion test bar broke. The fracture surface was nearly but not quite perpendicular to the axis of the bar. The upper specimen in Fig. 12 shows the rupture surface of a tension test which had a relatively small torque imposed upon it. This break appears much the same as the pure tension rupture. Fig. 6 shows that its stress-strain diagram was not much lower than the pure tension test.

Two bars which carried a good portion of both tension and torsion loads are shown in Fig. 13. Bar *A* is from a tension test with an added torque, while bar *L* was tested in torsion with an added tensile load. Both broke with a helical fracture; the helix angle, however, was not as great as is encountered in brittle materials in pure torsion.

In Fig. 14, specimen *P* shows the fracture of a notched bar in pure torsion. The rupture surface of bar *M* shown in the lower half of Fig. 14 is probably the most interesting in the group. This was a notched bar tested with combined tension and torsion. The fracture has two distinct regions. Presumably the outer portion where shear stresses predominate failed in shear, while the inner portion which is forced to carry the axial load failed in tension. The phenomenon of the two regions seems to accord with theoretical considerations based upon accepted theories of strength. It is the kind of fracture which might be expected for the case in Fig. 1.

In the tests to show the flow lines in mild steel, the bars were first loaded to the point where yielding had just started. They were then heated to and held at 200 C for 1 hr. Then they were cut along an axial plane through the center of the bar and the exposed sections were polished and etched. The results can be seen in Fig. 15. The portions which have yielded are shown by the dark areas running at about 45 deg to the axis. The dark lines running in the axial direction are probably due to some structure effect or to machining strains and are to be disregarded. In the bar with the single notch, there was some bending stress present and consequently the bar yielded more on one side than on the other. It is evident from this illustration that, for a mild-steel bolt, yielding would start on a conical surface or surfaces. Whether or not a bolt from standard bolting materials at high temperature would start to yield in a similar manner cannot be

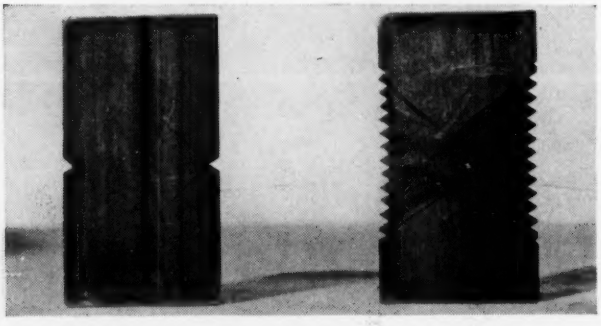

FIG. 15 INITIAL FLOW LINES AT ROOT OF THREAD

determined, for these slip lines can only be made visible on mild steel which exhibits a marked yield point. These flow lines do not show where ultimate failure will occur, but they point out where the stresses are most unfavorable in the elastic state and where the plastic strains will be localized. Ultimate failure would probably occur along a plane surface perpendicular to the axis of the bar and passing through the notch or one of the threads.

CONCLUSIONS

A summary of the test results on the cylindrical bars is shown in Fig. 16. The ratio of the maximum tensile stress in any test to the maximum stress in the pure tension test is plotted as ordinates and a similar ratio of the moments is plotted as abscissas. The test points all fall close to a circle of unity radius passing through the points of the pure tension and pure torsion tests. All points fall outside of a circle the center of which is at the origin and the radius is 0.9.

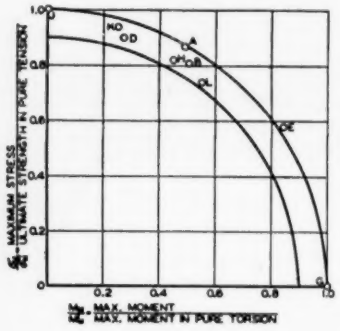

FIG. 16 TEST RESULTS

A sharp V notch in a ductile material does not cause any stress concentration that can be detected in a short-time tension test, but it does seriously affect the amount of strain at rupture. This latter statement is particularly true if torsion loads are present. In the pure tension tests, the maximum strain was reduced from 27 per cent for the cylindrical bar to 7 per cent for the notched bar. In the case of pure torsion, the angle of twist was similarly reduced from 584 deg to about 60 deg.

The fact that the stress-concentration factor for the notch turned out to be unity erased any effect which the compound notch might have shown in a more brittle material.

The amount that the bars necked down was roughly proportional to the amount of ultimate tensile load. When heavy torques were present, the bars failed before any appreciable necking occurred. Initial yielding in a circumferentially notched mild-steel bar occurs on a conical surface and not in the plane where the bar will eventually fail.

ACKNOWLEDGMENTS

The author wishes to acknowledge the help of Dr. A. Nádai who supervised this work. He also wishes to thank Mr. L. W. Chubb and Mr. F. T. Hague of the Westinghouse Elec. & Mfg. Co. for permission to present these results, and Messrs. G. H. Heiser and M. Manjoine for their assistance in making the tests.

Discussion

C. W. MacGregor.[4] Referring to Fig. 6 of the paper, stress-strain diagrams are included in which the load divided by the original area is plotted against the over-all strain between the heads of the test specimen for various amounts of applied constant torque. It was found that the total axial strain, as usually defined, is considerably reduced when a high torque is applied to the bar. The writer has been interested recently in plotting stress-strain curves for tensile tests in which the average true axial stress P/A is plotted as a function of the true axial strain ϵ or q' obtained from diameter measurements where $q' = \epsilon = \log \frac{A_0}{A}$ (A = actual area; A_0 = original area).

It is realized that the problem of expressing the true stress-strain relationships in the cases treated in the paper is indeed complicated, as mentioned by the author. It would be of interest, however, if the author will include in his closure a comparison of the average true axial breaking stress and strain values as thus defined for the final points in the various curves plotted in Fig. 6. The axial-strain values can be determined from diameter measurements in the constricted portions of the test bars. This may give some additional information as to the effect of torque moment on these quantities.

Joseph Marin.[5] The research reported by the author is particularly important since load-deformation relations for combined stresses are seldom reported beyond the yield point and to rupture. One aspect of the combined-stress problem is the evaluation of working stresses for such a state of stress. In order to do this it is necessary to have some rational theory defining rupture. The author points out that most investigators consider the problem of defining the beginning of yielding rather than final rupture.

Considering the test results reported in the light of theories of failure as applied to rupture, it is of interest to compare tests and theories. In doing this there is encountered the difficulty of evaluating the stresses at rupture. An approximate value of the shearing stress can, however, be obtained by using relations (2), page 578 of the paper for a slope of the torque-twist curve at rupture equal to zero. With this assumption the shear stress is

$$\tau = \frac{3M}{2\pi a^3} \quad [1]$$

where M = torque at rupture and a = radius of specimen.

For tension the stress at rupture is

$$\sigma_x = \frac{P}{\pi a^2} \quad [2]$$

Considering the test results plotted in Fig. 16 of the paper, the equation of the circle representing the test points is

$$(M/M_0)^2 + (P/P_0)^2 = 1 \quad [3]$$

where M_0 = twisting moment in pure torsion at rupture,
and P_0 = axial tension in pure tension at rupture.

Placing values of the stresses from Equations [1] and [2] in [3], the relation between the stresses at rupture is

$$(\tau/\tau_0)^2 + (\sigma_x/\sigma_0)^2 = 1 \quad [4]$$

Using the values of the stresses obtained experimentally, Equation [4] becomes

$$(\sigma_x/\sigma_0)^2 + 1.84(\tau/\sigma_0)^2 = 1 \quad [5]$$

Equation [5] defines the experimental relation between the stress components. The theoretical relation corresponding to this, using the shear theory is

$$(\sigma_x/\sigma_0)^2 + 4(\tau/\sigma_0)^2 = 1 \quad [6]$$

In the same way using the stress theory

$$(\sigma_x/\sigma_0) + (\tau/\sigma_0)^2 = 1 \quad [7]$$

For purposes of comparison Equations [5], [6], and [7], and the test results are shown in Fig. 17 of this discussion. An inspection of this illustration shows that the stress theory agrees best with the test results except for the test in pure torsion. On the other hand, the beginning of yielding for ductile materials is closer to the shear than the stress theory. It is necessary, therefore, to use a different basis in defining working stresses, depending upon whether the yield point or ultimate is considered.

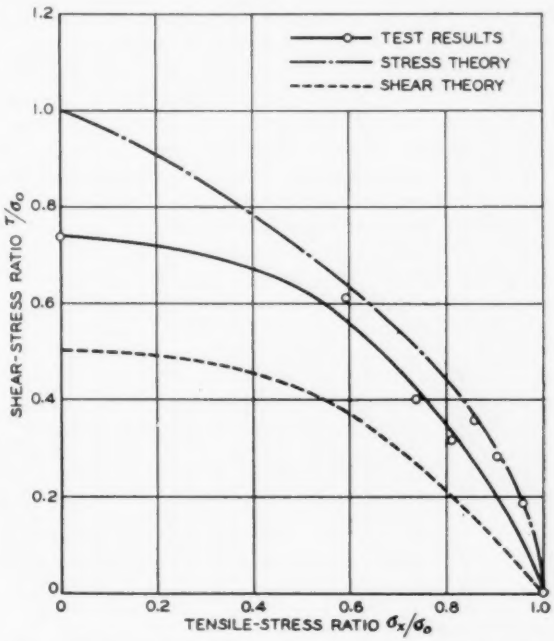

Fig. 17 Comparison of Test Results With Shear and Stress Theories

TABLE 1 ENERGY REQUIRED FOR RUPTURE

Specimen	Tensile-stress ratio σ_x/σ_0	Torque ratio (M/M_0)	Energy in in-lb per cu in. $\div 10^4$
J	1.00	0	2.02
K	0.95	0.25	2.33
D	0.90	0.38	2.12
A	0.85	0.49	2.06
H	0.82	0.44	2.25
L	0.74	0.55	2.37
E	0.59	0.83	3.15
G	0	1.00	3.10

A consideration of the energy required for rupture in the foregoing tests is of interest. Table 1 of this discussion shows the energy in in-lb per cu in. for all of the specimens tested. The values show that there is not a constant value of energy for rupture but an increase from pure tension to pure torsion.

Author's Closure

The writer appreciates the interest shown by Professors MacGregor and Marin in their discussion. The information regarding the dimensions of the necked portions of the plain (those without notches) bars is given in Table 2 of this closure.

B	0.465	99,000	0.75	46,800	0.76

[a] Based on Equation 1 of discussion.

In regard to Professor Marin's analysis of the shear stresses at rupture it may be well to repeat again that it is difficult to evaluate the stresses and strains at rupture. If Equation [1] of the discussion is used it must be remembered that in several of the curves the slope $dM/d\theta$ is not zero but is actually negative. If, however, this equation is used in conjunction with the reduced diameter at the necked portion and also if the reduced area is used to compute the tensile stress at rupture the stress ratios given in Table 2 are obtained. These results which are plotted in Fig. 18 will agree much more closely with Equation [6] than with Equation [7] of the discussion. This is evident from the fact that the maximum shear stress in the pure torsion test is roughly one half of the maximum tensile stress in the pure tension test and that most of the points lie close to the circle

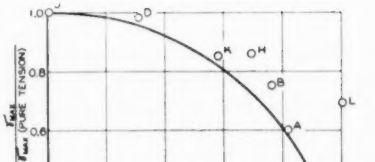

FIG. 18 RUPTURE STRESSES BASED ON REDUCED DIAMETER

drawn in the figure. This is not offered as an ultimate analysis of the stresses at rupture but is merely given to point out the improbability that the actual stresses would agree with a maximum-stress theory of strength.

Since the paper was presented, the carbon and manganese content of the steel used in the tests has been determined. Chemical analysis showed that the steel contained 0.47 per cent carbon and 0.71 per cent manganese.

The Engineering Method in Management

By ANDREW I. PETERSON,[1] NEW YORK, N. Y.

Professional management in modern industry demands competence and vital direction of a high order, approached only with scientific objectivity. Engineering and economics are the basic tools of the profession. The author reduces the problems inherent in applied economics to four types: The selection, replacement, and apportionment of elements of production; the analysis of optimum enterprise economy; the rationalization of the dynamics of specific industries; and the interpretation and guidance of the trends and adjustments in the parent social environment. The paper indicates the necessity for more critical research and broader training in industrial management.

THE transformation of a people in primarily local agricultural pursuits to an industrial society with complex and extensive markets is generally designated as industrial revolution. Since engineering has been a principal factor, it has long had concern for the organization, direction, and economy of such enterprise. But the economic problems created by technological progress have taxed our collective ingenuity with recurrent maladjustments sufficient to jeopardize free private industry. Professional management has been described most frequently as industrial engineering, or more elegantly as scientific management. But many engineers unfortunately have concerned themselves with the techniques of their specialties, allowing their responsibilities to management to be those of technicians and clerks. Truly professional management in modern industry demands competence and vital direction of a high order, approached only with scientific objectivity. We must give constant and critical scrutiny to our methods and qualifications.

Scientific method can briefly be regarded as a way of developing the stability of beliefs by minimizing errors and constantly searching for contradictions. We strive for absolute objectivity in a progressive spiral of hypothesis and test. It must be recognized, however, that in the social sciences it is difficult to exclude thoroughly the subjective or normative point of view. Scientific management, by definition directed to the most efficient performance of industrial enterprise, may involve such norms, particularly with its background of extreme individualism, concern for the welfare of labor, and an increasing responsibility for the rationalization of whole industries. Norms of political origin are not entirely separable from concepts of economic organization.

Competition, an Agency of Selection and Development

Competition has been specified as associating struggle with order; an agency of selection and development, if we recognize a Darwinian scheme of life. History describes the mutations of feudal dominance to the ideals of individual liberty to pursue and retain the yields of effort. If individual incentives are supplanted by abstract group responsibilities, it seems realistic to expect that the performance of the efficient would tend to a popular level. We have observed this in our wage experiences, in the recent Russian land experiments, and in many other cases.

That the competition underlying the petty trade of the days of Adam Smith should have suffered distortion and specialization in the evolution of modern enterprise is obvious. It now exists on many fronts of price, quality, advertising, and intangible services. We have groups of individuals in joint enterprise, still motivated individually by hope of gain but under an imperfect development of corporate mechanisms and an insulation of individual risks from control. Institutional presumptions in administration and finance have often driven the other factors of production to positions of marginal disadvantage. We have concentrated jurisdictions over market price with a logical maximizing of profits at a production volume below capacity and at a price above the social optimum. Overinvestment and rigid capitalization are additional concomitants with low utilization of capacity, high unit overhead, and a downward pressure upon price which, once released by a singular act of competition within an industrial group, leads to ruinous price war and instability.

Fundamentally, we appear to have two alternatives, namely, to discard the economic efficiency of large-scale enterprise by attempting a return to the atomistic competition of another century, or better, to adapt our still imperfect enterprise mechanisms for equitable competition in a broader sense than a ban upon "bigness." Many believe that support can be organized for reasonable but more effective police power which, through professional commissions and the use of the consent decree, will permit more efficient solutions of these problems to originate with the experience of business itself. Objective management and professional competence in both private and public practice are vital to the continuance of private enterprise on an economic scale. Failing this, the alternatives are unpleasant to contemplate.

It has taken many years to identify scientific management with a method rather than with a technique. A review of its development and the work of the truly professional men who have carried on the vision of Taylor, Gantt, and Gilbreth would be repetitious. Some of the procedures of recent years, however, seem predicated upon subjective techniques and many of our engineers appear to enter industry with untoward sophistication. The comments in this paper are therefore offered in examination of a few of the basic tools of professional management.

In classifying the infinite range of responsibilities, we find a convergence upon such derivatives as technical engineering, theoretical and applied economics, accounting, statistical analysis, and psychology. Economics and engineering are the warp and weft of the fabric. With more immediate objectives in production, we might visualize the problems of applied economics concerning the engineer as island families of contours, each containing more specific central issues surrounded by successive levels of environment with increasing complexity and scope. In each one, applied analysis is prone to make predictions of representative constants in place of the dependent variables relating them. The problems might be reduced to four types, namely, the selection, replacement, and apportionment of elements of production, the analysis of optimum enterprise economy, the rationalization of the dynamics of specific industries, and the interpretation and guidance of the trends and adjustments in the parent social environment. Such involution demands competent and professional insight rather than pragmatic philosophy.

---

Contributed by the Management Division and presented at the Annual Meeting, Philadelphia, Pa., December 4–8, 1939, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The insularity of specific design problems makes them appear concerned with elementary out-of-pocket economy alone, while in fact highly dependent upon the variables in each circumscribing environment. In selections between new alternatives the simple reckoning of current costs is confused with divergent concepts as to the annual equivalence of depreciable durable assets. Physical lives of general experience are sometimes postulated for probable economic lives in keeping with the obsolescence and actual utility of specific instances. Interest rates upon creditor funds are frequently used in place of anticipated gross rates of return upon capital. Increment- and sunk-cost concepts are imperfectly understood and applied in many situations. In the general employment of minimum-cost-point and break-even-point analyses for multiple alternatives, we have a frequent desire for universal working formulas which lead to mistakes in numerous specific applications. Economic lot-size formulas are frequent offenders in this regard.

Fallacies in Replacement Economy

In replacement economy we appear to have additional fallacies. Each problem strives to compare the significant factors of prospective costs of a new machine, method, or structure with the prospective costs of continuing in service the existing installation. The capital recovery costs in the latter seem properly based upon net realizable value and not the irrelevant book value of accounting, adding of course any modernizing investment necessary to equate reasonably the expected utilities of old and new. The use of book value creates a fiction since the true capital sacrificed by continuance is the realizable value.

There are accessory variations. A few claim that actually recovered capital should be deducted from the first cost of the new alternative in such comparison. This misconception is easily disposed of with the question: How much capital will be actually impounded in the new equipment? Others might profess that these contentions are met by including full book value for the old equipment and, for the new, the old machine's unamortized book value plus first cost. Here the error might arise in equal differences being written off at dissimilar lives in the average case. As to the procedural question concerning the disposition of the discrepancy between book and realizable values, it seems eminently proper to enter it against surplus. The higher book value, born of reluctance to reflect actual current losses in fixed assets, causes overstatement of the operating profit in like degree during the earlier part of the life. Still another form of error lies in the occasional treatment of indirect expense or burden. Being commonly expressed as a rate of some direct cost such as labor, it is often assumed in the case of some labor-saving investment, for example, that an actual reduction in overhead takes place. A realistic approach considers only the absolute changes in each item of indirect expense. The theory and practice of such engineering economy are perhaps nowhere more soundly presented than in the work of E. L. Grant (1).[2] If the degree of rationality which he presents were generally practiced, it would seem that many of the burdensome commitments in plants today would not exist.

In the circumscribing unitary aspects of enterprise we have similar problems, many of them susceptible to advanced quantitative analysis. It is easily established, for example, that the variability of cost functions with output, similar to the natural performance characteristics of machines, is peculiar and stable for every organization and situation. There has been much use of elementary break-even-point analysis, but the apparent lag in extending the introductory method of Rautenstrauch (2), Knoeppel (3), and others is a matter of some curiosity, particularly in view of its success in the management of power-utility industries. Statistical analysis of fixed- and variable-cost performance is vitally significant to finance, budgets, and forecasts. Realism in the internal dynamics of an enterprise is increasingly necessary for flexibility and survival in constantly changing environments.

As our scope proceeds beyond the internal systematics, we embrace the complex ramifications of general applied economics. Even a simple enumeration of the economic and statistical investigations appropriate to modern administration is impossible here. Much of it is of immediate current importance to executives in the timing of purchases, plant investment, or production activity. Other phases relate to the complex significances of change in the general economic environment and the incidence of policies promulgated by enterprises and industries upon the whole economy. We have, however, a variegation of economic doctrine on one hand and on the other a proclamation of half truths and impossible hopes by political extremists. Sincere businessmen are needful of action while scholars procrastinate. It appears inevitable that realistic utility of applied economics must come by way of more advanced economic scholarship in professional management.

Relation of Accounting to Economics

Completely integrated with economic activity is the institution of accounting and its characteristics are pertinent to this discussion. Its principles regard asset values as based upon original cost, except for current assets which are reported at cost or market, whichever is lower. The approach to earning statements is never to anticipate a profit but to provide for all losses. In economics, we fundamentally interpret true earnings or losses as being increases or decreases in actual net wealth. In accounting practice, employing original cost and barring unrealized profit, we have inimical fictions. If assets are reported above their true values, so must be the profits, regardless of the allocation of profits and losses between balance sheet and operating statement. The net worth is out-of-line in either case.

Accountants justify their approaches in various ways. Original costs are often defended upon the grounds of going-concern concepts, undervaluations upon conservatism, and both upon expediency and expense. Going value has had its particular uses but has become a too frequent defense of these discrepancies. In essentially permanent ownerships, a variation in valuation is adjusted by the corresponding long-term level of reported earnings but, with the diverse and short-term ownerships of today, the average stockholder or creditor must rationalize his position with distorted criteria. The claims of conservatism in undervaluation seem equally indefensible upon the same grounds. As for the regular and periodic reappraisal of assets, it has been competently maintained that such procedure need not be impracticable or costly.

Increasing criticism is jeopardizing the future of accounting and the value of much professional engineering research based upon it. It has been stated that accounting must either revise its concepts or be reduced to a level of secondary importance in industry. Some of its spokesmen have attempted to clarify the situation by a sermon of pure conventionalism for the balance sheet and an assignment of predominant accuracy to the operating statement. But there would seem to be an inevitable correlation of their inaccuracies and a futility in such approach. The author is not unmindful of the difficulties illustrated by the conventional requirements of public agencies but the fundamental and necessary realignments are inescapable.

Statistical Method

The third essential, which will be commented upon, is sta-

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

tistical method. We are generally familiar with its importance in all sciences and its powerful modern tools of probability analysis, although some engineering empiricists still popularly consider it as a largely manipulative presentation of data. Its momentous extension to product-quality control in scientific management has evoked a growing realization of its significance in other professional specializations. In time-and-motion studies there are promising speculations of more scientific method. Because of the elementary requisites in equipment and observational skill, and the permitted latitudes of judgment, time-study specialization has grown in popularity with remarkable strides. A good, if not major, proportion of the work done has been viewed as being of questionable value. Managements have in many cases appeared to give insufficient concern to the caliber of young men selected for it. Many of them have been trained in certain techniques of observation but it seems fair to question the number implemented for efficient and objective interpretation. We can easily visualize the potential destruction of managerial control and human values arising from superficial studies.

Time-study observations consist principally of elapsed times for the operating elements of a given job cycle, repeated for reliability from 10 to 50 times. Interpretation aims at establishing a representative time in each standardized element for production planning. The cycle of selected element times is ordinarily adjusted to a good performance level by studies of the concomitant variations of skill and effort. Further transformation produces the long-run performance standard based upon studies of reasonable net productive time per day in each class of work. The final prediction is a basis for wage-rate setting. The variously sponsored techniques are largely empirical and use statistically small samples of observations. It is fully understood of course that the degrees of analysis and accuracy permissible in practice are functions of the size of operations, and that labor's comprehension of the results is a significant factor. The fragmentary speculations raised consider the research that may prove fruitful in establishing more reliable tests and standards of procedure.

Man, like nature, cannot duplicate performance exactly, since many causes operate with unknown frequencies within any one system of conditions. If the latter remains constant, we have some degree of statistical control and establish characteristic limits of variability and credibility to make predictions of repeated performance. Obviously not all systems are found constant or controlled.

In the conventional study of operating elements, we have a row of repeated observations which fluctuate about a central tendency. We face the problem of estimating the underlying universe parameters with reasonable credibility from the corresponding sample statistics, in most cases circumscribed by small-sample errors and some uncertainty as to the form of the distribution function. Care is needed in the selection of sample sizes conforming to the degrees of variation and desired accuracy, and of statistics bearing optimum efficiency in such sample size. The representative time most often used is the mean, sometimes the mode or median.

A few methods attempt to reflect the degree of variation, either to eliminate wild readings or as a part of leveling for continuous performance. The Merrick method, for example, discards extreme readings deviating from their adjacent times by more than approximately 30 per cent of the adjacent times. It also averages the ratios of each mean to its remaining minimum time as a supposedly stable dispersion characteristic of the worker. Superficial tests upon one set of data would appear to suggest that the variation is more peculiar to the operation than the worker. In the description of the Merrick method, there is implied the possibility that minimum times in specific elements are inherently constant for all workers. In view of the increasing fluctuations due to sampling as we go from the median reading to the extreme reading, which are much larger in small samples than in large, it is hazardous to base estimates upon one extreme observation, particularly if arbitrarily selected. If substantiated, this promising hypothesis can be implemented with more reliable statistical tools.

Study of Forms of Time Distribution Needed

The forms of the time distributions also might be more usefully studied. Underlying each operation we have a finite but unknown number of causes contributing time minutiae with individual probabilities of occurrence. The theoretical frequencies of various possible times are those expected in long-run observations under control. Where we have equalized individual cause effects and uniformity in their probabilities of occurrence, the theoretical distribution is based upon the point binomial, positively skewed when the causes are relatively few in number and approaching the bell-shaped symmetrical curve when increased to the limit. In any case it decreases "smoothly" from the mode. When there are predominating causes, these distributions take irregular forms, depending upon the factors present. When we lack a priori knowledge of these causes the distribution smoothness, degree of variability, and symmetry may suggest the degree of control present. Further, the employment of χ^2 against fitted theoretical or graduation functions can give us some test of conformance to control. Do we not have here a promising criterion of the efficiency of motion-study work?

In the establishment of truly representative element times, however, it would seem necessary to make more complete patterns of observation than those taken for short time intervals with one or two operators. The results are dependent upon the time of day, variations from day to day, differences between operators of equal skills and efforts, and actual differences in skill, all in addition to the basic variation within the operation itself. With reasonable care in design, it is possible to take observations over a range of hours, days, operators, and observers by organized sampling, providing complete information for all purposes. Advanced modern methods of statistical analysis presented by R. A. Fisher (4), W. A. Shewhart (5), and others (6, 7)[3] permit practical tests of control, extensive separation of the variables involved, and greater accuracy in determining representative times and variations. Further, the distribution of complete cycle times is a sum function of the element time distributions, where theory establishes their relationships as to mean and variance, depending upon the degrees of correlation between element distributions. With this in mind, the distribution of cycle times has interesting possibilities because of its tendency to greater control. Investigation may support the practical prediction of cycle variance as well as mean time, permitting the use of probability in forecasting performance levels and subsequent operating controls as established in statistical quality-control methods.

It is hoped that these speculations suggest lines of research and a new approach. The statistical competence required for development should not prove unreasonably advanced. As for any misgivings as to the simplicity and economy of such approaches in actual plant applications, the final procedures do not promise any greater involution than other standards resulting from management research.

In general, this paper presents a few thoughts in the direction of more critical research and broader training in industrial management. Engineers in practice, and on college faculties too,

[3] Several working texts for analysis of variance and covariance have recently appeared. The two references cited in the Bibliography are representative.

have a share of human complacence as to their general proficiency in fields outside of immediate experience. Industrial engineering may not have as many of the handicaps of inbred technical specialization, but with three-dimensional responsibilities and opportunities—technology, economics, and scientific management—its success as a profession seems to turn upon a level of fundamental competence which demands the best talent that engineering schools can produce. In management's rapid growth, however, there has been a tendency to conventionalize its practice and research. Rationalization of the rigidities of modern dynamic economy seems to demand a concurrence of experience and scholarship at higher levels than ever before. The marriage of engineering and realistic economics promises a stock that will improve upon the existing parent strains.

The responsibility for development is obviously divided between the engineering schools, industry, and the professional societies. In the first, as recently pointed out by Robert E. Doherty (8), the revision of engineering curricula is hampered by unwarranted insistence upon specialization, vested interest, and rigid viewpoint. To industry would appear to belong the applied specializations in each field, making possible more advanced scholarship in fundamental engineering, economics, and management within the usual span of undergraduate and graduate work. The professional societies bear equal responsibility. It is hoped that the Management Division of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS can continue to support actively a critical and progressive integration of research and publication, interesting the best minds in our profession so that the rest of us may more efficiently serve our common purpose.

Discussion

E. L. GRANT.[4] Two comments occur to the writer as pertinent to the author's observations on incorrect methods in economy studies and his interesting summary of critical views on conventional accounting practices:

1 The voices of those who are critical of the misuse of accounting figures have not yet been heard by a great many of the users of those figures. This statement is based in part upon personal observation and in part upon the confusion of thought evidenced in current writings on such matters as replacement economy.

2 There is no way in which accounting practice can be reformed so that accounting figures may always be used without modification as a safe guide to business decisions. The diversity of business alternatives to be compared is too great for their differences to be measurable by any routine systematic process such as accounting necessarily must be.

A recently observed incident may serve as a simple illustration of the latter point. An engineer redesigned a certain part for a technical product to reduce its cost. The new design effected a $2 reduction in the direct material cost of each unit but involved a $1 increase in its direct labor cost. This he believed to be a $1 cost reduction per unit.

However, the cost-accounting system in the plant allocated indirect manufacturing expense in proportion to direct labor cost; the "burden rate" in this department was 175 per cent of direct labor cost. Thus the $1 increase in direct labor cost was responsible for a $1.75 increase in allocated indirect manufacturing expense, making the net result of the new design an increase of 75 cents in the unit cost as shown by the accounts. Despite this indication by the accounts that the new design was uneconomical, a critical consideration of the facts showed that the company would really save money by using it. None of the individual items, e.g., superintendence, shop transportation, cleanup, heat, light, power, depreciation, taxes, and insurance, which entered into indirect manufacturing expense seemed likely to be altered by the proposed change in design.

At first glance one might be inclined to say that the cost-accounting system should be reformed if it seemed to show costs going up as a result of a policy which actually made them go down. However, careful examination of the circumstances indicated that this was not the correct inference. Considering all of the various purposes of cost accounting, this cost system seemed as good a one as could be devised without excessive clerical expense. What was really necessary was a recognition by management that, to compare specific alternatives, it was essential to look beneath the surface of the cost figures to find the true difference between the alternatives. No possible reform of the cost system could eliminate the necessity of doing this in some cases.

P. T. NORTON, JR.[5] In referring to fallacies in replacement economy, the author correctly states that the capital-recovery costs of the existing installation should be based upon its net realizable value and not upon its irrelevant book value. There are so many ways of proving that the book value of an existing installation should not be used in an economy study, unless it happens that this book value is equal to the net realizable value, that the writer is unable to understand why this obvious fallacy should appear so frequently in discussions of replacement economy.

While the author has proved that any such use of the book value of an existing installation is incorrect, it seems to the writer that there is another way of disposing of this fallacy which should be even more readily understood by the average person. It is obvious that one of the principal purposes in setting a depreciation rate is to bring the book value down to the realizable value at the time the asset is displaced. If the book value is not equal to the realizable value at the time the asset is displaced, it is because the book value is in error by the amount of the difference. Replacement-economy studies should be based upon conditions as they will be if the replacement is actually made and not upon what it was estimated some years ago would be the situation today.

J. A. PIACITELLI.[6] In appraising the time-study work, the author points out that a good portion of it has been viewed as being questionable. The writer is in sympathy with this view, for many a study has been rendered incredible by improper methods of observation, inadequate sampling, improper analysis of the

data, or inappropriate allowances. No matter how much one may do to establish a credible result in any one of these phases, the final answer, or standard, can only be as accurate as the degree of accuracy of each of them. It would be of but slight benefit to work to a high degree of accuracy in the statistical analysis of data when there is doubt as to whether the allowance for fatigue and unavoidable delays should be 10, 15, or 20 per cent.

Viewing the problem as a whole, that is, the development of adequate standards of performance, it is the writer's opinion that attention should be directed toward the standardization of the technique. It appears that we have been too busy standardizing manufacturing operations to get together, examine our own technique, and standardize it. In indicating the desirability of research toward this end, the author has indicated a cause which when removed will contribute greatly toward a more uniform procedure and consistent results.

As for the statistical analysis of data, it is not felt that more accurate methods are needed than the simple ones now at our disposal. Determinations are made for (*a*) the selected minimum, (*b*) lowest third, (*c*) mode or modal average, (*d*) median, (*e*) selected average, and (*f*) the arithmetic average. Which of these is used in the establishment of a standard depends upon the point of view of the analyst. Their use in turn affects the amount of allowance to be applied. For instance, a much higher-percentage allowance must be applied to the selected minimum than the average. What we need is a more common use of the statistical method which would result in the most representative measure of the operator's performance. Investigation by the writer into the relative values of these various statistical methods has led to the adoption of the mode, or modal average, as the simplest means that would yield the most representative results. The modal average, being the value about which most cases recur, is the most reliable method of determining the characteristic or typical performance of an operator. This determination is made possible with relatively few observations as compared with the number that are required when using the method of averaging.

In this connection the writer would like to present for consideration a few facts pointing to the degree of credibility which may be placed upon the modal-average method. What the writer has in mind is the time required to perform an element of a weaving operation in the silk-textile industry. On the basis of slightly over 1000 observations made in approximately 20 silk and rayon mills, the modal average was 0.098 min. Adding to these about 7000 more observations, the modal average was still 0.098, while the arithmetic average dropped from 0.124 to 0.108, or 12.9 per cent. It is interesting to note that the arithmetic average, becoming more representative as the number of observations is increased, approached the modal average to a point within 0.01 min when the quantity of data was increased sevenfold.

Taking at random the observations made on one weaver during one study period, the modal average was 0.116 on the basis of 46 occurrences. When this study was extended to 262 occurrences, the modal average was 0.115 or a change of 0.9 per cent, while the average increased 5.6 per cent. It appears from these data that the modal-average method yields the most consistent results.

The "selected average," determined by the elimination of abnormal readings, is often used as a means of approaching the representative time, but the element of judgment tends to place it on a selective rather than factual basis.

The writer was interested in the author's suggestion pertaining to tests of conformance to control. While it may be desirable to investigate the possibilities of predicting cycle variances "permitting the use of probability in forecasting performance levels and subsequent operating controls," the writer is somewhat pessimistic of the fruitfulness of such an endeavor. A frequency distribution of data is the result of many factors:

1 Degree of standardization of method.
2 Effectiveness of the method (a poor method as well as a good one may be highly standardized).
3 Tools, equipment, and work place.
4 Operator's automaticity in the method.
5 Application or attitude of the operator.

Keeping these factors in mind, the smooth distribution of data, degree of variability, and symmetry may suggest the degree of control present, but it is not believed they will serve as a measure of the efficiency of motion-study work. A symmetrical, smooth frequency distribution with low variability indicates to the writer that the operator is earnestly following a method which is highly standardized. However, it does not suggest that the method is the best which can be devised. Therefore, the writer could not consider the characteristics of the distribution as a criterion of the efficiency of motion-study work. Again, when we have a frequency distribution which is uneven and highly variable, it would appear rather difficult to determine from the array of data whether the operator lacks the required degree of automaticity in the method or is not applying himself, or both.

In closing, may the writer suggest that our immediate attention be directed toward the problem of allowances as one of the steps in the establishment of standards of performance which is far below the recording and analyzing from the point of view of accuracy. A real contribution can be made in supplementing the meager amount of factual data now available to us on this subject. Based as they are largely on judgment and supported by a few scattered actual studies, they tend to nullify the accuracy now possible in our observation and analytical work.

WALTER RAUTENSTRAUCH.[7] The author quite properly emphasizes the need for a more scientific procedure in dealing with the problems of management. It is true, as he says, that we have been concerned more with techniques of management, that is, formulas and rules than we have with the broader concepts of management out of which may be evolved fundamental and basic principles to guide us in the operations of our industries.

The paper states: "Professional management in modern industry demands competence and vital direction of high order, approached only with scientific objectivity." As a matter of fact, how much scientific objectivity is permitted in the management of business enterprise? Those who are engaged as professional consultants in the field of management are expected to show their clients how to meet the competitive conditions of the market place. These clients, being very "practical" people, expect profits to flow from such advice. Frankly, much of the work which has gone under the name of management, particularly that involving revisions in the methods of wage payment, standardization of jobs, etc., has largely resulted in lowering the wage cost of production and in altering the relative claims of capital and labor to the goods produced to unworkable proportions.

Management engineers have never, except in rare instances, examined into the economic consequences of these so-called systems nor taken into account their effect on the national economy as a whole. The writer fails to see how we can have any scientific objectivity on the larger problems of management so long as management is expected only to produce profits for individual enterprise without regard to the effects on the entire national economy. As the author points out, scientific management should be "directed to the most efficient performance of individual

[7] Professor, Industrial Engineering, Columbia University, New York, N. Y. Mem. A.S.M.E.

enterprises." This raises the question of the units in which efficient performance shall be measured. After an extremely rapid growth in so-called efficient performance of industrial enterprise from 1918 to 1929, we suffered a most disastrous collapse in our industrial economy. Was there real efficiency during this period? What was it we did not take into account as managers of industrial enterprises which caused our industries to break down?

Our engineering societies have been lax in addressing themselves to this most important problem. Perhaps this may be due to a misinterpretation of what the author refers to as the "Darwinian scheme of life." The misinterpretation of Darwin's theory has perhaps done more harm to the national economy than most people realize. The world has yet to learn that only by an intelligent integration of the processes of civilization can we hope to attain a high rate of productivity and an increase in the standard of living. It is true that the solution of the problems of industrial enterprise involves continuous struggle but the object of this struggle, in the writer's opinion, has been falsely directed. It has been directed mainly toward competition between the elements of the national economy, which should be operated on a cooperative basis, rather than upon a competitive basis.

Private enterprise was quick to learn, as it did since the beginning of this century, that its growth and development depended upon an intelligent integration of its departments of operation. How long will it take us to learn that the same intelligent integration of the parts of the national plant as a whole must be accomplished before we can stabilize its performance?

The questions of detail of operation within an individual unit of our economy which the author raises are important and should be inquired into more fully as he suggests. We do need to apply scientific principles to many of the problems that we now solve empirically. We also need to re-examine many of the so-called scientific solutions to determine whether or not they are really scientific.

Very often we have gone into elaborate statistical processes in the solution of problems before we have determined fully the functional relations of the elements about which we are endeavoring to obtain statistical interpretation.

The writer presented a paper[8] before the Philadelphia Section of this Society in 1917, in which was pointed out the imperative need for a closer integration of our banking system with our manufacturing enterprises and the need for their integration on a functional basis. In that paper a quotation was made from the records of The Annals of the American Academy of Political and Social Science, concerning the manner in which the Commonwealth of Massachusetts dealt with the problem of farmer and banker relationship, as follows:

"Several of the banks have opened special farm departments and employed men whose business it is to investigate the applications of farmers for credit. The Plymouth Trust Company, of Brockton, has for two years employed two men, graduates of the Massachusetts Agricultural College, to aid the farmers in applying business methods to the business of farming. The object of the directors of the institution was to get acquainted with them so as to make a businesslike application of credits to those engaged in this important industry. This bank has helped the farmers of their vicinity to buy seed, livestock, etc., and stimulate production by offering prizes to the young people on the farm. It is showing the farmer how to keep cost accounts and how to make cost statements; in short, to know his business both from the technical and from the business standpoint. To worthy persons they stand ready to make a small loan to be used for construction work or for improvement under the supervision of the bank's field agent. Every banker will ask himself, "Does it pay?" It has cost the Plymouth Trust Company $4000 a year net to supply this service to farmers in and about Brockton, but as a result of this and similar activities the deposits have increased in the last five years from $400,000 to $3,000,000."

What forces in our national economy have militated against a further extension of such relationships, not only between the bankers and the farmers but also between the bankers and the manufacturing industries. While it is true that we need better scientific methods to solve the internal problems of industry, we should not close our eyes to the fact that by far the most important problems of management lie in the area of our total economy. While it is almost universally believed that Adam Smith developed the principles of the laissez faire economy, and most people are of the opinion that our economy can be operated most effectively according to these beliefs, it may be instructive to read what Adam Smith actually wrote[9] about some of the problems which he saw developing in the economy of the western world:

> The progress of the enormous debts which at present oppress, and will in the long run probably ruin, all the great nations of Europe, has been pretty uniform.
>
> In the reign of King William, and during a great part of that of Queen Anne, before we had become so familiar as we are now with the practice of perpetual funding, the greater part of the new taxes were imposed but for a short period of time (from four to seven years only), and a great part of the grants of every year consisted in loans upon anticipations of the produce of those taxes. The produce being frequently insufficient for paying within the limited term the principal and interest of the money borrowed, deficiencies arose, to make good which it became necessary to prolong the term.
>
> In consequence of those different acts, the greater part of the taxes which before had been anticipated only for a short term of years, were rendered perpetual as a fund for paying, not the capital, but the interest only, of the money which had been borrowed upon them by different successive anticipations.
>
> A sinking fund though instituted for the payment of old, facilitates very much the contracting of new debts. It is a subsidiary fund always at hand to be mortgaged in aid of any other doubtful fund, upon which money is proposed to be raised in any exigency of the State. Whether the sinking fund of Great Britain has been more frequently applied to the one or to the other of these two purposes, will sufficiently appear by-and-by.
>
> In Great Britain, from the time that we had first recourse to the ruinous expedient of perpetual funding, the reduction of the public debt in time of peace has never borne any proportion to its accumulation in time of war.
>
> When funding, besides, has made a certain progress, the multiplication of taxes which it brings along with it sometimes impairs as much the ability of private people to accumulate even in time of peace as the other system would in time of war. The peace revenue of Great Britain amounts at present to more than ten millions a year. If free and unmortgaged it might be sufficient, with proper management and without contracting a shilling of new debt, to carry on the most vigorous war. The private revenue of the inhabitants of Great Britain is at present as much encumbered in time of peace, their ability to accumulate is as much impaired as it would have been in the time of the most expensive war had the pernicious system of funding never been adopted.

When the debt structure of the nation increases at a greater rate than the rate of production, our economy is in peril and the business of every manufacturer is in jeopardy no matter how scientifically its internal problems are managed. Has there been any scientific inquiry into this problem to which Adam Smith called our attention over two hundred and fifty years ago?

If then we are to have a more scientific approach to the prob-

[8] "Manufacturing in Relation to Banking, Research, and Management," by Walter Rautenstrauch, *Journal* of the Engineers' Club of Philadelphia, Philadelphia, Pa., February, 1918.

[9] "Wealth of Nations," by Adam Smith, 2 volume edition, Oxford University Press, New York, N. Y., 1869. Quotations in order presented are from vol. 2, pp. 581, 583, 585, 587, 594, and 600.

lems of management, should we not inquire into the following types of problems:

(*a*) *A Theory of Organization.* It is unfortunately true that, with all the work which has been done on organization, we have never yet developed a rational theory of the principles of an organized procedure. Until we have a frame of reference or a set of guiding principles, by which to judge the adequacy of an organized procedure in relation to objectives and resources, we can never make much progress in solving the problems of organization.

(*b*) *Operating Characteristics of Our National Economy.* Few attempts have been made to describe how our national industrial economy really functions. Until we understand the functional nature of the sum total of our industrial processes, we will never be in a position to suggest how they may be more efficiently managed or how a particular unit of industry should be operated as a part thereof.

When an engineer examines a particular machine the first thing he does is to find out how it functions, that is, how its parts are related to each other and what are the basic principles underlying its operation. When he understands the functional relationships, he is then in a position, and not before, to derive quantitative relationships concerning its operation.

Management which, up to the present, has been almost wholly concerned with the problems of internal operations is now compelled to give increasing attention to the problem of the individual enterprise as a part of the national economy as a whole if our economy is to be preserved.

When the United States Steel Corporation's net earnings dropped from $195,000,000 in 1929, to a net loss of $59,000,000 in 1932, it certainly was not due to the failure of its management to apply scientific principles to its internal operations. What the managers of the steel corporation and the managers of all other corporations failed to do was to lift their eyes from their own financial statements and observe the march of the economic forces bearing down upon them. After 10 years of disastrous depression, how many managers are familiar with the results of the excellent researches of the National Bureau of Economic Research? How many management and engineering societies have given any consideration to the interpretation of these researches?

The present paper is both timely and important and should urge us to give more careful consideration to the scientific aspects of management problems. It is also high time that we select the most important problems to be solved. Perhaps the Management Division of this Society will help us to select these problems. It is not at all unlikely that, in this search for the important problems of management to which scientific procedure may be applied, we may find the very important question: Management for what?

Author's Closure

To the practical difficulties of recasting general accounting techniques precisely to reflect economic reality, the author readily agrees. But a principal issue remains; that the conventionalized record-keeping so vital to business control, like the shadows of the carried lantern, must be interpreted according to the expediencies of each situation. The oracular pronouncements of its disciples in industrial economics are often in conflict with underlying reality, and erudition as to its detail is sometimes mistaken for professional wisdom. The work carried on by Professors Grant and Norton in the applied economics of engineering selections and replacements and the well-known work of Dr. Rautenstrauch in enterprise characteristics, are encouraging signs. We hope that these are the foundations of a new realistic economics, neither at the extremes of record-keeping technique on the one hand nor abstract "cultural" economics on the other. We need an approach resting upon rigidly scrutinized evidence.

As regards the possibilities of advanced statistical analysis in a more scientific approach to time-study work, the author is interested in the views expressed by Mr. Piacitelli. He indirectly suggests an important issue, in that every investigation, no matter what the precision and objectivity employed in basic interpretation, is overlaid with administrative allowances and the opportunistic motivation of management. That standardization of inevitably personal and subjective factors can usefully be employed is readily granted. That standardization of basic measurement technique can be a guarantee of valid interpretation and homogeneous underlying conditions is respectfully denied. Unassignable or chance causes play a leading role outside of the research laboratory.

Statistical analysis is a vital and powerful tool, not to be casually acquired as a convenient set of arithmetic techniques, nor to be approached with the elegant abstraction of the professional mathematician. Th. von Kármán[10] recently observed: "The engineering application of mathematics is not based on purely logical principles alone; its purpose is the correct interpretation of physical phenomena."

In the scientific aspects of time study, we would appear to aim at an objective determination of the actual sustained basic operating time and the degree of variance of the average good operator under statistically constant underlying conditions. If the latter do not obtain, we can neither combine phenomena in similar investigations nor project them as logical expectations. Since any finite set of observations is merely a sample of an underlying universe of values, we must draw inferences cautiously from efficient statistics which minimize the always present chance variations.

If all of the information underlying the data which Mr. Piacitelli presents were available, it would be expected that a critical appraisal might reveal dissociated conditions which explain the otherwise surprising behavior of the statistics reported. Two possibilities suggest themselves, i.e., that the data have not arisen from the same underlying universe; that the modes have been obtained by the usual approximation techniques, where at best the mode is a very uncertain parameter to estimate. In the first instance cited, the mean of the initial sample of 1000 is given as 0.124 and, by the elementary relationship of the sample means to their weighted mean, we find that the mean of the second sample must have been 0.1057. Also we have the elementary large-sample test of significance for the difference between the means of the two samples under the hypothesis that they come from the same universe

$$T = \frac{\overline{X}_1 - \overline{X}_2}{\sigma_p \sqrt{\frac{1}{N_1} + \frac{1}{N_2}}} \quad \text{or} \quad \sigma_p = \frac{\overline{X}_1 - \overline{X}_2}{T \sqrt{\frac{1}{N_1} + \frac{1}{N_2}}}$$

where the standard deviation in the denominator is that of the common population. The value T can be expected to be distributed normally and, taking the most favorable maximum value in standard error units, common to tests of significance as 2.576, we would arrive at a standard deviation estimate of 0.2066 which is the minimum permitting an acceptance of the null hypothesis. It would be a very skewed distribution indeed that had only 0.1057/0.2066 or 0.512 standard deviation units between the second sample mean and its zero origin, and only a fraction of this between its mean and the minimum reading or ob-

[10] "Some Remarks on Mathematics From the Engineer's Viewpoint," by Th. von Kármán, *Mechanical Engineering*, April, 1940, pp. 308–310.

servation.[11] Furthermore, we seem to have a uniquely small difference between the mode and mean of this second sample when associated with such a standard deviation. In fact, the employment of the relations between the mean and mode in known functions that are at least nearly appropriate to this type of distribution gives a skewness measure that seems incompatible with the conditions suggested. If the originally estimated standard deviation is actually smaller, the means are significantly different. Such questions pile up to an extent that makes it not inappropriate to raise the issue as to the propriety of considering the data comparable or of combining the two samples of observations referred to.

Mr. Piacitelli's stressing of the importance of establishing standard allowances to supplement the basic operating times is well taken. The author's comments and interest were only in the research possible as regards operating-time measurements themselves and their interpretation, in the use of more critical tests of stability of the phenomena, and in the suggestion of modern analysis. The author is convinced that the latter will not only improve the objective determination of the sustained and controlled good operating levels but permit the isolation of the component variances. Space does not permit attempting an exposition of well-established statistical theory that can be employed but it is to be hoped that students, who are advanced in their grasp of both fields, will find the opportunity at least to investigate another dimension which has been of proved success in other branches of science.

The author does not presume even to a modest competence in the time study that is so tremendously important in our industrial economy and in which Mr. Piacitelli has deservedly attained such eminence. However, if it is to acquire the highly objective statistical tests of research employed in science, a thorough employment of applied statistical theory is necessary. Simple numerical generalization so common to what may be popularly described as business statistics would merely compound the dangers of purely empirical approaches to professional engineering. The author does not recall the savant who remarked that a tragedy is a beautiful generalization wrecked by a single obstreperous fact.

[11] For purposes of simple illustration no distinction is made between population and sample values of standard deviations since the samples are very large.

Fuels for Diesel Engines in Marine Transportation

By W. F. JOACHIM[1] and H. V. NUTT,[2] ANNAPOLIS, MD.

After reviewing briefly developments in the field of Diesel fuels over the last 30 years, the authors discuss in detail the present-day requirements for marine-Diesel-engine fuels. A summary of engine troubles and casualties caused by unsuitable fuels is also given. The paper includes a series of tables and explanatory matter concerning Diesel-fuel specifications for various types of marine engines.

THIRTY years ago, hot-bulb-type engines, using solid-injection systems with large-orifice, open-type nozzles, and full Diesel air-injection engines, were operating as pumping engines in the oil fields, using fuels varying from raw crude to 43 gravity kerosene. Many of these engines are still in service. Their efficiencies were relatively low for Diesels, their rate of wear was high, and sometimes they were hard to start, but they burned the fuel at hand and produced the power required with relatively small maintenance and other expense, compared to contemporary steam engines. Like stationary land units, the marine engines of that day were making a name for themselves by burning cheap fuel with an efficiency which has as yet been unequaled except by a few high-pressure high-temperature "modern" steam turbines.

The fuel available at that time was no better and little worse than that available today. Cheap fuel was dirty and contained much residuum. However, cracked fuels had not made their appearance, which normally precluded many present-day combustion and maintenance problems. Clean fuels were all straight-run distillates and gave little trouble, except for injection and combustion difficulties, caused by unsuitably high or low viscosities. Typical fuel specifications for that period, one formulated by Dr. Diesel, are given in Table 1.

During the period when "air injection" was used exclusively, little attention was paid to the properties of the fuel, except that the operating engineer knew from experience the approximate degree of purity and viscosity required to produce passable results in his engines. With the advent of the first commercially successful solid-injection system, manufactured by Vickers in 1914, more attention was given to fuel oil, especially from the viscosity standpoint.

Several investigators published papers covering their work on Diesel fuels during the change-over from air to solid injection about 1918 to 1930, and in 1928 members of this Society formed a committee for the investigation of Diesel fuels with the aim of establishing standard specifications. This committee proposed two fuel-specification standards in 1929, one for light high-speed engines, the second for heavy-duty slow-speed engines. Several series of tests were also made to determine the effect of various impurities on engine operation.

As a result of this and other work on Diesel fuels, a combined A.S.M.E., S.A.E., and A.S.T.M. group submitted several "Diesel-Fuel Classifications," one, in 1934, consisting of five fuel grades, in which ignitibility was considered an important factor for medium- and high-speed fuels. These specifications are given in Table 2.

It was found impossible to obtain sufficient funds to carry out the extensive test program outlined by the joint A.S.M.E.-S.A.E. committee, due to the current financial depression, but, in 1933, a group of men formed the Volunteer Group for C. I. Fuel Research and carried out several series of cooperative experiments during succeeding years on the most promising methods of measuring ignition quality (1).[3] The present ignition quality-test method is described in the 1938 transactions of the A.S.T.M.

The original "Volunteer Group" has now become the Automotive Diesel Fuels Division of the Cooperative Fuel Research (C.F.R.) Committee, Society of Automotive Engineers, whose work was broadened in 1939 to include investigations of the effect of fuel volatility, cetane number, viscosity and gravity on full-scale performance, and engine deposits. Other factors such as the effects of sulphur, gums, carbon residue, and impurities on performance, maintenance, and engine wear are to be investigated in the future (2).

MARINE-DIESEL-ENGINE FUEL REQUIREMENTS

The essential requirements for a marine-Diesel-engine fuel are given in Table 3. They are listed according to their order of use rather than their relative importance.

Storage and Handling

A primary consideration of Diesel fuels is that of storage and handling, as the fuel must be safe in storage, it must not deteriorate, and suitable handling methods must be available.

Fire Hazard. Although a Diesel-fuel vapor has a lower autoignition temperature than some of the more volatile hydrocarbons, fire hazard with Diesel fuel is considerably reduced because of its greatly lowered volatility. Tests have proved that Diesel fuel at its flash-point temperature, being run into a tank with sufficient force to produce considerable foam on its surface, will still not burn, only the foam being burned off when ignited by an electric spark. At temperatures below the flash point, only a small portion of the foam on the surface will burn. Therefore, Diesel-fuel fires, caused by electric sparks or open flames in or adjacent to Diesel-fuel storage, are practically nonexistent.

Aging and Deterioration. Tests covering a period of years have shown that, for the distillate fuels investigated, including straight-run and cracked fuels and their blends, no reduction in the more important fuel properties occurred during long-time storage. Experience shows, however, that certain fuels are incompatible, and when mixed will precipitate compounds which affect engine operation by forming sludge, gums, and lacquers.

Corrosive Properties. All Diesel fuels are not chemically neutral, some containing small amounts of acidic materials. Such acids may effect engine wear and corrode injection equip-

from 30 sec SU to 200 sec SU, although engine performance will differ markedly with widely varying viscosity fuels.

Pour Point. Pour point is the principal criterion of the fluidity of the fuel at reduced temperatures, although the cloud point should be considered as the minimum temperature permitting certain pumping. Experimental work (4) shows that an exact indication of the pumpability of fuels intended for low-temperature service requires actual low-temperature pumping tests because of the different behavior of the wax structures and inconsistencies in injection failure in relation to fuel cloud and pour points.

Preheated Fuels. Fuels too heavy to pump at existing temperatures may be handled by

TABLE 3 MARINE-DIESEL-ENGINE FUEL REQUIREMENTS

1 Storage and handling
- *A* Minimum fire hazard
- *B* Minimum aging–deterioration
- *C* Minimum separation–settling
- *D* Minimum corrosive properties
- *E* Pumping
  - *a* Adequate fluidity without preheating
  - *b* Minimum sediments and waxes

2 High engine performance
- *A* High efficiency
  - *a* Balanced ignition and combustion
  - *b* Combustion without exhaust smoke
- *B* High ignitibility for cold starting

3 Low maintenance
- *A* Adequate ignitibility minimizing combustion shock, cracked bearings, and engine wear
- *B* Minimum lacquer, gum-, and carbon-forming tendencies
- *C* Minimum lubricating-oil sludging

4 Minimum Wear
- *A* Adequate lubrication for injection pumps and nozzles
- *B* Minimum abrasive compounds
- *C* Minimum corrosive compounds
- *D* Minimum slow, acid combustion

5 Adequate supply—minimum cost
- *A* Production from domestic crude oils
- *B* Refining by commercial processes

ment and storage tanks. Also, increased engine maintenance and casualties may occur through the action of metallic oxides which are not always removed by either centrifuging or filtering.

Pumping. Pumping of the fuel must be considered from several standpoints as follows:

a Pumping under cold-starting conditions, particularly in small-boat service.

b Losses in volumetric efficiency of either transfer pumps or fuel-injection equipment, due to excessively high or low viscosities.

c Preheating of the fuel, either in the storage tank or at the engine.

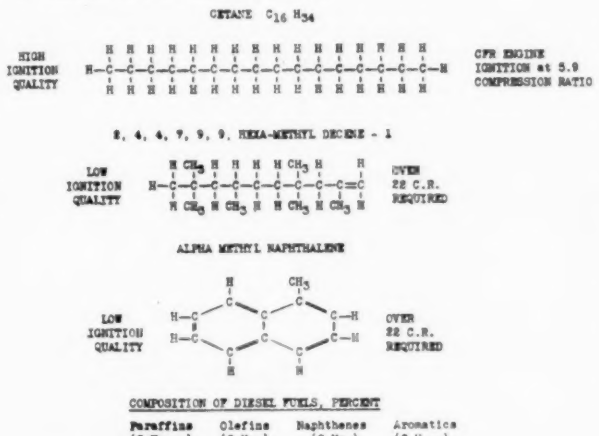
d Precipitation of sediment and waxes on filters and in transfer lines.

Tests have proved (3) that no difficulty in pumping will normally be encountered with fuels having viscosities ranging

first heating them, thus reducing their viscosities to obtain sufficient fluidity for efficient pumping. Relatively elaborate heating equipment, however, is necessary, together with high rates of flow. Therefore, heavy fuels are usually used only in large installations. Somewhat reduced maneuverability, due to inability to get under way quickly, increased fuel-bunker and engine maintenance, and danger of excessive engine wear and casualties, practically eliminates such fuels for modern, high-specific-power engines in the military services.

Filtering and Pumpability. Some fuels are difficult to pump because of precipitation of waxes at normal temperatures, which clog filter bags, strainers, and pipe lines. These ill effects can only be guarded against by using suitable heating equipment or fuels having pour points from 15 to 20 deg below the lowest atmospheric temperatures encountered.

Engine Performance



The performance of a Diesel engine is measured by many factors, all interdependent. The effects of various fuel properties on some of these factors have been investigated, while other effects are not yet fully known.

The principal engine-performance characteristics are as follows:

a Specific fuel consumption
b Combustion shock
c Exhaust-gas temperature
d Exhaust-smoke density
e Maximum cylinder pressure
f Cold starting
g Engine wear

The principal fuel properties believed to affect the engine-performance characteristics are as follows:

a Ignition quality
b Viscosity
c Volatility and distillation range
d Carbon residue and impurities

FIG. 1 DIESEL-FUEL CHEMICAL STRUCTURE AND IGNITION QUALITY

Ignition Quality. Ignition quality can be briefly defined as that property of a Diesel fuel which causes it to ignite readily after injection. It is measured by determining the percentage of cetane in a blend of cetane and alpha-methylnaphthalene which produces the same time delay between the beginning of injection and ignition as the fuel under test, a standard C.F.R. Diesel engine being used. An exhaustive treatise on this subject by T. B. Hetzel (5) together with an excellent bibliography has been published.

The factors which govern ignition quality are chiefly chemical:

a Structure of molecule
b Oxidation stability of molecule
c Size of molecule.

Fig. 1 shows the chemical structure of two hydrocarbons, each composed of 16 carbon atoms, one of which has two more hydrogen atoms than the second. The straight-chain saturated compound, cetane $C_{16}H_{34}$, has greater thermal instability than "2,4,4,7,9,9-hexamethyl decene-1," $C_{16}H_{32}$, which is more compact due to the six side chains in its structure. The third molecule, alpha-methylnaphthalene, $C_{11}H_{10}$, is even more compact than the second and, due to its ring structures, will decompose and combine with oxygen only at very high temperatures.

Compounds such as organic nitrates or peroxides are still more unstable in the engine cylinder than cetane, due to free oxygen liberated at comparatively low temperatures. The addition of such compounds in proportions of 1 to 2 per cent will increase the cetane number of an average Diesel fuel by as much as 10 to 30 cetane numbers.

The chemical factors influencing ignition quality cause fuels manufactured from certain crudes to have higher ignition qualities than others. Fig. 1 shows the relative percentages of the four general hydrocarbon families in the three general crude-oil types, which thus provide indications of their true average ignition qualities. The general order of the hydrocarbon families with respect to ignition quality is as follows:

Paraffins—highest ignition quality
Olefins—second highest ignition quality
Naphthenes—third highest ignition quality
Aromatics—lowest ignition quality

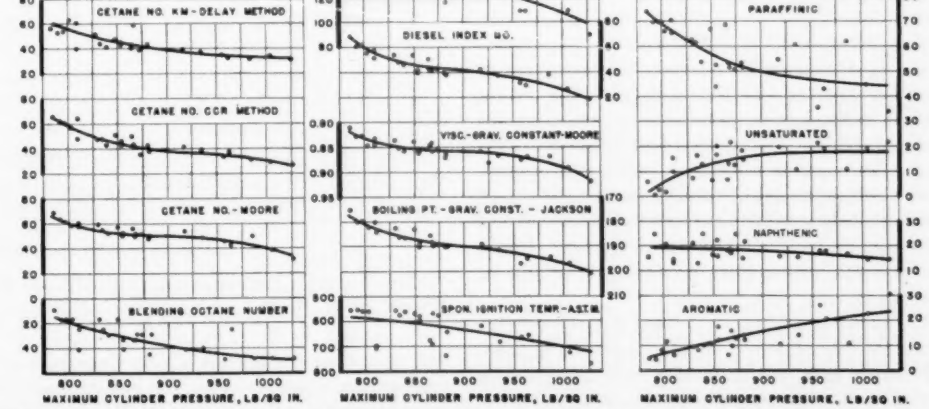

FIG. 2 CORRELATION OF C.F.R. ENGINE PHYSICAL-CHEMICAL AND CHEMICAL-COMPONENT FUEL-IGNITION INDEXES OF 25 DIESEL FUELS WITH THE MAXIMUM CYLINDER PRESSURES DEVELOPED IN A 4-CYCLE DIESEL ENGINE

(Bore and stroke, 4¼ in. by 6 in.; speed, 1200 rpm; 10-bhp single-cylinder engine. Data are for 8 bhp at 1200 rpm.)

Fig. 2 shows the correlation of thirteen methods of measuring ignition quality and the maximum cylinder pressures developed. Inspection of these curves shows that certain of these methods have greater sensitivity per unit of cylinder pressure, and that their data points lie closer to their average curves. They are, therefore, more accurate than the other ignition-quality indexes.

These ignition-quality data were also similarly plotted against the ignition delay of the engine and computed combustion shock.[4] This work indicated that the calculated order of merit of the best seven of these ignition-quality-rating methods was as follows:

1 Boiling point-gravity constant
2 Cetane number, CCR
3 Diesel index number
4 Cetane number (Moore)
5 Viscosity-gravity constant
6 Aniline point
7 Cetane number, KM delay

Since aniline point is included in the now proved, more accurate Diesel index number, and cetane number (Moore) has been

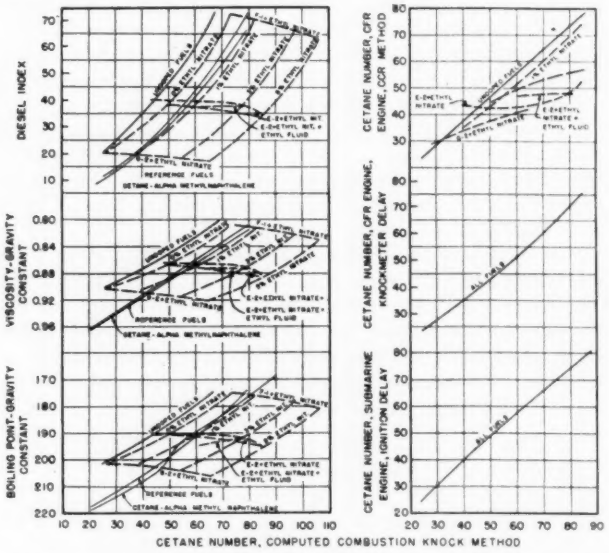

FIG. 3 CORRELATION OF C.F.R. ENGINE AND PHYSICAL-CHEMICAL FUEL-IGNITION INDEXES OF 83 DOPED AND UNDOPED DIESEL FUELS WITH COMPUTED COMBUSTION-KNOCK CETANE NUMBERS DETERMINED IN A 2-CYCLE DIESEL ENGINE

superseded by engine tests using cetane, they were dropped from further consideration.

Further tests using doped fuels, Fig. 3, showed that the physical-chemical indexes, i.e., Diesel index number, viscosity-gravity constant, and boiling point-gravity constant, plus the cetane number by the CCR method, were unreliable in predicting the performance of doped fuels. Thus Diesel-fuel ignition-quality determinations must be made in a running Diesel engine, preferably expressed as that percentage of cetane in a blend of cetane and alpha-methylnaphthalene which performs similarly to the fuel under test as regards ignition, i.e., equal ignition delays, equal critical compression ratios (just producing ignition), or other ignition criteria.

The effect of fuel ignition quality on several engine-performance characteristics for four different engines is shown in Figs. 4, 5, 6, and 7. In every case, the maximum cylinder pressures

[4] Computed combustion shock

$$= \frac{\text{explosion pressure rise} \times \text{burning rate}}{10^4}$$

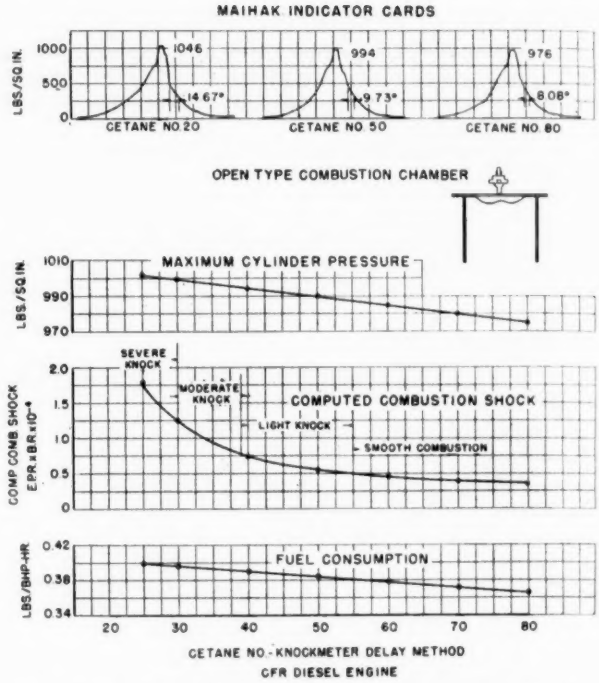

FIG. 4 FUEL PERFORMANCE IN A 2-CYCLE DIESEL ENGINE (Bore and stroke, 8 in. by 10 in.; speed 750 rpm; 75-bhp one-cylinder engine. Data presented are for 83 fuels, including 24 doped fuels, tested at 75 bhp and 750 rpm.)

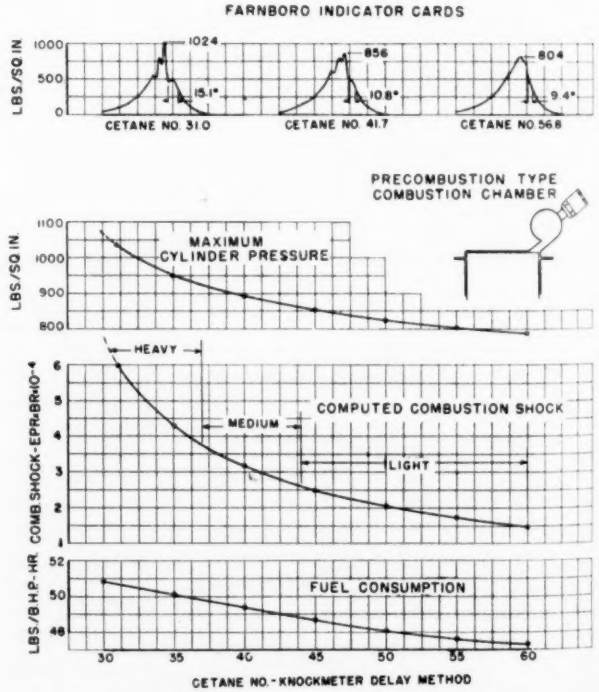

FIG. 5 FUEL PERFORMANCE IN A 4-CYCLE DIESEL ENGINE (Single-cylinder, 4¼-in. by 6-in., 1200-rpm, 10-bhp engine. 25 Diesel fuels tested at 1200 rpm and 8 bhp.)

and computed combustion shocks decreased with an increase in fuel-ignition quality. Also, the specific fuel consumption in the open-type combustion-chamber engine, Fig. 4; the precombustion-type chamber engine, Fig. 5; and the air-cell-type chamber engine, Fig. 7, decreased with higher ignition-quality fuels. This

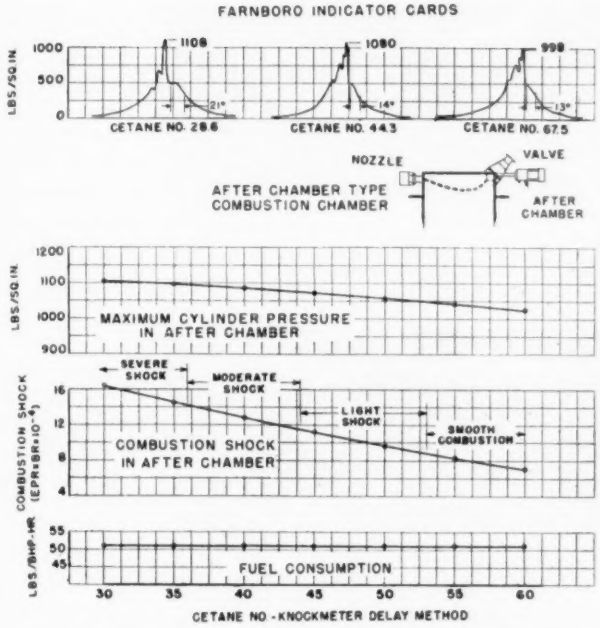

FIG. 6 FUEL PERFORMANCE IN A 4-CYCLE DIESEL ENGINE

(Four-cylinder, 3½-in. by 4½-in., 1400-rpm, 25-bhp engine. Ten fuels tested at 1200 rpm and 15.74 bhp.)

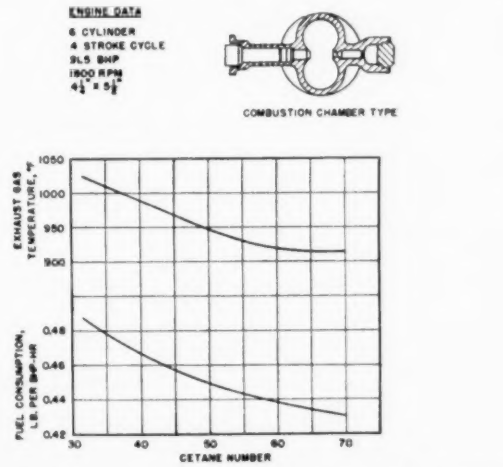

FIG. 7 EFFECT OF CETANE NUMBER ON EXHAUST-GAS TEMPERATURE AND FUEL CONSUMPTION

was not true, however, of an engine using another type of air-cell combustion chamber Fig. 6, as there was no noticeable change in fuel consumption between the limits of 30 and 60 cetane number.

Cold Starting. Fig. 8 shows the results of cold-starting tests on a high-speed marine-Diesel engine. The graph is separated into four regions indicating the relative difficulty of starting the engine. A marked increase in the ease of starting was found as the ignition quality was increased from 20 to about 50 cetane number. Any given cold-starting temperature also required a given minimum cetane number before a start could be obtained. This minimum cetane number decreased as the air temperature was increased.

A wide region of temperatures and cetane numbers was found which produced ignition, but insufficient power due to very late, slow, and irregular combustion to enable the engine to continue running when the starting motor was disengaged. The extreme lower left-hand corner of the graph shows a region where no ignition occurred in any cylinder at any time.

Cetane Number Versus Smoke. Some investigations of Diesel-engine-exhaust smoke (6) show that smoke density is inversely proportional to cetane number, but that other factors have a greater influence on smoke than does ignition quality. This is particularly true of engine design. Fig. 9 shows the effect of fuel ignition quality and engine speed and load on the smoke density of a marine-Diesel engine when using three fuels of 35, 44.4, and 55.4 cetane number which had similar 50 per cent distillation temperatures, i.e., 518, 526, and 525 F, respectively. At full load and speed, 25 bhp and 1400 rpm, the 55.4 cetane-number fuel produced the greatest smoke; the 44.4 cetane-number fuel the next greatest, and the low cetane-number fuel the least smoke. The fuel consumption and exhaust-gas temperature were also minimum at from 30 to 35 cetane number. As the viscosity,

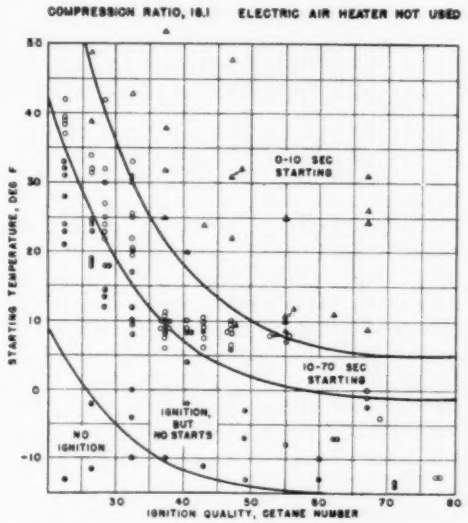

FIG. 8 EFFECT OF FUEL-IGNITION QUALITY ON COLD STARTING OF POWERBOAT DIESEL ENGINE

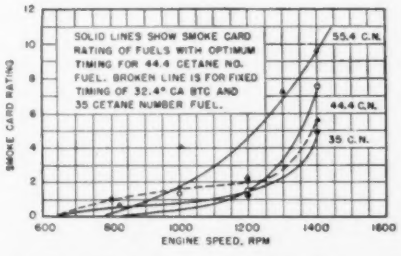

FIG. 9 SMOKE-CARD RATING VERSUS FUEL CETANE NUMBER AND ENGINE SPEED

(Four-cycle powerboat Diesel engine.)

carbon residue, sulphur content, and other properties, except for cetane number, were about the same, the difference in smoke density was largely due to ignition quality.

MAINTENANCE AND WEAR

A severe criticism of Diesel engines has been the high weight-to-horsepower ratio required by the high maximum pressure and shock loading imposed on the working parts. These factors also tend to increase maintenance and replacement of parts. It is recognized that proper fuels can alleviate these conditions considerably.

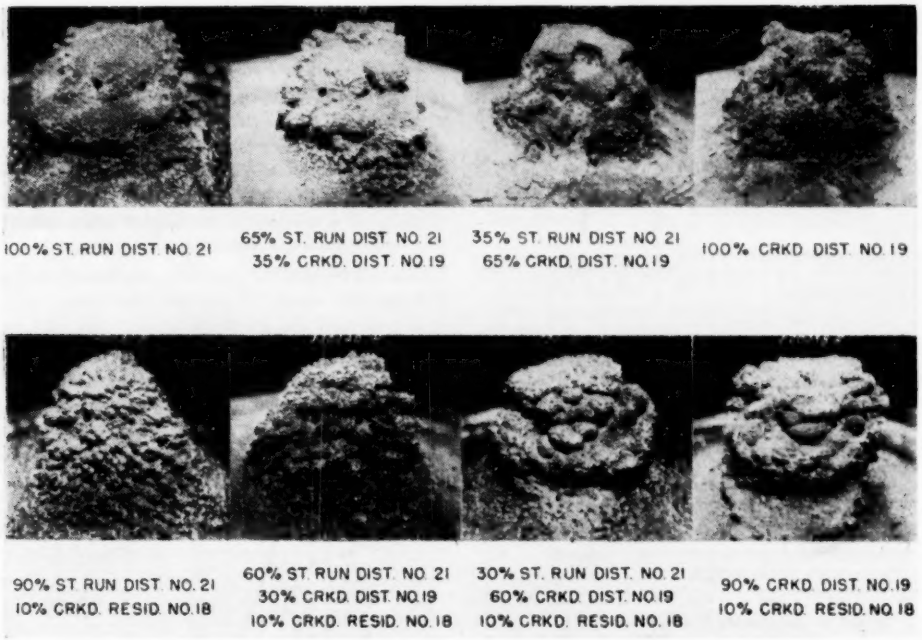

FIG. 10 FUEL-NOZZLE CARBONIZATION WITH VARIOUS FUELS AND FUEL BLENDS

Computed Combustion Shock. An index of the effectiveness of the fuel in reducing the maximum pressures and shock-loading has been developed by one of the authors (7), which includes the sudden pressure rise following ignition and the rate of burning during this combustion. This index also correlates well with cetane number, as indicated by Figs. 4, 5, 6, and 7. These show that, in four different engines, an increase in cetane number results in a corresponding decrease in computed combustion

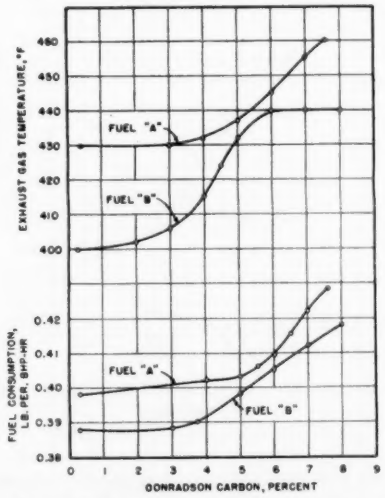

FIG. 11 EFFECT OF CARBON RESIDUE (CONRADSON) ON FUEL CONSUMPTION AND EXHAUST-GAS TEMPERATURE
(14-in. by 17-in. airless-injection, 2-cycle, single-cylinder Diesel engine.)

shock and thus a decrease in maintenance, replacement of parts, and a permissible reduction in specific weight.

Nozzle-Tip Carbonization. Fig. 10 shows the wide difference between fuels in forming objectionable carbon on fuel-nozzle tips. Such crater-like formations tend to distort the fuel spray, which in turn produces poor combustion, high fuel consumption, excessive cylinder-head and piston temperatures, reduced power

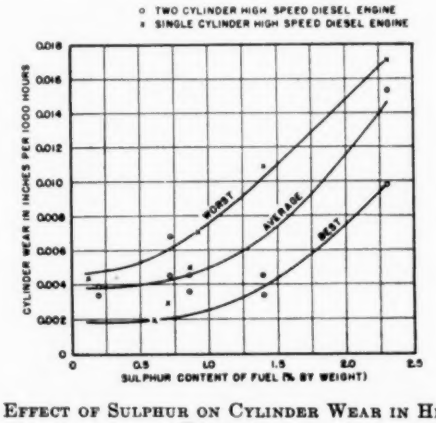

FIG. 12 EFFECT OF SULPHUR ON CYLINDER WEAR IN HIGH-SPEED ENGINES
(Results drawn from 85-hr tests.)

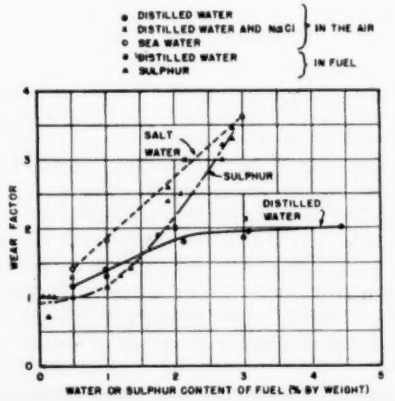

FIG. 13 INFLUENCE OF WATER AND SULPHUR ON RATE OF WEAR
(One-cylinder low-speed air-injection engine. Wear factor = ratio of wear under conditions investigated to standard conditions when using reference fuel having 0.7 per cent sulphur.)

output, and excessive smoke. These factors all influence engine maintenance adversely.

Carbon Residue. The effects of fuels having high carbon residues (Conradson carbon) are shown in Fig. 11. In a large engine of the type tested, a percentage of carbon residue above about 3 per cent resulted in a decided increase in fuel consumption and exhaust-gas temperature. The true effects of carbon residue are not ascertainable in short-time tests, since carbon residue is closely connected with and involves other fuel properties such as high distillation temperatures, cracked and lacquering hydrocarbon products, and impurities, which cause gradual changes in engine performance and increased maintenance costs and wear.

Sulphur. Figs. 12 and 13 have been selected from the literature (8) and are believed to present some of the best results on the effect of sulphur and water on cylinder wear. It may be noted that sulphur above approximately 0.7 per cent causes a marked increase in the wear rate. These investigators also state that such wear is of a corrosive nature due to the presence of sulphur trioxide in the products of combustion rather than sulphur dioxide as has been commonly believed.

Water and Sediment. The wear of cylinders, pistons, and rings is affected by sand, grit, and dust, either from the fuel, lubricating oil, or the air. An unusual incident of dust affecting marine-engine wear is that of a Mississippi work boat, powered by Diesel engines which experienced excessive cylinder wear; requiring replacements of liners, pistons, and rings at an abnormal rate. After long investigations of fuel, lubricating oil, and other common causes of wear, it was ascertained that the boat was required to pass between long stretches of sandy bluffs overlooking the river. The prevailing winds kept the air full of fine silica which caused the damage. The trouble was then easily corrected by the installation of efficient intake-air filters.

Salt water, whether taken into the engine with the fuel or with the air, accelerates wear considerably as shown by Fig. 13. This action is almost wholly corrosive. Small amounts of chemically neutral water do not appear to affect cylinder wear.

Wear Versus Combustion. The manner in which combustion takes place also affects the wear of Diesel engines. Poor combustion can many times be directly traced to unsuitable fuels, i.e.:

1 Viscosity may affect the deposition of fuel on combustion-chamber walls, since it controls fuel-spray penetration, atomization, and distribution.

2 Volatility controls the rate of vaporization, the richness or leanness of the mixture, and distribution of the fuel spray, and thus the progress and completeness of combustion.

3 Ignition quality controls the timing and location of ignition and, therefore, the condition of the fuel-and-air mixture during the initial stages of combustion. This in turn has a marked effect on all subsequent burning, during which the ignition quality further markedly influences the completeness and efficiency of combustion.

4 High distillation-temperature fractions, cracked products, excessive carbon residues, and some impurities all influence the rate and completeness of combustion.

These major factors determine, from fuel standpoints:

1 The dilution of lubricating-oil films on the cylinder walls and their wear.

2 The deposition of fuel carbon and lacquers on valves, pistons, rings, and cylinder walls, and their sticking and abnormal operation, causing combustion-gas blowby, destruction of lubricating-oil films, increased friction, overloading, overheating, and increased or excessive engine maintenance and wear.

3 The types and amounts of corrosive combustion products formed, causing direct, slight, but cumulative corrosion, during each combustion cycle, on dry cylinder-wall areas and thus their corrosive wear.

Engine Troubles and Casualties Caused by Fuels

As soon as arrangements had been completed for presentation of this paper, letters were written to twenty-six selected companies requesting copies of current Diesel-fuel specifications for marine-Diesel engines and records of engine troubles and casualties caused by unsuitable fuels. While some companies claimed to have had no trouble from fuels, others cooperated by submitting comments and records. Too few records were received to permit of classification by fuel properties. However, Table 4 gives a summary of the essential data derived from this survey:

TABLE 4 SUMMARY OF REPORTS ON ENGINE TROUBLES AND CASUALTIES CAUSED BY FUELS

Engine troubles and casualties		Fuel-property causes
1 Excessive carbonization:		
a Exhaust valves and piston rings	(PC)[a]	High carbon residue; hard asphalt; cracked, lacquering compounds; impurities
b Fuel nozzles	(KC)[b]	High carbon residue; hard asphalt; cracked, lacquering compounds; impurities
2 Lacquer formation:		
a Excessive lacquering of engine in few hours prevented operation	(KC)	Fuel was known cause; probably highly cracked fuel or a blend containing residual products
b Stuck fuel pump plungers, prevented engine operation	(KC)	Fuel was known cause; probably contained lacquering gums
3 Corrosion, pitting:		
a Fuel - pump plungers, valves, and fuel nozzles were badly corroded and pitted	(KC)	Fuel contained saline salts
4 Poor combustion:		
a Lubricating trouble; wear	(KC)	Excessive viscosity; probably also high carbon residue; high distillation end point; impurities
b Bearing failures	(KC)	High distillation end point; low cetane number; high sulphur
5 High maintenance:		
a Fuel-injector valve sticking; cracked cylinder heads	(KC)	Incompletely refined, corrosive fuel; plus small amounts of water and silica
b Generally increased maintenance	(PC)	High carbon residue; hard asphalt; cracked, lacquering compounds; impurities
c Generally increased maintenance	(PC)	High carbon residue; hard asphalt; cracked, lacquering compounds; impurities

[a] (PC) = probable cause.
[b] (KC) = known cause.

Since more is often learned from troubles and casualties, if analyzed, than from "clear sailing," it is hoped that a thorough, cooperative survey and classification of troubles and casualties caused in engines of various types by Diesel fuels may be made and correlated with the unsuitable fuel properties, in a future paper.

DIESEL-FUEL PROPERTIES AND SPECIFICATIONS

Major Classifications

There is considerable evidence to support the belief that Diesel fuels can be separated into four major classes, as follows:

1 Fuels requiring heating and centrifuging or other cleaning before use.

2 Fuels for large, slow-speed engines; about 14 in. cylinder diam or over and speeds below about 300 rpm.

3 Fuels for medium-size, medium-speed engines; about 6 to 14 in. cylinder diam and 300 to 1200 rpm.

4 Fuels for small, high-speed engines; below about 6 in. cylinder diam and speeds from about 1200 to around 2600 rpm.

Low cost is the principal reason for that class of fuels requiring heating and cleaning. Such fuels are not usually suitable for Diesel engines without thorough settling, centrifuging, or filter-

ing and heating by the user. There are sound technical as well as economic reasons for the existence of the slow-, medium-, and high-speed-fuel classes:

1 Differences in the time available between various engines for all injection, ignition, and combustion processes.

2 Differences in cylinder sizes and types of combustion chambers.

3 Differences in the tolerations of kinds and amounts of deposits formed on pistons and cylinders and in maintenance and wear.

Time Available. A basic difference between all types and sizes of Diesel engines is speed or rpm. In large, slow-speed engines, each crank-angle degree is equal to a longer period of time than in a higher-speed engine and thus produces many effects on engine performance, viz.:

1 Ignition delay, instead of comprising a period of from 15 to 20 deg of crank angle as in the high-speed engine will only require from 2 to 5 deg, thus greatly reducing combustion shock and maximum cylinder pressure.

2 Lower rates of injection are possible which again tend to reduce maximum cylinder pressures and effect better combustion control.

3 Combustion will be completed much earlier in the power stroke, which produces higher thermal efficiencies, lower exhaust-gas temperatures, and cleaner exhaust gases. It further decreases exposure of portions of the dry areas of the cylinders to the corrosive gases formed as intermediate products of combustion.

4 More complete burning of the fuel is possible, tending to eliminate many of the partial products of combustion which accelerate cylinder wear such as carbon, gum, and organic acids.

These effects greatly reduce the importance of narrow and restricted limitations on fuel ignition quality, viscosity, volatility, and carbon residue.

Cylinder Size and Combustion-Chamber Type. Increases in cylinder sizes result in higher compression temperatures due to reduced heat losses on the compression stroke, better mixing of fuel and air, and less impingement of fuel on cold walls. The ultimate results are, again, shorter ignition delay, lower injection rates, and shorter and more complete combustion. Thus, fuel properties are affected by reducing the importance of narrow and restrictive specifications.

Differences in Classifications

Number and Range of Properties Specified. Because the importance of fuel properties increases with engine speed, the number and range of property values change accordingly. Thus, high-speed-fuel properties are controlled by 12 to 16 property specifications and low-speed and heater-type fuels by 3 to 7 specifications. The spread allowed in fuel-property values is usually very great for slow-speed as compared with high-speed fuels. The range in viscosity for a slow-speed unheated fuel is from 40 to 150 sec SU, as compared to a high-speed range of 35 to 45 sec SU.

Amount of Impurities. The maximum allowable amount of impurities may be increased in slow-speed fuels as compared to high-speed fuels and this is generally done as shown in Table 5 which gives average values from several typical specifications in each class.

Cost. A major consideration when choosing a Diesel fuel is over-all cost, which includes the cost of the fuel and the effects of the fuel on maintenance, replacements, and efficiencies. There is little doubt that a slow-speed fuel will be the most economical to use except where lower costs, including maintenance factors, have been obtained from the use of the heater-type fuels.

Engine Deposits and Wear. Due to reduced exposure of cylinders to corrosive, intermediate products of combustion, the possibility of more complete burning, the tendency toward elimination of partially burned fuel, and the practical toleration of greater quantities and kinds of deposits and, consequently, wear in large engines, the specifications limiting the maximum amount of impurities become more liberal as the engine size increases and speed decreases.

Availability. It is difficult to make rigid statements with regard to the comparative availability of the four classes of Diesel fuels, as conditions with regard to supply and demand change frequently. In general, the great range in Diesel fuels, from a light kerosene distillate to a heavy cracked residual fuel, greatly increases the availability of Diesel fuels as compared to carburetor-type fuels.

Examples of Diesel-Fuel Specifications

Heater-Type Fuels. Table 6 shows examples of fuels requiring heating and cleaning before use. They are included in the general class of residual or bunker fuels and are characterized by high densities, sometimes heavier than water, high viscosities, 1000 sec SU and above, high carbon residues, high percentages of asphaltic matter, and ash.

Large Slow-Speed-Engine Fuels. Fuel specifications for large slow-speed engines are given in Table 7. These fuels are characterized by large ranges in viscosity, in one case, from 40 to 200 sec SU, large distillation ranges, approximately 375 to 850 F, high percentages of impurities, and ignition qualities down to 30 cetane number. The maximum limits for carbon residue vary considerably from a low value of 0.75 per cent to a high value of 3 per cent. The British fuel shown in Table 7 is of the heater type because of its high viscosity limit and percentages of impurities.

Medium-Speed-Engine Fuels. The ranges in viscosity and distillation temperatures for the medium-speed class, Table 8, are definitely less than for the slow-speed classification, ranging from about 35 to 75 sec SU and 350 to 750 F, respectively. The maximum allowable percentage of impurities is reduced and the ignition quality has been raised to a minimum limit of 35 cetane number and above.

High-Speed-Engine Fuels. High-speed-engine fuels range from a light gas oil up into the kerosenes as shown in Table 9. They are typified by narrow ranges in viscosity and distillation temperatures, viz., about 32 to 45 sec SU and approximately 350 to 650 F, respectively. Ash, sulphur, carbon residue, water, and sediment and corrosion are kept as low as is practical from the refining, handling, and cost standpoints. The pour point may be specified at zero, or below, as this type of fuel is often used in services where efficient cold starting and low-temperature pumping are important. The minimum allowable ignition quality has also been increased to an average of about 45 cetane number.

Conclusions

1 The approximate fuel ignition quality, in general, increases with engine speed, viz.:

Heater-type fuel	No limits
Slow-speed fuel	25–35 Cetane number
Medium-speed fuel	35–45 Cetane number
High-speed fuel	45 Cetane number and above

2 The allowable viscosity and distillation ranges become narrower, with lower values, as the size of the engine decreases and its speed increases, viz.:

Type of fuel	Viscosity range, SSU	Distillation range, temp F
Heater-type	200–6000	No limits
Low-speed	40–200	375–850
Medium-speed	35–75	350–750
High-speed	35–45	350–650

3 Carbon residue above approximately 3 per cent may cause marked increases in fuel consumption and exhaust-gas temperatures in relatively large slow-speed-type engines.

4 Salt water, either in the fuel or the intake air, has progressively increased engine wear.

5 Corrosive compounds inherent in the fuel or resulting from refining processes and subsequent incomplete removal have caused corrosion of storage facilities and injection systems resulting in engine failures.

6 Sulphur above approximately 0.7 per cent has caused relatively rapid increases in engine wear.

7 Ash should be held to a practicable minimum in all fuels, but the maximum allowable amount may increase with cylinder size.

8 Sufficient data are not available to show, quantitatively, the effects of volatility, high boiling-point fractions, and carbon residue on the combustion characteristics of a Diesel engine.

9 Sufficient data are not available to make analyses and draw comprehensive conclusions on the effects of sulphur, water, corrosive impurities, ash, incomplete combustion, gum- and lacquer-forming constituents, and cracked products on engine wear.

10 The use of heater-type fuels, i.e., bunker fuel oils, in Diesel engines can be justified, generally, only on the basis of low overall cost, including possible adverse engine performance and increased maintenance, wear, and casualties which, together with somewhat reduced engine availability, practically eliminate their use for modern, high-specific-power engines in the military services.

11 The large variation in fuel-property specifications existing

within each fuel classification is caused by the large differences in present injection-system and combustion-chamber types and design details, which, in turn, prevent practical, fuel-specification standardization.

Superheat Control and Steam Purity in High-Pressure Boilers

By MARTIN FRISCH,[1] NEW YORK, N. Y.

The author discusses the problem of designing a high-pressure boiler to deliver steam at high temperatures. The problem becomes more difficult as the capacity increases since proper selection and maintenance of boiler materials, design of the separate boiler and furnace units, and maintenance of the latter becomes increasingly more difficult if superheat control and steam purity are to be maintained. The author analyzes these design features and points out the compromises necessary to meet varying operating conditions. He discusses superheater design, maintenance of heat-absorbing surfaces, boiler circulation, relation of furnace-exit temperatures to slagging and boiler performance, and safe metal temperatures in waterwalls and superheaters.

THE problem of designing a high-pressure steam-generating unit to deliver steam at high temperature becomes increasingly difficult as the capacity increases. The most important of the many phases of the problem are:

1 The maintenance of external cleanliness of the heat-absorbing surfaces. (Freedom from slagging.)

2 The maintenance and control of the desired steam temperature over the desired load range.

3 The production of steam of the required purity.

4 The maintenance of safe metal temperatures in the pressure parts of the superheater and boiler.

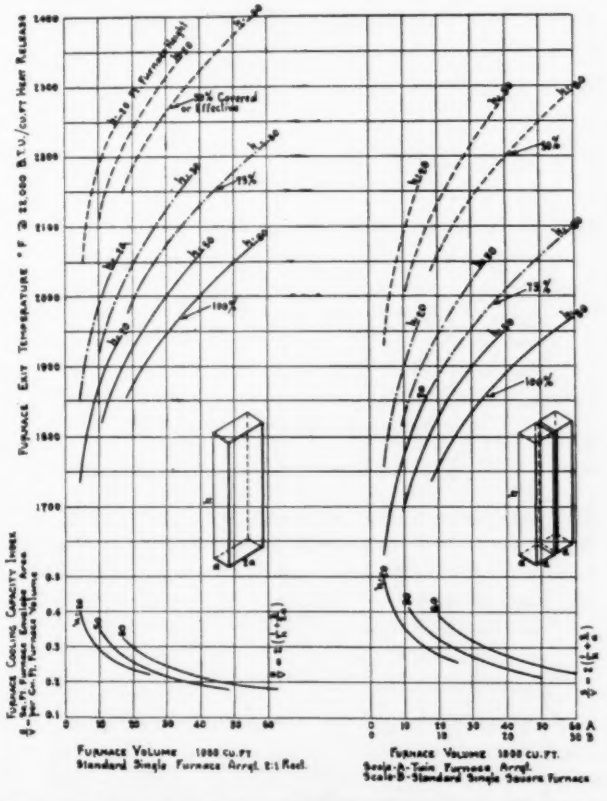
The first two phases of the problem are difficult to reconcile because with the low furnace-exit temperatures conducive to slag-free operation it becomes difficult, if not impossible, to obtain high steam temperatures over a wide load range with a convection superheater of practical size.

Increases in steam-generator capacities are generally provided for by proportional increases in furnace volume. But slag-free operation with a unit of one size, and coal, does not mean that slag-free operation will follow at the same liberation rate with the same coal if the size and capacity are materially increased, because, at the same rate of heat release in the furnace per cubic foot of furnace volume, the larger the furnace, the higher the furnace-exit temperature. Fig. 1 shows that as the furnace volume increases, there is a rapid decrease in the available furnace perimeter per cubic foot of volume which may be covered with radiant-heat-absorbing surfaces. This ratio may be considered as an index of the cooling capacity of the furnace. For example, if the furnace volume is doubled, the cooling-capacity index decreases 25 to 30 per cent. The furnace-exit temperature, as shown by the upper left-hand curves for a furnace of constant height increases rapidly with furnace volume. Furthermore, if 100 per cent of the available surface perimeter is not covered with heat-absorbing surfaces, or if the surface is installed but made ineffective by slag, the furnace-exit temperature rises rapidly. Thus if 25 per cent of the surface is not effective or not cooled, the furnace-exit temperature will be about 200 F higher than would be the case if 100 per cent of the perimeter is cooled.

If a limit is placed on the maximum permissible furnace temperature, the size of furnace which may be designed to comply is definitely limited. The lower the height of the furnace and the smaller the portion of the furnace perimeter that is cooled, the smaller the size of unit that may be honestly considered to comply, unless (*a*) the heat release is reduced as the capacity is increased in about the same ratio as the furnace-cooling index decreases, or (*b*) the amount of radiant-heat-absorbing surface installed per cubic foot of furnace volume is increased in some suitable manner.

Alternative (*a*) means larger and higher furnaces with lower and lower rates of heat release as the capacity is increased and is the simplest solution if the space is available. If space conditions limit the amount of furnace volume which may be provided, it is possible to subdivide the available furnace volume into two or more furnaces using radiant-heat-absorbing partition walls. Each subdivision adds two such walls with a possible increase of 25 to 30 per cent in the cooled wall surface per cubic foot of furnace volume. This corresponds to a reduction of about 100 F or more in the furnace-exit temperature.

The curves at the right of Fig. 1 indicate the marked increase



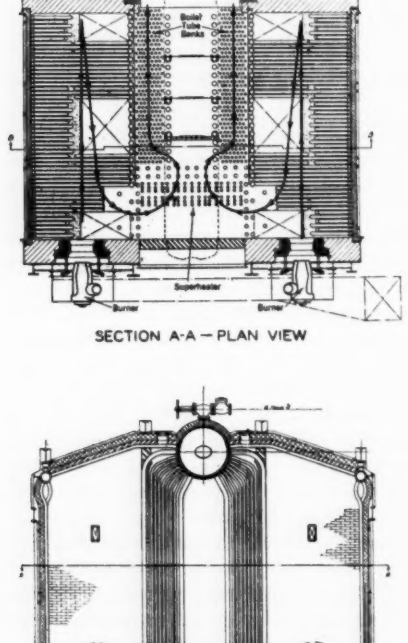


FIG. 1 FURNACE SIZE VERSUS COOLING CAPACITY AND EXIT TEMPERATURE

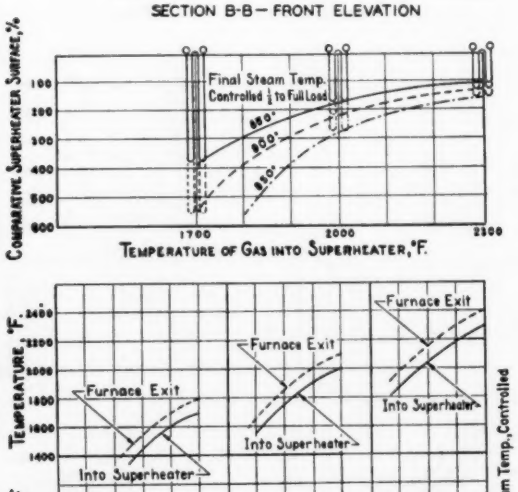

FIG. 2 FURNACE-EXIT TEMPERATURE VERSUS SUPERHEATER SIZE AND CONTROL RANGE

in available furnace-wall area per cubic foot of furnace volume obtainable by subdividing the furnace into two furnaces. There is a correspondingly lower furnace-exit temperature for a given furnace volume for the same heat release per cubic foot. The same low furnace-exit temperature could be attained at the same capacity in a conventional single-furnace unit by reducing the heat release 25 to 30 per cent or for the examples used from 22,000 to between 16,500 and 15,400 Btu per cu ft per hr.

While low furnace-exit temperatures are desirable to prevent slagging of the boiler and superheater, the permissible temperature reduction is limited by the superheater characteristics desired and by the type of superheater used. If a convection type superheater must produce a very high steam temperature at a very low load, its proportions may be impractical, or uneconomical, unless the furnace-exit temperature is so high that slagging of the superheater becomes certain.

For example, the lower curves of Fig. 2 show typical superheater characteristics obtainable with full-load furnace-exit temperatures of 1800, 2100, and 2400 F and corresponding gas inlet temperatures to superheater of 1700, 2000, and 2300 F.

With an 1800-F furnace-exit and a corresponding 1700-F superheater inlet temperature, it is possible to design a superheater for a constant final steam temperature of 850 F at 1350 psi from half load to full load. With a superheater of prohibitive and impractical size it might be possible to obtain the same control range with a final steam temperature of 900 F. However,

it would be impossible to obtain 950 F, except at loads exceeding 70 per cent of full load. If the gas temperature to the superheater is increased to 2000 F, it is possible to obtain 850 F final steam temperature down to about 30 per cent, and 900 F final steam temperature down to 40 per cent of full load. With a gas temperature of 2300 F, it would be possible to obtain 850 F final steam temperature down to 27 per cent, and 900 F final steam temperature down to 40 per cent of full load. The relative cost of superheaters for 850, 900, and 950 F final steam temperature over a load range from one half to full load may be approximated from the upper curves of Fig. 2 which show the comparative surfaces for these various gas temperatures. Assuming as a basis gas at 2300 F and 850 F steam temperature over 50 per cent load range, it may be seen that 60 per cent more surface is required when the superheater inlet gas temperature is 2000 F, and 260 per cent more surface is required when the gas temperature is 1700 F.

To obtain 900 F final steam temperature over a 50 per cent load range, the amount of surface required with a superheater gas-inlet temperature of 1700 F is four times that necessary with 2300 F and 2.6 times the surface adequate at 2000 F.

Obviously, the designer limited to the use of a convection superheater is forced to compromise between low furnace-exit temperature—slag-free operation—and sufficiently high gas temperature for a practical superheater to give the desired steam temperature over the required load range.

Many purchasers who have been, or are, troubled by slagging difficulties arbitrarily specify that new units for them should be designed so that the furnace-exit temperature will be below the lowest expected ash-fusion temperature. In some cases it is even more drastically demanded that the furnace temperature should be less than the initial deformation or agglomeration temperature. For eastern coals this temperature may be as low as 1800 to 1900 F.

Such severe specifications cannot be honestly complied with by conventional units with convection superheaters, especially in large units for high pressures and temperatures if fired with low-grade coals of high ash content and low ash-fusion temperature. If sufficient furnace and radiant-heat-absorbing surfaces can be provided to cool the gases to the desired low value before leaving the furnace, it may be found impossible to obtain the desired final steam temperature over the required load range with any practical convection-superheater arrangement. This difficulty may only be side-stepped by accepting a furnace-exit temperature which may be several hundred degrees higher than originally prescribed, or by using radiant-superheating surface in place of waterwall surface for furnace cooling.

Slagging of superheaters and boiler tubes ahead of them is responsible for a great deal of capacity reduction, outage, and cleaning expense. Periodic or continuous hand lancing is often required to keep such units in service because soot blowers and deslaggers fail to check fouling. Furthermore hand lancing is laborious, disagreeable work, and there may come a time when men willing to do such work will be scarce. It is possible to design steam-generating units in which slag formation may be kept under control and the desired steam-temperature characteristics obtained.

The use of multiple furnaces offers a happy solution of the problem of getting high steam temperatures over a wide load range with low furnace-exit temperatures and comparative freedom from slagging. One of the chief limitations to the use of all superheaters, namely, the difficulty of keeping metal temperatures within safe limits during the starting period, can be eliminated with a multiple furnace arrangement by confining the radiant superheater to one furnace which is fired up only after the boiler starts to generate steam. In such a case, the radiant superheater is never exposed to fire unless steam is flowing through it.

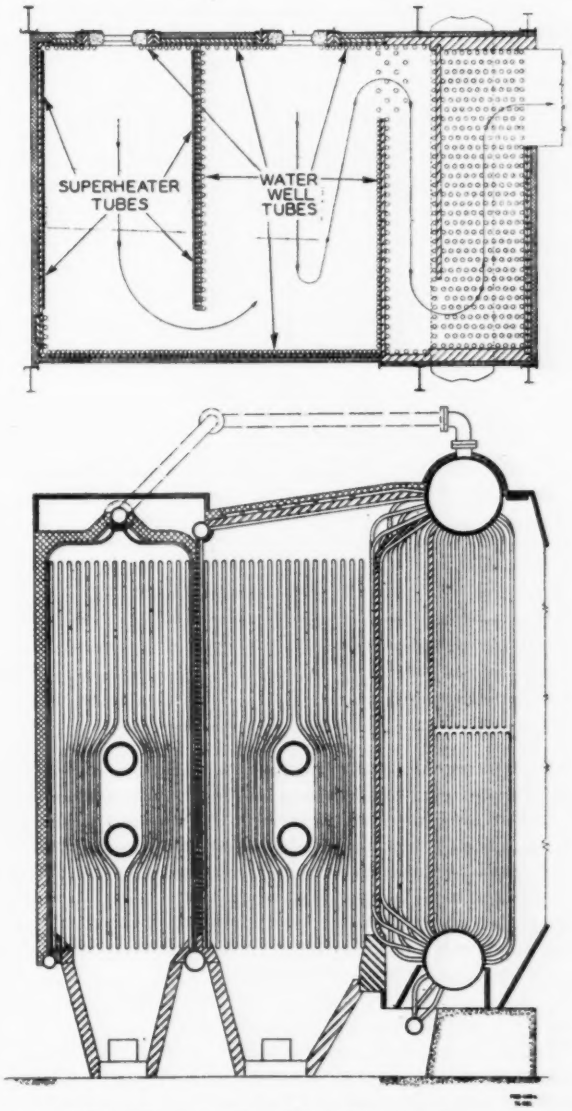

FIG. 4 A TWIN-FURNACE UNIT WITH RADIANT SUPERHEATER IN ONE FURNACE, HAVING A CAPACITY OF 120,000 LB OF STEAM PER HR, INSTALLED AT MOOSE JAW, SASK., CANADA

A number of successful twin-furnace boilers have recently been put into successful operation with and without radiant superheaters. Fig. 3 shows a twin-furnace unit, with only a convection superheater, which has a capacity of 100,000 lb per hr at 725 psi and 750 F final steam temperature. It was installed at Oil City, Pa., in 1935 and was followed by a duplicate order in 1939. Fig. 4 shows a twin-furnace unit at Moose Jaw, Saskatchewan; one furnace is cooled by a radiant superheater while the other is cooled with waterwall tubes only. This unit has a capacity of 120,000 lb of steam per hr at 650 psi and 850 F final steam temperature. It includes no convection superheater. Fig. 5 shows a twin-furnace unit at the Windsor Plant with a radiant superheater in one furnace, in series with a booster convection superheater receiving gases from both furnaces; the capacity is 750,000 lb of steam per hr at 1350 psi and 925 F final steam temperature. The units shown in Figs. 3, 4, and 5 all burn pulverized coal having an ash-fusion temperature often as low as 1900 F.

While the use of multiple furnaces with or without radiant

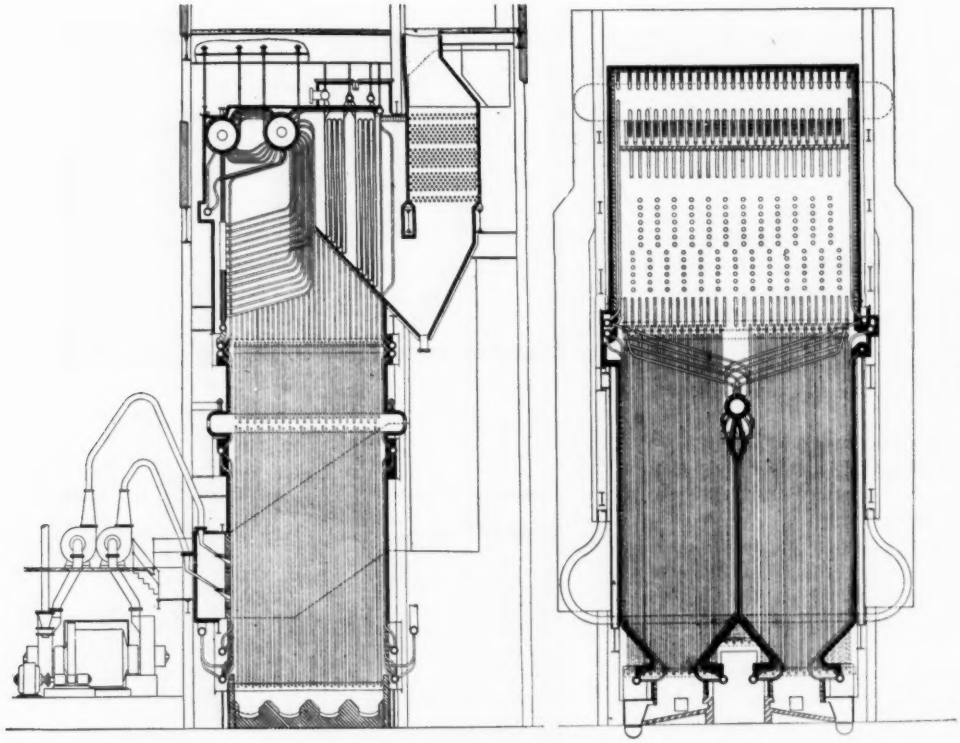

FIG. 5 A TWIN-FURNACE UNIT WITH RADIANT SUPERHEATER IN ONE FURNACE IN SERIES WITH CONVECTION SUPERHEATER RECEIVING GAS FROM BOTH FURNACES. THIS UNIT HAS A CAPACITY OF 750,000 LB OF STEAM PER HR AND IS LOCATED AT POWER, W. VA.

superheaters permits the reconciliation of the conflicting objectives of high steam temperatures and low furnace-exit temperatures, there are sometimes obstacles in the way of applying such designs. Then conventional, single-furnace units, as shown in Fig. 6, must be designed to satisfy the operating conditions as well as possible. This unit, located at New Castle, Pa., is one of seven of the type in operation in various parts of the country with a variety of coals. It generates 400,000 lb of steam per hr at 900 psi and 900 F final steam temperature.

Table 1 shows comparatively the furnace characteristics of the units illustrated in Figs. 3, 4, 5, and 6.

Whether or not it is possible to reduce the furnace-exit temperature as much as desired, the slagging tendency may be minimized by fine pulverization. Fine particles burn faster than coarse particles and may be expected to contain less unburned fuel residues when they pass out of the flame into the clear gas space between the flame and the furnace exit. Such particles can then give up heat by radiation to cold surrounding wall surfaces. If the particle path with respect to the furnace cooling surfaces and the flame is correct, the rate of heat dissipation by radiation from the particle will exceed the rate of heat reception by the particle by radiation from the flame and by convection from the

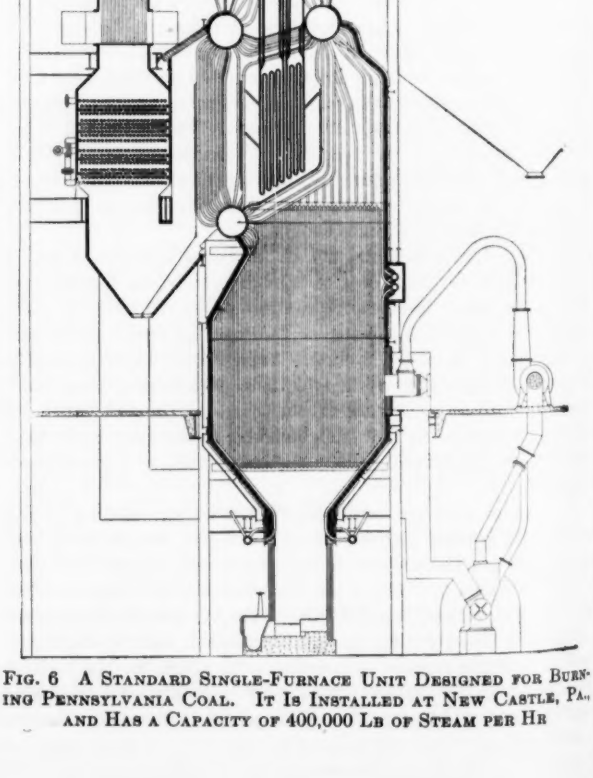

FIG. 6 A STANDARD SINGLE-FURNACE UNIT DESIGNED FOR BURNING PENNSYLVANIA COAL. IT IS INSTALLED AT NEW CASTLE, PA., AND HAS A CAPACITY OF 400,000 LB OF STEAM PER HR

surrounding gases. The smaller the particle, the more certain it is to be frozen throughout by the time it passes into the boiler and superheater.

The additional cost of grinding fine will be partially offset by fuel savings due to reduced carbon loss and more than offset by the reduced cost of boiler cleaning and savings due to fewer outages and resultant loss of production. For example, experience indicates that in the average installation burning Pittsburgh coal one may expect the relationship between fineness, fuel loss due to incomplete combustion, and power consumption and maintenance for a ball-mill job, to be approximately as given in Table 2.

TABLE 2 RELATION BETWEEN FINENESS OF PULVERIZED COAL, FURNACE PERFORMANCE AND MAINTENANCE

Coal fineness, per cent through 200 mesh...	65	70	80	90
Fuel loss due to incomplete combustion, per cent of fuel fired.....	2.0	1.8	1.4	1.0
Fuel loss, lb per ton burned.....	40	36	28	20
Power consumption, kwhr per ton.....	13	15	21	30
Coal equivalent of power at 1.5 lb per kwhr	19.5	22.5	31.5	45
Maintenance cost, cents per ton.....	0.9	1.0	1.4	2.0
Coal equivalent of maintenance cost for coal at $5 per ton.....	3.6	4.0	5.6	8.0
Net coal equivalent of carbon loss + power consumption + maintenance.....	63.1	62.5	65.1	73.0
Per cent of coal fired.....	3.16	3.12	3.26	3.65

Under these conditions the minimum coal consumption occurs at a fineness between 70 and 75 per cent through 200 mesh. If the power consumption or its coal equivalent is lower, or the carbon loss higher, the economical fineness is higher. Actually one may safely conclude that considerable increases in fineness may be made without materially increasing the over-all fuel cost. If the savings due to reduced slagging, reduced boiler-cleaning expense, outage, and loss of production are considered, increased fineness will actually be found to result in lower over-all costs of steam production. The value of fineness should really be evaluated in terms of its effect on slagging, unit reliability, and availability. Fig. 9 shows the effect of fineness on the over-all cost of making steam, in terms of the fuel used for three sizes of plant, if cleaning crews, as indicated, receiving $40 per week per man are used.

While steam-generator reliability and availability depend to a large extent on adequate provisions for slag control, the acceptance of a unit depends also on its ability to deliver steam of extremely high purity.

Steam which is to all intents chemically pure is now required by nearly every steam-generator specification in order to minimize turbine-capacity loss due to blade deposits or hazards due to turbine control-valve fouling. The problem of producing steam of such purity is tied up with boiler circulation, water-level control, and feedwater conditioning. The problem of feedwater conditioning will not be discussed in this paper. Nor can the design problems involved in providing a safe circulating system be completely discussed in the space available. However, it is well to review general principles governing natural circulation. These are as follows:

(*a*) Circulation is easier to maintain in vertical or nearly vertical tubes than in horizontal or slightly inclined tubes.

(*b*) The water flow to be provided per tube in order to maintain it in a furnace at the highest rate of heat input likely to occur is based entirely on experience which indicates that an internally clean tube will not fail if the entering velocity of steam-free water is over 1 fps, and the ratio of water by volume leaving a tube is not less than 5 per cent.

(*c*) The total circulation in a circulating system suitable for high-pressure operation increases as the operating pressure decreases. The system, therefore, may be safely operated at lower pressures up to limiting capacities which vary with the pressure. The superheater pressure drop, rather than circulation, limits the capacity attainable at low pressure for, except at very low pressures, the circulation is good enough to permit operation of the boiler and waterwall at capacities up to or in excess of the maximum capacity at the design pressure.

(*d*) The total circulation decreases slowly with decrease in output, except at extremely low loads, when the decrease becomes more rapid.

(*e*) The total circulation in a given system is a maximum if the water supplied to the circulating system is free of steam. Therefore, it is important to so design the system that the waterwall supply tubes or downtakes entrain as little steam as possible.

Fig. 7 summarizes a circulation analysis of a completely water-cooled steam-generating unit designed to deliver 300,000 lb of steam per hr at 1375 lb per sq in. at the superheater outlet with 1450 lb per sq in. in the drum. Three groups of curves show the characteristics of the waterwall circulation system at the full drum operating pressure of 1450, 850, and 200 lb per sq in. abs, respectively. The dashed curves show the effect of steam entrainment of as much as 25 per cent by volume by the downcomers. This amount of steam entrainment reduces the total circulation materially but not sufficiently, except at a drum pressure of 200 lb per sq in., to limit the safe capacity of the system. A capacity limitation at this low pressure would be advisable because of the reduction in amount of water by volume at the discharge ends of the front wall tubes.

A high-pressure unit would not ordinarily be operated at such low pressure and high capacity because superheater pressure drop would increase rapidly with decrease in superheater outlet pressure. Nor would a good design lack provisions to prevent steam entrainment by the water-supply tubes. Therefore, the real significance of the curves is that the tubes of a properly designed circulating system would be safe under most conceivable operating conditions.

The rate of circulation in the furnace waterwall system has a controlling effect on the behavior of the water levels in the boiler and on the problem of steam purification.

Since the bulk of the steam produced by the steam-generator unit is made by the waterwall system and the first four rows of the boiler, the bulk of the water circulation will be in these elements. Only a small fraction of the total steam produced and a correspondingly small portion of the total circulation will occur in the other boiler tubes. In view of this, if only the steam produced by these relatively inactive tubes is delivered to the rear drum below the water line, the turbulence in this drum from this source will be slight and the density of the water-steam emulsion below the water line relatively high. Therefore, it is usual practice to locate the steam purifier, through which the steam passes on its way to the superheater, in this the most quiet drum *Q* and to limit turbulence in the drum by connecting all waterwall risers or discharge tubes to drum *T* in which the turbulence is naturally greater. This means that the bulk of the circulating water flows into the more turbulent drum *T* first where a preliminary separation of steam and water is induced. The steam flows to the quiet drum *Q* through the steam circulators *SC*. The problem is to return the water to the circulating system. This is accomplished by taking it through the water circulators *WC* into the quiet drum *Q* whence it flows to the lower drum *D* and thence through the downtakes *DT* to the waterwall system.

The head for causing the water to flow through the water circulators is made up of two elements:

a = The head corresponding to the pressure difference between drums *T* and *Q*, and
b = the elevation of the level in *T* above the level in *Q*.

Element *a* increases approximately as some power (about 2) of the load.

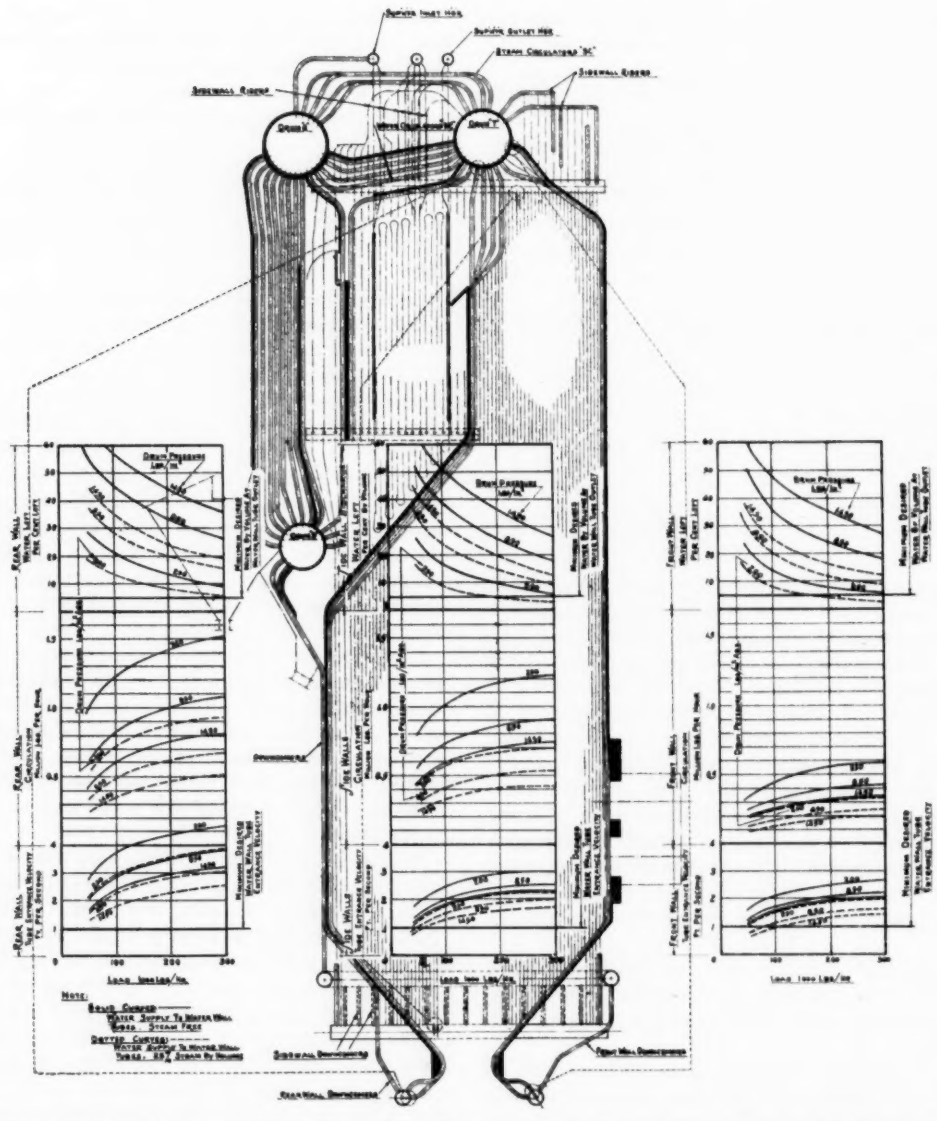

FIG. 7 CIRCULATION ANALYSIS OF A THREE-DRUM HIGH-PRESSURE STEAM GENERATOR AT VARIABLE-PRESSURE OPERATION

Element b depends on the magnitude of a, the density of the water in T and Q, the total amount of water delivered to drum T by the circulatory system and which must be returned to the quiet drum and thence to the circulating system. If the steam circulators were infinite in number and a were zero, b would be independent of a. If the value of b under these conditions is indicated by b_0, then

$$b = b_0 - a$$

The value of b_0 as shown by Fig. 8 changes slowly with load since the total circulation as may be seen by Figs. 7 and 8 does not change very rapidly with load above a certain low load.

Fig. 8 shows approximate relationship between b, b_0, a, and the load.

The elevation of the water in the turbulent drum varies with load as shown by the curve b. Obviously, it is desirable that at no load should the elevation b rise to the level of the lowest steam circulator. This is less important from the point of view of carry-over (if an adequate purifier is installed in the other drum) than from the point of view of having a steady water level. If the level b is allowed to rise above any of the steam circulators, these become water circulators and the number of steam circulators is correspondingly reduced. If one row of steam circulators out of three become water circulators and cease to become steam circulators, the steam velocity in the circulators increases by 50 per cent and a increases approximately 125 per cent. The water-circulator capacity is correspondingly increased and the effect is to instantly depress the level in the turbulent drum. As soon as the level is depressed below the steam circulators the original pressure and head conditions are re-established and the level starts to rise again. This process repeats itself indefinitely and causes the often observed swinging water level. This may be corrected in five ways:

1 Raise the turbulent drum.

2 Lower the controlled level in the quiet drum.

3 Increase the number of water circulators or take some of the water supply for the waterwall system directly from the turbulent drum so that the water circulators will not have to handle it.

4 Decrease the number of steam circulators.

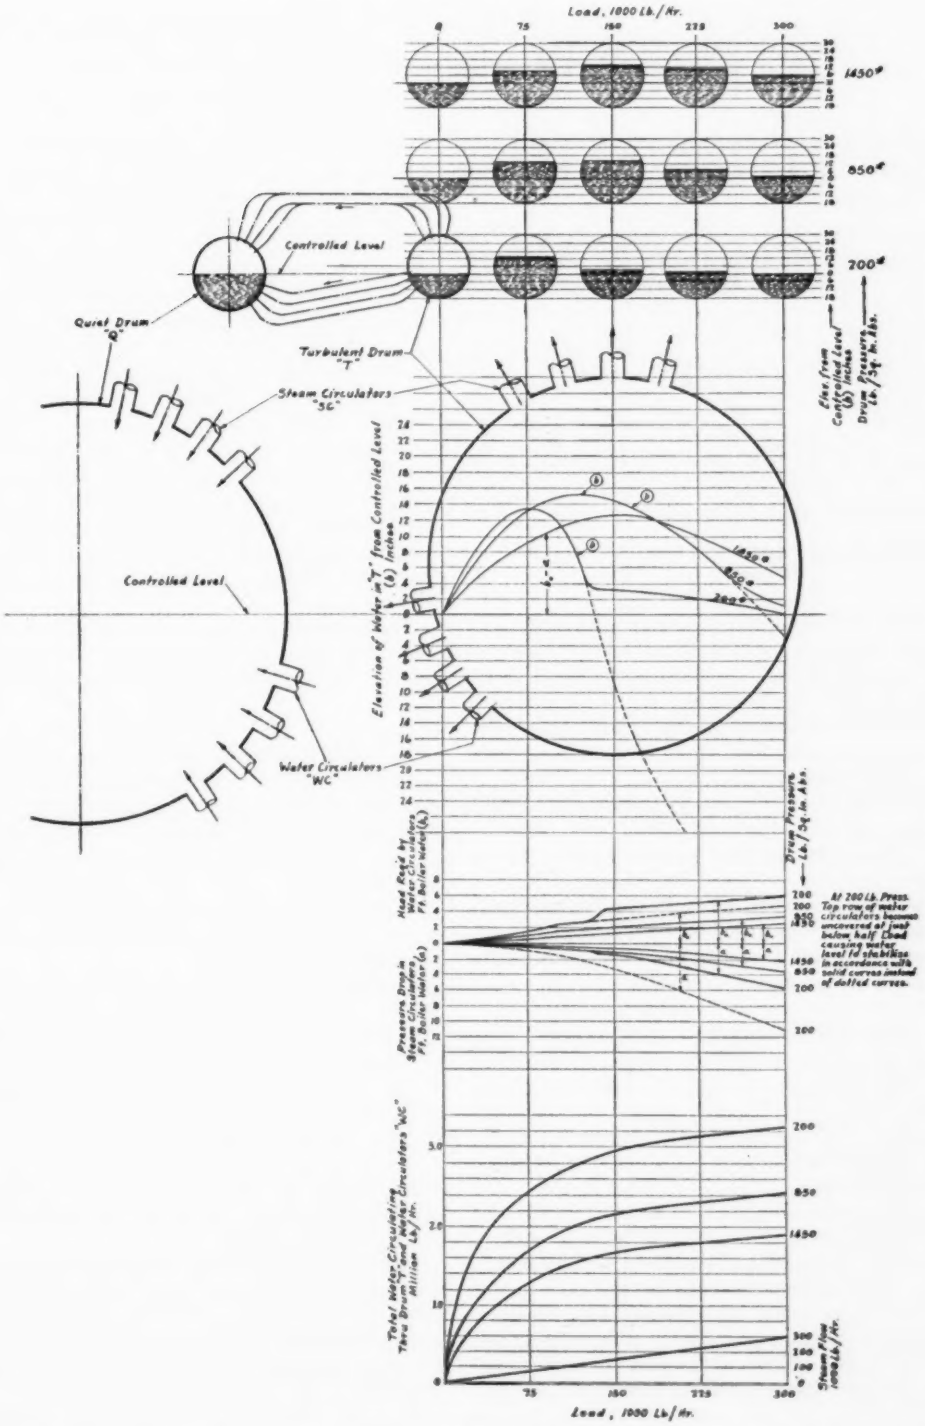

FIG. 8 STUDY OF WATER-LEVEL BEHAVIOR IN A THREE-DRUM HIGH-PRESSURE BOILER AT VARIABLE-PRESSURE OPERATION

5 Arrange the waterwall discharge tubes to have as many as possible discharge above the water line in the turbulent drum, thus making the density of the steam-water mixture below the water line as great as possible.

Of these five correctives, the fourth one does not have as much effect as one might expect. Tests of a number of boilers have borne this out. The reason for this may be seen by referring to Fig. 8 which makes it clear that the effect of increasing the pressure drop between drums by decreasing the number of steam circulators becomes marked only at very high loads. On the other hand the maximum elevation of the level in the turbulent drum above that in the quiet drum occurs near half load when the pressure drop a through the steam circulators is small compared with the head required to cause the circulating water to be transferred from the turbulent drum T to the quiet drum Q through the water circulators WC.

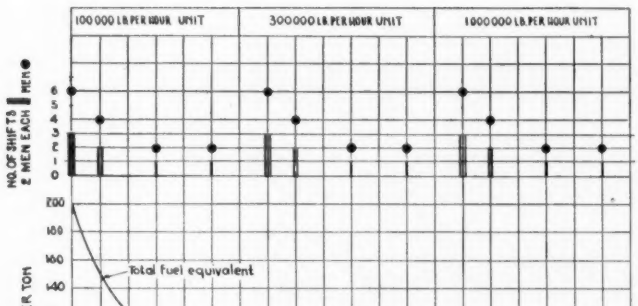

FIG. 9 EFFECT OF FINENESS ON THE OVER-ALL COST OF MAKING STEAM

Most three- and four-drum bent-tube boilers built in the past and still being built are not equipped with an adequate number of water circulators between drums. In this may be found an explanation, at least in part, for the absence of water in the back drum of a four-drum boiler at high loads and for fluctuating water levels and the swamping of the front drum of most three-drum boilers at intermediate loads.

The desirability of elevating the turbulent drum with respect to the quiet drum a reasonable amount and of connecting this drum to the quiet drum with as many water circulators as possible is self-evident.

Steam of uniformly high purity under all conditions is more certainly obtainable if the water levels behave in a predictable manner. Too much emphasis cannot be placed on the necessity of having the waterwall and boiler circulation properly coordinated to this end.

Having taken steps to establish proper water-level behavior, steam of high purity may be obtained by washing or by the use of moisture-eliminating devices which, if the boiler-water concentration is very high, must be nearly 100 per cent effective. With steam washers, since the entrained moisture contains smaller quantities of impurities than the boiler water, the drying of the steam need not be as effective.

Steam washers work on the principle of exchanging for the very impure boiler water, feedwater of much higher purity and then subjecting the mixture of steam and entrained feedwater to a drying operation. One effective exchange method is to bubble the steam through the feedwater at extremely low velocities. The exchange efficiency of this type of washer is between 80 and 90 per cent, and steam with as little as one part per million may be obtained with a boiler-water concentration of 2500 ppm using a feedwater for washing which contains up to 200 ppm of impurities. Certain types of feedwater treatment make the advisability of steam washing questionable because of the tendency of the washer to sludge up too rapidly. Under such conditions the washer should be easily accessible and cleanable so that it may be washed out periodically. It is not advisable to use washers for extremely low pressure because of the difficulty of providing sufficiently low steam velocities through the washer.

When the steam delivered by the boiler is of the purity required by the turbine, safe metal temperatures in the pressure parts of the superheater will be a natural consequence if the superheater design gives sufficiently high steam flow through the tubes. For a 2-in. tube the flow should be in excess of 2000 lb per tube per hr and preferably of the order of 3500 to 4000 lb per hr. This makes it necessary and wise to allow for a reasonably high pressure drop through the superheater. For a 1200 to 1350-lb per sq in. job the pressure drop should certainly not be less than 50 lb per sq in., and if the unit is to be operated at very low loads for considerable periods the pressure drop might better be 75 to 100 lb per sq in. in order to assure good distribution at the lowest load. For example in a unit operating at one-fifth load the superheater would have a pressure drop of only 4 lb per sq in. if the full load pressure is 100 lb per sq in.; at one-tenth load the drop would be 1 lb per sq in.

The metal temperatures in the pressure parts of the boiler and waterwall system will be safely low if the circulation is satisfactory and obeys the criteria previously outlined.

CONCLUSIONS

The chief problem in the design of steam generators of high reliability especially for high-pressure and high-temperature operation in large sizes is the proper reconciliation of the opposed aims, low furnace-exit temperatures with freedom from slagging and high steam temperatures over a wide range with a practical superheater.

High fineness of pulverized coal helps to minimize the slagging problem as does the use of multiple furnaces with radiant or combination superheaters.

Freedom from circulation troubles can be attained by proper design of the circulating system. This involves the use of an adequate number of waterwall supply and discharge tubes so distributed that all parts of the system receive their proper share of the circulating water as free of steam as possible and utilize a proper share of the available pumping head. Internal cleanliness of the tubes must not be overlooked.

Steam of high purity may be obtained more easily if the circulating system is so designed as to assure proper behavior of the water in the boiler drums so that the maximum amount of steam space is always available.

Superheater-metal temperatures will be safe if the steam is pure and the steam flow rate through the superheater elements is sufficiently high. Waterwall-metal temperatures will be safe if internal cleanliness of the tubes is maintained by adequate water treatment and periodic cleaning and if the circulatory system is of proper design.

Properties of Hydrogen Mixtures

By A. W. BRUNOT,[1] LYNN, MASS.

With the increased use of hydrogen as a cooling medium in rotating electrical machines, it has become important to know the properties of hydrogen diluted by small amounts of another gas. Using these properties it is possible to predict the operation of the machine in a hydrogen mixture from the results of tests made in air or pure hydrogen. It is the purpose of this paper to present a summation of data on the properties of hydrogen, air, nitrogen, and carbon dioxide, as well as empirical formulas for the properties of the mixture of hydrogen with any of the other three gases, and to show how accurately the performance of a heat exchanger in hydrogen or hydrogen mixtures may be predicted from tests in air.

Nomenclature

The following nomenclature is used in the paper:

p = pressure, lb per sq in. abs
t = temperature, F
ρ = density, lb per cu ft
c = specific heat at constant pressure, Btu per lb per deg F
μ = viscosity, lb per ft per hr
k = thermal conductivity, Btu per ft per deg F per hr
$(1-y)$ = fraction by volume of hydrogen in a binary mixture
y = fraction by volume of second gas in the binary mixture
h = local gas-side heat-transfer coefficient, Btu per sq ft per deg F per hr
G = weight velocity, lb per sq ft per hr
ΔP = pressure drop, in. water

General Conditions

In this study of the properties of hydrogen diluted by small amounts of another gas, since the pressures encountered in hydrogen-cooled machines are generally less than 2 atm, the effect of pressure on specific heat, viscosity, and conductivity has been neglected. The relations given are for atmospheric pressure but variation in pressure causes little change in properties except density for which a pressure term is included.

In hydrogen-cooled machines the per cent by volume of the second gas is small; therefore, the range of mixtures over which information is desired is 0 to 15 per cent by volume of the second gas. Fig. 1 shows the variation of the properties of mixtures of hydrogen and nitrogen at 70 F as a function of the composition. From the curves it is evident that most of the variation takes place as the first 15 per cent of the second gas is added. The rapidity of the variation, as the heavier gas is added to the hydrogen, may be due to the wide difference in molecular weights but, whatever the cause, the result is that the presence of small amounts of a heavy gas in hydrogen causes a marked change in properties and, hence, a change in the operating characteristics of the fans or heat-transfer equipment.

Due to the scarcity of data on the subject of tertiary mixtures, there has been no attempt made to cover such mixtures in this paper. Instead the paper will deal only with binary mixtures of hydrogen with air, nitrogen, or carbon dioxide.

Density. The density of the individual gases may be calculated directly from the perfect-gas laws. The densities thus computed check very closely the values reported in the International Critical Tables and are the basis for the formulas to be presented.

The density of a mixture of two gases may be calculated directly from Dalton's law. The author has found it more convenient to use, instead of the actual density of the mixture, a density factor, which is merely the ratio of the density of the mixture to the density of pure hydrogen under the same conditions of temperature and pressure.

The density of pure hydrogen is given by the relation

$$\rho_H = 0.188 \frac{p}{t + 460}$$

The density factors are as follows:

Hydrogen-air.....$\rho_m/\rho_H = 1 + 13.36y$
Hydrogen-nitrogen.....$\rho_m/\rho_H = 1 + 12.90y$
Hydrogen-carbon dioxide...$\rho_m/\rho_H = 1 + 20.83y$

Specific Heat. The data on the specific heat of gases at constant pressure are quite plentiful and the results of various investigators check quite closely. The most recent and reliable data have been published by G. B. Taylor (1)[2] and W. M. D. Bryant (2). Their formulas hold throughout a range of 0 to 3500 F with a maximum deviation of 1 per cent for hydrogen and 3 per cent for nitrogen and carbon dioxide. The data for hydrogen, nitrogen, and carbon dioxide were taken directly from these sources, while the data for air were calculated from Bryant's data on nitrogen and oxygen, assuming the air to be 20.9 per cent oxygen and 79.1 per cent nitrogen by volume.

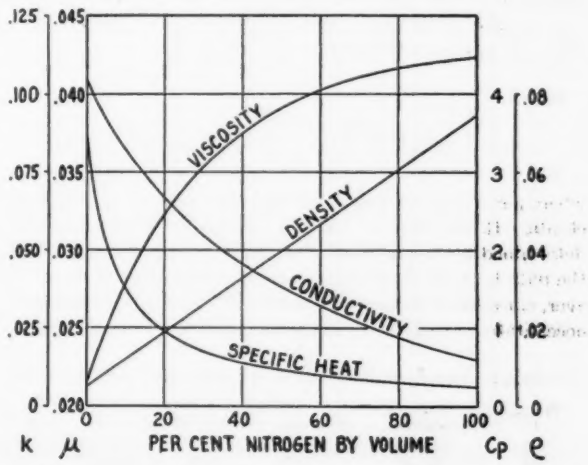

Fig. 1 Properties of Hydrogen-Nitrogen Mixtures at 70 F

The specific heat of a gas mixture appears to obey the well-known law of mixtures, that is

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

$$c_m = w_A c_A + w_B c_B$$

where w_A and w_B are the fractions by weight of the two gases present and c_A and c_B their specific heats. The specific heats of the pure gases and the mixtures are given by the following relations:

Hydrogen..... $c_H = 3.430 + 5.75 \times 10^{-5}t + 4.27 \times 10^{-8}t^2$

Air..... $c_{air} = 0.2341 + 3.44 \times 10^{-5}t - 0.463 \times 10^{-8}t^2$

Nitrogen..... $c_N = 0.2407 + 3.26 \times 10^{-5}t - 0.380 \times 10^{-8}t^2$

Carbon dioxide.. $c_{CO_2} = 0.2016 + 9.18 \times 10^{-5}t - 1.736 \times 10^{-8}t^2$

Hydrogen-air.... $c_m = \frac{1}{1 + 13.36y}[3.430 - 0.068y + (5.75 + 43.65y)10^{-5}t + (4.27 - 10.92y)10^{-8}t^2]$

Hydrogen-nitrogen.. $c_m = \frac{1}{1 + 12.90y}[3.430 - 0.084y + (5.75 + 39.56y)10^{-5}t + (4.27 - 9.55y)10^{-8}t^2]$

Hydrogen-carbon dioxide..... $c_m = \frac{1}{1 + 20.83y}[3.430 + 0.971y + (5.75 + 194.65y)10^{-5}t + (4.27 - 42.17y)10^{-8}t^2]$

Viscosity. The available data on the viscosity of pure gases were investigated; the values used as a basis for this paper being selected from the International Critical Tables (3). Formulas to fit these data over the range of 0 to 250 F were then determined.

A search of the literature for a means of calculating the viscosity of a mixture of gases showed that several different formulas had been proposed. Gille (4), working with helium and hydrogen, referred to the work of Puluj and Theisen on the viscosity of mixtures. Trautz (5) proposed a different formula and Schröer (6) and Adzumi (7) give semitheoretical methods of determining the constants in the equation of Theisen. Application of these equations to data on hydrogen-nitrogen mixtures indicated that the equation of the form proposed by Theisen best fitted the data. This equation is of the form

$$\mu_{12} = \frac{\mu_1}{1 + A_1\left(\frac{y}{1-y}\right)} + \frac{\mu_2}{1 + A_2\left(\frac{1-y}{y}\right)}$$

where y is the fraction of volume of gas 2, and A_1 and A_2 are constants. It was found that the constants in the equation as determined by the method of Schröer (6) and Adzumi (7) fitted the data fairly well and included a term for temperature. However, since the relations proposed by Schröer (6) and Adzumi (7) necessitate an empirical determination of one term and since the variations of the constants with temperature are small over the range of 0 to 250 F, the author chose to determine empirically the constants at an intermediate temperature and apply them over this temperature range. Table 1 shows the variation in the values obtained for the viscosity of hydrogen-nitrogen mixtures, using the methods of Puluj, Trautz, Schröer, and the equation of Theisen with empirical constants as determined by the author. The table shows the ratio of the calculated value to the value reported in Tables Annuelles de Constantes et Données Numeriques (8).

TABLE 1 VISCOSITY OF HYDROGEN-NITROGEN MIXTURES

Temp, F	Nitrogen, per cent	Ratio of calculated to reported value — Puluj	Trautz	Schröer	Author
66	19.23	1.0482	1.1454	1.0301	0.9999
66	33.28	1.0329	1.0995	1.0369	1.0034
66	49.47	1.0139	1.0522	1.0320	1.0000
66	79.79	1.0048	1.0140	1.0193	1.0033
212	20.49	1.0586	1.1599	1.0528	1.0136
212	32.81	1.0355	1.1078	1.0319	1.0073
212	49.47	1.0171	1.0571	1.0334	1.0042
212	81.95	1.0012	1.0105	1.0132	1.0003

Rammler and Breitling (9), in an article dealing with the viscosity of flue gases, mention two approximate equations for the viscosity of a mixture but application of these equations to mixtures of hydrogen and nitrogen shows a variation from the data reported in the Tables Annuelles de Constantes et Données Numeriques (8) which is comparable to that obtained using the method of Trautz.

It will be noted from Table 1 that the variation between the calculated and reported values increases as the per cent of nitrogen is decreased in all cases except the author's formulas. Since the region in which we are interested is the region of small amounts of the second gas, the author has in each case determined the constants to be used in the equation by direct substitution of the selected data and these are the values reported.

The data used in determining the empirical constants for the hydrogen-nitrogen mixture were taken from the Tables Annuelles de Constantes et Données Numeriques (8), while those for the hydrogen-carbon-dioxide and hydrogen-air mixtures were taken from the International Critical Tables.[3]

The viscosity of the pure gases and their mixtures are given by the following relations:

Hydrogen..... $\mu_H = 0.02035\left(\frac{t + 459.6}{491.6}\right)^{0.696}$

Air..... $\mu_{air} = 0.04136\left(\frac{707.6}{t + 675.6}\right)\left(\frac{t + 459.6}{491.6}\right)^{3/4}$

Nitrogen..... $\mu_N = 0.04259\left(\frac{732.4}{t + 658.7}\right)\left(\frac{t + 459.6}{533.3}\right)^{3/4}$

Carbon dioxide..... $\mu_{CO_2} = 0.03361\left(\frac{923.6}{t + 891.6}\right)\left(\frac{t + 459.6}{491.6}\right)^{3/4}$

Hydrogen-air.. $\mu_m = \frac{\mu_H}{1 + 1.803\left(\frac{y}{1-y}\right)} + \frac{\mu_{air}}{1 + 0.345\left(\frac{1-y}{y}\right)}$

Hydrogen-nitrogen.. $\mu_m = \frac{\mu_H}{1 + 1.529\left(\frac{y}{1-y}\right)} + \frac{\mu_N}{1 + 0.385\left(\frac{1-y}{y}\right)}$

Hydrogen-carbon dioxide... $\mu_m = \frac{\mu_H}{1 + 1.704\left(\frac{y}{1-y}\right)} + \frac{\mu_{CO_2}}{1 + 0.265\left(\frac{1-y}{y}\right)}$

Fig. 2 shows a comparison of the viscosity as calculated from the foregoing equations and the values reported for hydrogen-nitrogen mixtures in reference (8) and for hydrogen-air and hydrogen-carbon-dioxide mixtures in the International Critical Tables.[3]

Thermal Conductivity. The experimental data on the thermal conductivity of gases were scanty and quite scattered as to value, probably due to the difficulty of measurement.

The available data for the last 20 years or so were plotted and showed a marked increase in the value for any particular gas over this time. The amount of increase was 4 to 5 per cent and was definitely upward for all gases, hence, the most recent data were selected for use in this paper. While it is common to see the formula for thermal conductivity of pure gases written in a form

[3] Bibliography (3), pp. 5 and 6.

using Sutherland's constant, the author could not find enough variation from a straight line to warrant the use of any formula but the straight line $K = k_0(1 + at)$, hence this is the formula used in calculating the conductivity of the pure gas. The equations reported for the pure gases do not strictly follow any particular set of data but rather represent an engineering estimate of the probable value over the range of 0 to 250 F.

There were few data on the conductivity of gas mixtures and no formula was found in the literature to fit the data. However, the same type of equation as used for the viscosity of a mixture was found to fit the data very well if the constants were empirically determined from two test points.

There were available no data on the thermal conductivity of a hydrogen-air mixture. There were, however, data on hydrogen-nitrogen[4] at 32 F and hydrogen-oxygen[5] mixtures at 72 F. Since

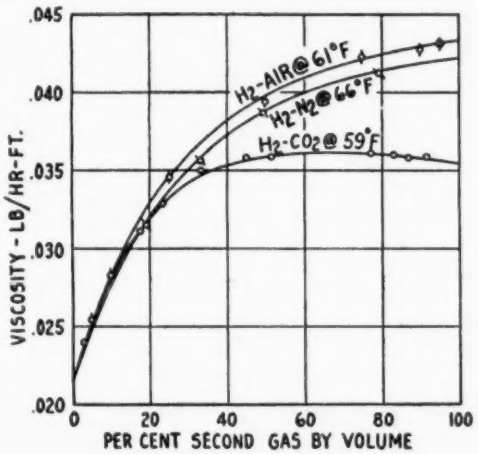

FIG. 2 VISCOSITY OF HYDROGEN MIXTURES; COMPARISON OF CALCULATED AND REPORTED VALUES

air is nearly a 4:1 mixture of nitrogen and oxygen, an attempt was made to predict the conductivity of hydrogen-air mixtures from these data. The constants for mixtures of hydrogen-nitrogen and of hydrogen-oxygen were determined empirically from the data mentioned. Calculated curves for these two mixtures were then drawn at 70 F and the curve for the hydrogen-air mixtures drawn between them. Because of the 4:1 ratio of nitrogen to oxygen in air, the estimated curve for hydrogen-air mixtures was drawn so that the distance from the hydrogen-oxygen curve was $^1/_5$ the distance between the hydrogen-nitrogen and hydrogen-oxygen curves.

The data on the hydrogen-carbon-dioxide mixtures were taken from Physicalish-Chemische Tabellen (10).

The formulas for the thermal conductivity of the pure gases and their mixtures are given as follows:

Hydrogen..... $k_H = 0.0942(1 + 0.00148t)$

Air..... $k_{air} = 0.0133(1 + 0.00170t)$

Nitrogen..... $k_N = 0.0130(1 + 0.00170t)$

Carbon dioxide..... $k_{CO_2} = 0.00783(1 + 0.00266t)$

Hydrogen-air..... $k_m = \dfrac{k_H}{1 + 2.70\left(\dfrac{y}{1-y}\right)} + \dfrac{k_{air}}{1 + 0.243\left(\dfrac{1-y}{y}\right)}$

Hydrogen-nitrogen.. $k_m = \dfrac{k_H}{1 + 2.90\left(\dfrac{y}{1-y}\right)} + \dfrac{k_N}{1 + 0.280\left(\dfrac{1-y}{y}\right)}$

Hydrogen-carbon dioxide.... $k_m = \dfrac{k_H}{1 + 2.85\left(\dfrac{y}{1-y}\right)} + \dfrac{k_{CO_2}}{1 + 0.200\left(\dfrac{1-y}{y}\right)}$

Fig. 3 shows a comparison between the values as calculated using these equations and the values as reported[4] for hydrogen-nitrogen mixtures and for hydrogen-carbon-dioxide mixtures in reference (10).

Prandtl Number. One of the common dimensionless groups

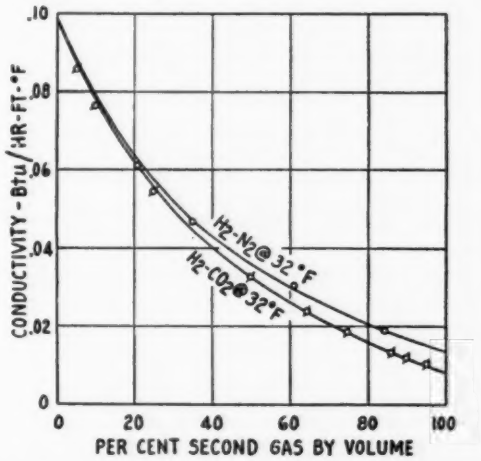

FIG. 3 CONDUCTIVITY OF HYDROGEN MIXTURES; COMPARISON OF CALCULATED AND REPORTED VALUES

used in heat-transfer work is the Prandtl number $c\mu/k$. According to the kinetic theory of gases, this group is a constant for all gases having the same number of atoms per molecule. This is true for ideal and pure gases but there is a variation in the value for impure gases. It was believed that, when two diatomic gases were mixed, this constant remained the same for all compositions, since the value was the same for either of the pure gases alone. Fig. 4 shows a plot of this constant as a function of composition for the three gas mixtures treated in this paper. It will be noted that the "constant" is far from a constant and varies nearly 50 per cent from its value for a pure gas.

The value of the Prandtl number for the pure gases, as determined from the data given in this paper, will vary slightly with temperature instead of remaining constant. This variation is due to the manner in which the equations for the various properties are expressed. The variation over the range of 0 to 250 F is less than 0.5 per cent and for all practical purposes this is negligible.

Application of Data. To illustrate how closely the performance of a heat exchanger in hydrogen can be predicted from the results of tests made in air, the data in the paper were applied to a commercial surface air cooler of the extended-surface type, manufactured by the author's company. This cooler was tested, using air and pure hydrogen and five runs were made with 8.22 per cent nitrogen in the hydrogen.

From the tests using air, the pressure drop and gas-side heat-transfer coefficient were determined. From these values, and the properties of hydrogen and nitrogen, the pressure drop and gas-side coefficient were estimated for pure hydrogen and a mixture of 91.78 per cent hydrogen and 8.22 per cent nitrogen by volume.

The pressure drop ΔP in inches of water is plotted against a modified Reynolds number in Fig. 5. The dotted lines show the estimated pressure drop based on the air tests, while the points show the values as obtained by actual test. It is apparent that

[4] Bibliography (8), p. 60.
[5] Bibliography (3), p. 214.

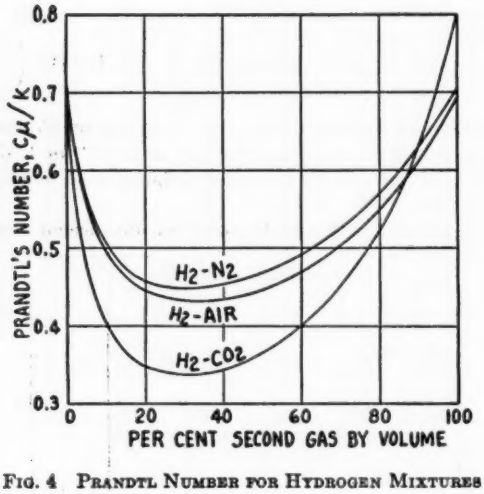

FIG. 4 PRANDTL NUMBER FOR HYDROGEN MIXTURES

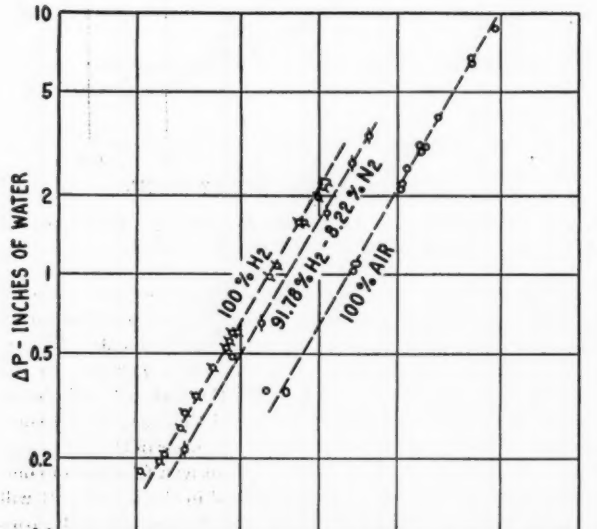

FIG. 5 GAS-SIDE PRESSURE DROP IN HEAT EXCHANGER; COMPARISON OF ESTIMATED AND TEST VALUES

the predicted values are well within the accuracy of the tests and it is possible to predict accurately the pressure drop of a heat exchanger when operating in a medium other than that in which it was tested.

In Fig. 6 is shown the local gas-side heat-transfer coefficient h plotted against a modified Reynolds number. Again, the dotted lines show the estimated values based on the air tests, while the points show the values obtained by actual test. Within the range of Reynolds' numbers covered by the air tests, the test values for the hydrogen lie close to the estimated curve. Below this range, the values depart from the estimated curve but are still within 10 per cent of the estimated value. This variation is due to the fact that the heat-transfer factor $j = \frac{h}{cG}\left(\frac{c\mu}{k}\right)^{2/3}$ is not a straight line when plotted against Reynolds' number but falls off slightly at the lower Reynolds number.

The points for the mixture of hydrogen and nitrogen are slightly below the estimated curve but, since only 4 points are shown, this cannot be conclusive. The 4 points shown are all within 10 per cent of the estimated value and the accuracy of the data on these particular runs was not very high.

CONCLUSION

The comparison of the estimated pressure drop and heat-transfer coefficient with the test values shows clearly that it is possible to predict the performance of a heat exchanger which is operating in a fluid other than that in which it was tested. Care must be exercised in extrapolating the available data but, within the range of the available test data, the estimated performance will be well within engineering accuracy.

It is the hope of the author that the information presented in this paper will further the application of hydrogen-cooled ma-

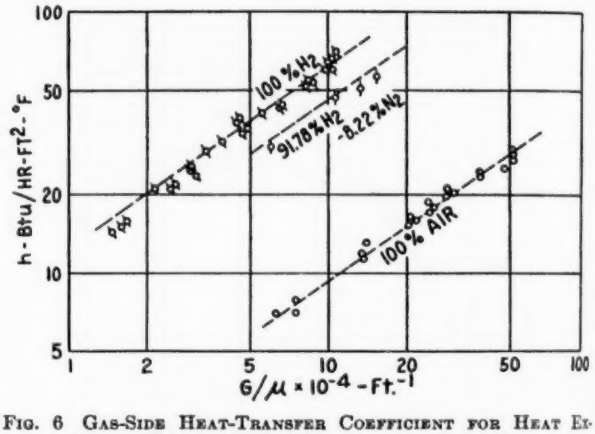

FIG. 6 GAS-SIDE HEAT-TRANSFER COEFFICIENT FOR HEAT EXCHANGER; COMPARISON OF ESTIMATED AND TEST VALUES

chines and will permit the extension of available test data on performance in air to cover the application of hydrogen and hydrogen mixtures.

ACKNOWLEDGMENT

Discussion

M. W. BEARDSLEY.[6] Specific-heat data have been published since the references cited by the author, and there are now available equations[7] which cover substantially greater temperature ranges and have at least equal accuracy. For the temperature range of interest in this case, calculations can be considerably simplified by using the constant specific-heat values given in Table 2 of this discussion.

TABLE 2 CONSTANT SPECIFIC-HEAT VALUES

Gas	c_p Btu per lb per deg F	Range, deg F	Maximum error, per cent
H_2	3.430	30–250	0.9
Air	0.243	0–250	0.5
N_2	0.249	0–250	0.3
CO_2	0.213	80–250	5.2
H_2-air	$\frac{6.91 + 0.085y}{2.016+26.81\ y}$	30–250 (all proportions)	< 1.0
H_2-N_2	$\frac{6.91 + 0.06y}{2.016+25.98y}$	30–250 (all proportions)	< 1.0
H_2-CO_2	$\frac{6.91 + 2.44y}{2.016+41.98y}$	30–250 (for $y \leq 0.10$)	< 2.0

y = per cent by volume of gas other than H_2

The constant values shown for air and N_2 are actually more accurate over the cited range than the equations given in the paper. The value for H_2 is not as accurate as the equations above 100 F. The value for CO_2 is not recommended for accurate work, but the author's equation for CO_2 is over 3 per cent high for temperatures less than 80 F.

This information on specific heats is offered as data that can be more easily employed in calculations covering a limited temperature range.

W. M. D. BRYANT.[8] The writer was gratified to observe that his gaseous molecular-heat data[9] had been of service in this research. The author has characterized these as "the most recent and reliable data." Neither designation is any longer strictly deserved, for several papers on the subject have appeared since 1933 and some have incorporated refinements of unquestioned value. For example, Murphy[10] has fitted a series of quadratic equations to some of the precision spectroscopic values later used by Dr. Heck. The loci of these equations are in some cases 2 to 3 per cent closer to the true values than those of the writer's equations. Also Sweigert and Beardsley[7] have derived some rather intricate equations which fit the spectroscopic curves with remarkable precision. However, it is doubtful that the use of these more recent data would alter the author's calculations to a significant degree.

H. W. EMMONS.[11] The data used by the author in constructing his formulas appear to be the latest now available. As a convenient reminder, the valid temperature ranges for the various formulas should perhaps have been listed with the formulas rather than being buried in the text.

In general, the formulas chosen are those with some theoretical support, the constants being evaluated from test data. The exception, noted by the author, in the formulas for k is entirely justified from the point of view of available (and reliability of) present data. The Sutherland constant appears in the theoretical formula for k because of its direct appearance in μ and the theoretical prediction that $f = k/\mu c_v$ is constant. Since the Sutherland formula for μ fits the data for gases quite well (the author uses this form for air, nitrogen, and carbon dioxide), while the relation f = constant is only approximately true for actual gases at various temperatures, the thermal conductivity could not be expected to fit a formula with the same Sutherland constant.

The formulas for μ and k of binary mixtures adopted by the author do not agree with the latest theoretical work.[12] However, for the limited data now available, the empirical formulas with the empirical constants as given fit the data very well and are much easier to use than the theoretically more nearly correct equations.

The considerable variation of Prandtl number with composition is interesting and is nicely verified for practical purposes by the accuracy with which the heat-transfer performance for hydrogen-nitrogen mixtures can be predicted from the test data with air.

The experimental checks on the accuracy of calculations made, using the data presented, are excellent. The general value of the paper to those not familiar with the field would have been greatly increased if the author had devoted slightly more space to the dimensionless relations used in predicting performance of heat exchangers from air test data.

F. G. KEYES.[13] The paper is well developed as regards subject matter. A suggestion of possible interest relates to the theoretical work of Enskog who developed the kinetic theory of viscosity and heat conductivity on a very broad basis using the van der Waals molecular-field concept. This leads easily to a theory of mixtures which might find application.

G. W. PENNEY.[14] The effect of small percentages of heavier gases in hydrogen has been of interest ever since the cooling of machines by hydrogen was seriously considered. As plotted in Fig. 6 of the paper, the heat transfer for 91.78 per cent H_2 and 8.22 per cent H_2 appears poorer than that of pure hydrogen. However, in electric machines there are many cases where the velocity may tend to be more or less fixed by peripheral speeds. At a given linear velocity, a small percentage of a heavy gas usually improves the surface heat transfer. This fact made the effect of mixtures of considerable importance when hydrogen was first being considered. In studying this effect, tests were made at the Westinghouse Research Laboratories 12 to 15 years ago. Fig. 7 of this discussion gives the results of a test on a duct which showed a marked improvement in heat transfer when a small percentage of carbon dioxide is added to hydrogen.

The effect of a mixture of CO_2 in hydrogen on the surface heat transfer is shown when the fan speed was held constant in the duct system tested. This closely approximated the condition in many electric machines when the gas composition was varied in a given machine. Under these conditions the gas velocity was 6350 fpm for pure hydrogen and increased to 6460 fpm for 22 per cent CO_2 by volume, and to 7040 fpm for pure CO_2. The heat transfer plotted is the heat dissipated from the external surface of a cylindrical member $1^3/_{16}$ in. outside diam by 18 in. long and located concentrically inside a cylindrical duct of 2 in. inside diam. The

heat transfer plotted is the watts per square inch divided by the logarithmic-mean temperature difference.

In Fig. 7, the heat transfer is plotted for a gas velocity which varied only slightly. In order to apply such results more generally, tests for a range of velocities are needed, and it is desirable to plot the results on some dimensionless basis. McAdams in his book on heat transmission gives many examples of this. In these

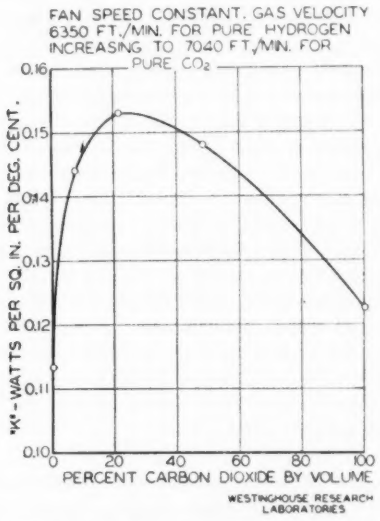

FIG. 7 HEAT-TRANSFER RESULTS OF TEST ON DUCT WITH SMALL PERCENTAGE OF CARBON DIOXIDE ADDED TO HYDROGEN

examples the abscissa is usually related to Reynolds' number and the ordinate usually contains the Prandtl number ($C\mu/K$). By this means the three curves shown in Fig. 6 of the paper can be reduced to one common curve by the proper choice of coordinates. Such curves are valuable, but their usefulness is limited because a given curve applies actually only to geometrically similar surfaces. In the examples given by McAdams, the effect of the Prandlt number varies widely, depending upon the shape of the surface being cooled. For heat interchangers, many different shapes are used so that the experimental data reported are insufficient to cover the various designs being used.

The author has given a concise review of information which was previously scattered through the literature, but he has avoided the question which seems to the writer to be of major importance, namely, the application of these data to the multiplicity of shapes occurring in electric machines. When tests have been made on one particular shape, it is, of course, easy to secure good agreement with calculations on a geometrically similar surface. But it is difficult to predict the effect when a different geometrical shape is used.

It would be of value, if the author in his closure would include a dimensioned sketch of the heat-interchanger surface on which the tests of Fig. 6 were made. Each manufacturer usually has such data for his particular type of surface, but it is difficult to get sufficient data on different shapes.

R. L. SWEIGERT.[15] It is the writer's belief that the author has made a use of specific heats which does not seem quite necessary in dealing with hydrogen mixtures under the conditions under which those mixtures exist when used as a cooling medium.

The specific-heat equations used in the paper do not possess the accuracy stated, within the temperature range which the author gives. The error of the nitrogen and carbon-dioxide equations becomes very large at the higher temperature given in the paper. The error for the hydrogen equation is considerably smaller. The type of equation used is unsatisfactory for a wide temperature range. More recent accurate data and equations[7] on specific heats are available, the new-type equation being $a - \frac{b}{T} + \frac{f}{T^3}$ rather than $a + bT + fT^2$.

For ordinary temperature ranges, relatively close to atmospheric temperatures, older data may vary less than 3 per cent from the new, and the results from such data may come well within the limits of practical accuracy.

In the author's case, constant values of specific heat could have been used just as well, with accuracy equal to that of the equations used. Regardless of the possible inaccuracy of the results for higher temperatures from the specific-heat equations used, the author's results for the temperature range with which he was concerned were not materially affected, as is indicated by the agreement of calculated and experimental results.

AUTHOR'S CLOSURE

The principal criticism of all the discussers appears to be that the specific-heat data used may be 2 to 3 per cent at variance with the latest values. This fact was admitted by the author in his presentation of the paper but it must also be admitted that, at the present time, there is no marked agreement as to the specific heat even of air. In view of the fact that most heat-transfer calculations are excellent if they are within 5 per cent of the true value, this variation of 2 to 3 per cent is not of too great consequence.

In answer to Mr. Penny's question, as to the application of the presented heat-transfer data to "the multiplicity of shapes occurring in electrical machines," it was not the author's purpose to enter into the prediction of the heat-transfer coefficient for a multitude of shapes but rather to demonstrate the accuracy with which the heat-transfer coefficient may be predicted for any gas if the value in air is known.

Mr. Penny's conclusion that the heat transfer was poorer for the hydrogen mixture with 8 per cent N_2 than with pure hydrogen is true if we consider constant values of Reynolds' number. If a

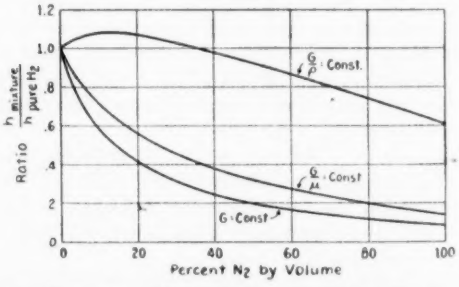

FIG. 8 EFFECT OF MIXTURE RATIO ON HEAT-TRANSFER COEFFICIENT

constant value of linear velocity or a constant value of weight velocity were used, the same would not be true. Assuming that $j = \frac{h}{cG}\left(\frac{c\mu}{k}\right)^{2/3} \propto \left(\frac{G}{\mu}\right)^{-0.38}$ then for values of constant G/μ constant G and constant linear velocity (or G/ρ), we would obtain three different curves as shown by Fig. 8 of this closure. It may readily be seen that, under conditions of constant linear velocity, the coefficient rises and then falls off in much the same manner as in Mr. Penny's tests. If the Reynolds number or weight velocity are held constant, the heat-transfer coefficient falls steadily as the fraction of impurity rises.

[15] Professor of Mechanical Engineering, Director of Freshman Engineering, Georgia School of Technology, Atlanta, Ga. Mem. A.S.M.E.

In electric machines, the velocity of the gas is nearly constant and is fixed by the machine speed. The heat-transfer coefficient may be improved by adding CO_2 or N_2 to the hydrogen. If this were the only result, this would be the proper procedure but it may be shown that adding nitrogen to 10 per cent of the total volume and maintaining constant velocity will give about 8 per cent increase in heat-transfer coefficient. It will also increase pressure drop by 75 per cent and the power required to circulate the gas by 75 per cent. In many cases, it is desirable to put in 8 per cent more heat-transfer surface in order to save 50 per cent of the power required; this fact must be borne in mind in all problems.

The author wishes to thank all the discussers for their helpful comments and criticisms and trusts that the data as set forth in the paper will prove helpful to those interested in hydrogen-cooled machines.

Experimental Drying

By D. L. COOPER and A. L. WOOD,[1] HALIFAX, N. S.

This paper deals with an investigation of moisture-regain values for salt-fish muscle which show a particularly rapid change in the range between 60 and 75 per cent relative humidity. The determination of experimental drying-rate curves in this range requires study, for much of the commercial drying as now carried out is done within this range. The author describes the system customarily used for this purpose. Dry- and wet-bulb regulators, employing thermionic relays capable of giving control of experimental air conditions in the order of 0.01 F dry and wet bulb, were used in the investigation. Drying-rate curves over a limited range using this method of control are presented.

THE experimental testing of materials, as a preliminary to commercial drier design and fabrication, is now recognized as essential in the development of such equipment. As a result, several types of laboratory equipment have been evolved for this purpose. In general, such equipment is suitable for the majority of requirements; it is only when an odd material is subjected to experiment that a more refined type of equipment is required. Necessary methods of securing satisfactory air flow are well established, but considerable improvement in control is now possible by the use of the newer types of equipment developed during the last decade.

The purpose of this paper is to describe certain refinements in experimental drier control but, in addition, an outline will be presented of the methods and limits of experimental testing as applied to the drying of salt fish, for the controls were developed to satisfy the requirements of this odd material.

Material to Be Dried

The material to be dried may be roughly considered as a biological structure, containing as formative matter 22 per cent salt, 56 per cent water, and 22 per cent protein. It may be further loosely defined as a saturated solution of common salt, given a definite form, and held by a substrate of protein, which was the original muscle of the fish. It has been shown that a more complex combination between salt and protein is formed which has an activity greater than the saturated salt solution itself but, since this could not be detected by equilibrium-moisture measurements, therefore, the first and more simple concept is sufficient for the needs of the drying engineer.

This protein-salt complex is highly hygroscopic, and severe shrinkage of the protein substrate complicates the problem. The formation of a tough, nearly impervious skin during drying under certain conditions is another factor which must be considered.

A further complication is introduced by the heat sensitivity of the system which, in common with all whitefish proteins, cannot be subjected to temperatures higher than approximately 72 F without breakdown. The temperature limit of salt-fish muscle depends to some extent on previous treatments but, in general, 76 F for short periods of time is the upper safe limit.

The problem may therefore be summarized somewhat as follows: To cause evaporation, into ambient air, of water from a saturated solution of salt, forming part of a system in which the remainder is a heat-sensitive, shrinking, skin-forming protein.

The theory of such removal will not be discussed but rather details will be given of the present state of experimentation, designed in a semiempirical manner to set up drying-rate curves without regard to theory, as a basis for drier design immediately required by the industry.

Little work of any value has been done on the drying of salt fish itself. Nor does the literature contain much information of interest on the evaporation from such solutions in protein base.

The complex nature of the material and the scarcity of information on like types made it imperative to disregard any previous work and lay down a program somewhat as follows:

1 Determination of the hygroscopy of the product, that is, determination of the regain values over all ranges likely to be encountered in practice.

2 To determine drying-rate curves for the material in experimental equipment.

3 To check drying rates thus obtained in commercial equipment.

4 To investigate the theory of evaporation from such systems.

So far results in connection with item 1 are complete; apparatus for item 2 has been devised and tested and a few results obtained. Work is proceeding on a commercial drier, designed and put in operation after the results of regain and drying rates were available. The theory is an interesting consideration which yet remains to be undertaken.

Equilibrium-Moisture Contents

A report of this work has been published previously (1).[2] Only sufficient detail will be given here to form a foundation for later discussion.

It is known that moisture regain in this class of material, particularly near the point of equilibrium, is very slow (2). Therefore, any method of determination, employing large samples, is likely to be slow. Unless conditions are controlled more accurately than is usually convenient, a slow method leaves a doubt as to whether the equilibrium recorded is a time equilibrium or one which represents the true equilibrium with vapor at a definite pressure (3). As will be shown later, this is particularly true in the case of salt fish in which the rate of change or regain is very sharp at high relative humidities.

The obvious method of making such measurements is by use of the McBain-Baker adsorption balance so arranged that the air may be removed from the measuring chamber.

In the experiments, the quartz spirals were turned to carry about 0.02 to 0.04 g of fish, and suspended in vacuo at constant temperature until equilibrium had been reached. Moisture at controlled pressure was supplied to these tubes, and an equilibrium read for each pressure of vapor admitted. Both the bath temperatures and vapor pressures could be varied to cover the range desired.

Results obtained in this apparatus are given in Fig. 1. The material was shown to be isohygrometric within the range and accuracy of experimentation, therefore, one curve expresses all the results.

[1] Fisheries Research Bureau.

Contributed by the Process Industries Division and presented at the Spring Meeting, Worcester, Mass., May 1–3, 1940, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

Three things require mention: (*a*) The fish system becomes saturated at 75.3 per cent relative humidity, which is the theoretical value of saturated solutions of sodium chloride within the range of temperatures studied; (*b*) the exceedingly rapid increase in water regain at or near this saturation value; and (*c*) the downward and regain values do not agree over the whole range.

The supposition is that the protein system acts as a hygroscopic medium which causes uptake of water until a part of the salt is in free solution. The uptake of water will then be continued until the solution is diluted to give a vapor pressure in equilibrium with that of the surrounding medium. When humidities increased beyond 76 per cent, drops of liquid formed on the sample. These grew until they dropped to the bottom of the measuring tube.

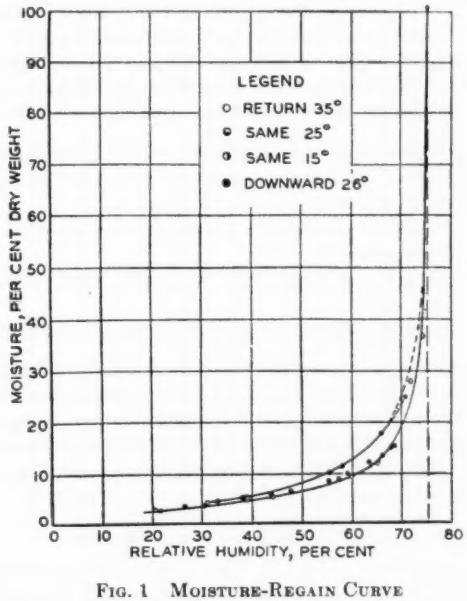

FIG. 1 MOISTURE-REGAIN CURVE

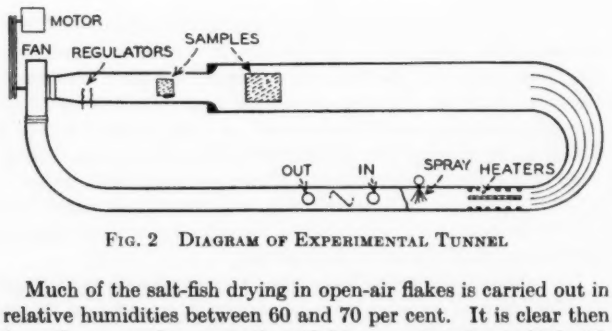

FIG. 2 DIAGRAM OF EXPERIMENTAL TUNNEL

Much of the salt-fish drying in open-air flakes is carried out in relative humidities between 60 and 70 per cent. It is clear then from the curves for regain that, if this range is to be studied with the object of obtaining drying-rate data, the control of experimental drier conditions had to be somewhat better than that usually attempted.

EXPERIMENTAL DRIERS AND APPLICATION OF CONTROLS

A most important consideration in the conduct of the experiments was the application of various types of regulating equipment suitable for the accurate control of conditions in the experimental driers. The systems to be described were all utilized in the experiments.

The drying equipment consisted of a conventional draw-through recirculating tunnel, Fig. 2, the design of which included the usual precautions for obtaining normal turbulent-flow distribution in those sections in which samples were suspended. No provision was made for dehumidifying air, low-humidity experiments having been carried out in winter months. Necessary air exchange to take care of evaporation and to maintain a humidity trend always lower than that desired was easily obtained by suitable adjustment of dampers.

Velocities were controlled at constant fan speeds by damper adjustments, or by varying fan speeds with adjustable drives. Temperatures were maintained with low-heat-capacity electric heaters, and humidities with a water-spray and manual damper control.

CONTROL OF AIR CONDITIONS IN SMALL TUNNELS

The difficulty usually experienced in obtaining accurate control in this type of equipment is caused by the lack of a sink or plenum which takes care of a lag or lead of the commercial type of control. This type will therefore be unsatisfactory except in circumstances in which the heat demand is constant and the supply accurately fixed to meet the demand. Otherwise, the lag together with the heat capacity of the heating elements will cause a hunting action, which becomes more serious if two dependent controls are used, as in the use of wet and dry controls for the regulation of temperatures and relative humidities. The modulating type constitutes an improvement in design. However, no commercial units of this type which were tried would give the required accuracy.

The best method of overcoming the difficulty is to use a combination of high-heat-output, low-heat-capacity heaters, which are operated by an on-off control of several times the required sensitivity.

The cause of failure in the commercial equipment tried appears to be the large currents required across the contacts of a thermoregulator. Even at low voltages and with careful contact design, cumbersome regulators easily disturbed by vibration were required, or regulators enclosed in an inert gas which are also fragile and subject to disturbance. Should this not be done, a change in the condition of the contact will cause excessive variations in the position of the control.

The solution of this difficulty is to use such low currents through the contacts that their resistance becomes negligible. This may be accomplished by several methods; as for example, the use of a very sensitive microrelay, which in turn operates a larger contactor carrying the heater or other load. The difficulties in the use of this system are caused by the sensitivity of the small relay which is usually also responsive to shock, dust, and other conditions. Several very sensitive and satisfactory relays are now available commercially but, as a rule, the second circuit which includes the main contactor must be carefully designed to avoid arcing at the contacts of the small relay. A better method is to use a thermionic tube as the sensitive relay or, if one of sufficient size can be purchased, as the only relay.

The author has tried both methods. The first always caused trouble, but the second has always been trouble-free. Several methods of operating thermionic tubes will be described, and details of others may be found in any standard text on vacuum tubes and their uses (4).

One major effect of systems of this type is to increase the response of common thermoregulators greatly. Thus, the bimetallic spiral regulator, usually sensitive to about $^1/_2$ deg in water and something over 2 deg in air of low velocity, when used with thermionic tubes, will give control of the order of 0.01 F in air.

System 1, shown in Fig. 3, is suitable where direct current is available and there is no objection to using a second relay to accommodate heavy loads. A suitable relay for use in this system is the mercury-in-glass type, tripped by a mechanism operated

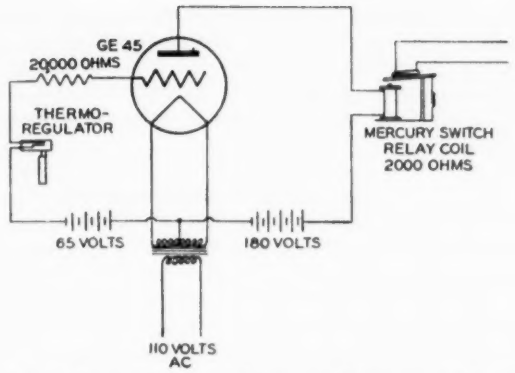

FIG. 3 DIRECT-CURRENT-OPERATED THERMIONIC RELAY

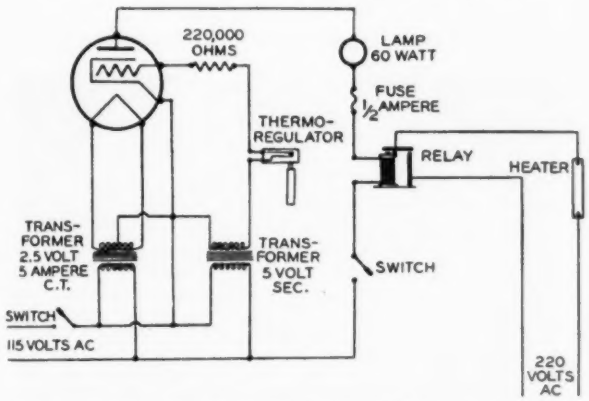

FIG. 4 ALTERNATING-CURRENT-OPERATED THERMIONIC RELAY

by a small magnet. The magnet may be wound to suit the characteristics of the tube used in the circuit.

System 2, shown in Fig. 4, employs the 3 or 4-electrode mercury-vapor-filled tube. One conventional method of use is indicated in Fig. 4, which employs an FG 97 thyratron. This tube is capable of handling small loads of the order of 300 w directly.

DRY-BULB CONTROL

It is clear that, if humidity is to be regulated by wet-wick thermoregulators, the accuracy of control of the dry bulb will affect the precision with which humidities may be maintained.

As previously mentioned, even for the most accurate control, the simple bimetallic type of regulator will be satisfactory if used in one of the systems already described. With suitable auxiliary equipment dry-bulb temperatures have been kept constant to about 0.01 F in this laboratory.

Accuracy of the type specified requires careful design of the auxiliary equipment. Relays, if used, must be of the quick-acting type and operate heaters of low heat capacity, the most suitable of which, for experimental use, is the open-wire electric type. These have very low capacity and no detectable lag. Furthermore, they can be easily adjusted to suit the load for cases where extreme accuracy is desired. A convenient method is to divide the heaters into two sections: (*a*) a variable-control bank, and (*b*) a variable-supply bank. The control bank operates from the thermoregulator through the tube and auxiliary relay (if needed), and the variable-supply bank is easily adjusted by hand, although it may be made automatic if required. The less the load variation, the closer these banks may be set, and the greater the accuracy of control. In practice it was found that, when using open-wire heaters, the supply setting could be varied about 50 per cent without affecting the accuracy materially.

Steam heaters may be used but only at the expense of some precision, since it is nearly, if not quite, impossible to reduce the heat capacity of such heaters to a negligible value for small experimental installations when working below steam temperatures. The thermionic type of control, operating some system of modulation for admission of steam, has been found to help somewhat, but great accuracy is difficult of attainment in spite of refinement of the thermoregulator circuit.

CONTROL OF RELATIVE HUMIDITY

Relative humidities may be controlled by two systems differing in fundamental arrangement: (*a*) a type in which the humidity-regulator setting is influenced by dry-bulb temperatures, and (*b*) a type in which it is not. The first generally employs the combination of wet- and dry-bulb regulators; the second uses a suitable isohygrometric material which is sensitive to changes in relative humidity. Either method has been found to be satisfactory, providing the precautions are such that the sensitivity of the regulator is several times the required amount, and the rate of vapor addition is adjusted approximately to the load.

The actual controls used in this laboratory have always required an addition of vapor to air, for all experiments have been carried out when natural psychrometric conditions permitted this system of control. Similar methods may, however, be applied when dehumidification equipment is available.

THE REGULATOR

Method 1. Almost any type of low-heat-capacity regulator may be used. In practice it has been found that the simple bimetallic-spiral type with the wet wick placed on the spiral gives satisfactory results, providing it is used to operate the control circuit of a vacuum-tube relay, which in turn operates to admit vapor or steam as required.

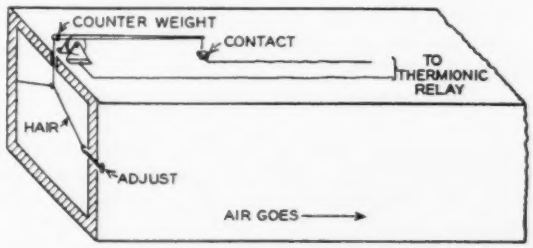

FIG. 5 HUMIDITY CONTROL

The familiar precautions of maintaining the wet-wick regulator in air moving at a velocity of 400 fpm or greater must be taken. In cases of experiments in which very low velocities are used, the regulator may be placed at the downstream side of a shaped nozzle, or fixed in a by-pass, the velocity in which is increased by an auxiliary fan.

Method 2. This method, employing the isohygrometric material, is equally as sensitive as the first, providing arrangements are satisfactory. The material may be either defatted human hair or white Russian horsehair, arranged as shown in Fig. 5. A fine wire, cemented to the long lever arm, ends in a contact which may be made as light as required, since contact resistances are negligible It is essential that the lever fulcrum be as frictionless as possible and that the lever be counterbalanced as shown to take nearly all the strain from the hair. The balance wheel of a cheap clock, mounted in the original frame, has been found to be satisfactory.

This system has the advantage in that it will maintain relative humidities constant, irrespective of changes in dry-bulb temperature. The hair must be reconditioned after each adjustment,

and is, therefore, not suitable when the experiment calls for changes in relative humidities. Further, it loses sensitivity, and usually wanders, when the relative humidity goes above 70 or below 20 per cent.

The use of this system is particularly suitable for a predetermined dry-bulb cycle.

Introducing Vapor. Solenoid valves, operating to regulate the admission of steam or water vapor, are convenient for operation from the controls. Steam is most suitable where the quantity required is small and adds no appreciable heat load to the equipment.

Weight Recorders. It was necessary to continue drying operations for 12 hr or more on light samples, and small interruptions causing slight changes in air conditions affected the rates of loss of water. Therefore, it was desirable to incorporate some automatic method of recording weight changes.

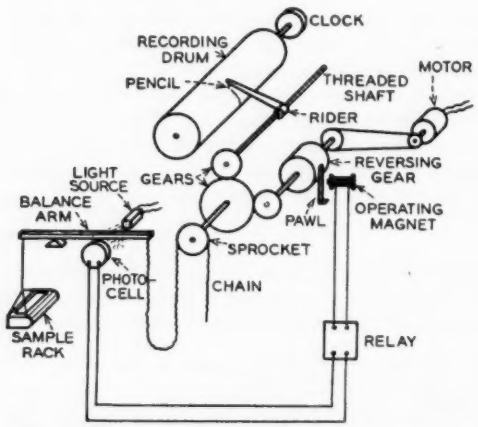

FIG. 6 ARRANGEMENT OF AUTOMATIC BALANCE

Continuous weight recorders have been made in many types from the simple spring-and-stylo, to the various types of weight-dropping balances capable of great accuracy. The simple spring is generally not suitable for investigations on small samples, and the weight-dropping types are too expensive for the average laboratory.

A recording balance, Fig. 6, depending upon the action of a reversing gear, was devised (5) in 1935. It is the most versatile and suitable apparatus for recording loss in weight of a sample being dried.

This type of balance mechanism has the advantage in that it can be made from simple parts such as are supplied by any manufacturer of small gears. The reversing gears in use in this laboratory were made from standard Mecanno parts. These gears may be adapted for use with the finest chemical balances, or the common steelyard capable of measuring several tons. Since they maintain any weighing mechanism in dynamic balance, they increase its sensitivity markedly. A common steelyard loaded with several hundred pounds of rusty iron radiators will record differences in weight, caused by changing relative humidities, with consequent increase or decrease in the amount of absorption on the rusty iron (5).

The equipment consists of two parts: (*a*) the balance proper, and (*b*) the reversing gear with which is incorporated the recording drum. The reversing gear carries a chain, one end of which is attached to the balance, the other to a sprocket on the gear, which is connected to a worm carrying a pencil over the recording drum. The balance works as an automatic chainomatic balance and, if a simple ladder chain be used, the weight of the chain per unit length may be varied to suit the load expected.

The reversing gear is normally motor-turned to keep the sprocket moving forward. When the movement of the gear is interrupted by a pawl, acting on signal from the balance arm, the forward motion of the gear is stopped, the train of gears in the case coming into play and causing the chain sprocket to reverse.

At any position of equilibrium of the balance arm, the gear reverses about 30 times per min, keeping the balance in equilibrium about a point which is determined by the loss in weight of the sample. If the equilibrium is disturbed either by loss or gain in weight of the sample, the balance arm signals the change to the tripping pawl, which causes the gear to rotate in one direction until a new point of equilibrium is reached. This change is recorded on the drum actuated by clockwork and a continuous weight-change record is obtained.

The schematic diagram, Fig. 6, shows the essential actions of the recorder.

losses in experiments carried out at the laboratory with which the author is associated.

Fig. 7 was recorded by a Cambridge two-pen mercury-in-steel recording thermometer. The bulbs, being solid, were not particularly suitable for following rapid changes in air temperatures

A mercury-in-glass Beckmann thermometer reading to 0.004 F, placed in the same plane as the recorders, showed variations of the order of 0.01 F. The control in this case was by wet and dry bimetallic spiral regulators acting through thyratron relays to activate (*a*) a self-atomizing spray for humidity control, and (*b*) a contactor which in turn operated electric strip heaters for dry-bulb control.

Fig. 8 is a copy of a typical weight curve taken directly from the graph drawn by the pencil of the automatic recorder. The recorder in this case was made of standard Mecanno parts. The drum was operated by a hand-wound clock. The balance was a common laboratory trip scale which had been in constant use about the laboratory for 4 years and was not in good condition. The weight of the sample and rack averaged 500 g; that of the sample itself about 35 g.

Experimental Results

Experimental drying curves were obtained in the usual manner by suspending the collodion-coated sample, fitted in a streamlined sample holder, from the end of the recording balance. The evaporation occurred from the top of the sample. All samples had a face area of 44 sq cm and were 7.1 mm thick.

TABLE 1 SUMMARY OF EXPERIMENTAL RESULTS

Run	Velocity, fpm	Relative humidity, per cent	Rate (avg), $cm^3/15\ hr \times 10^{-3}$
A	30	65	2.84
B	99	60	5.28
C	200	60	6.85
D	30	50	6.63
E	200	50	6.25
F	600	50	7.25

The results given in Table 1 are insufficient in number to permit conclusions of humidity, velocity, and temperature effects.

The curves shown in Fig. 9 give an idea of the nature of the drying process. The curves for all runs except *A* are similar in form to that of *E*.

One qualitative result of interest was noted as follows: When the average rate was less than approximately 3 to 4 $\times 10^{-3}$ the evaporation caused a heavy deposition of salt crystals on the surface of the sample. Above this range, the sample dried with a smooth nearly salt-free skin. It appears that this is a visual demonstration substantiating the theory of underskin evaporation in processes in which diffusion controls, and the drying potential is high. Measurable limits of undersurface evaporation

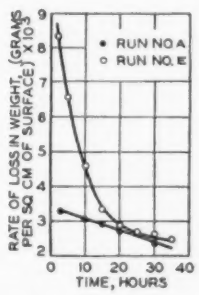

Fig. 9 Curves Indicating Nature of Drying Process

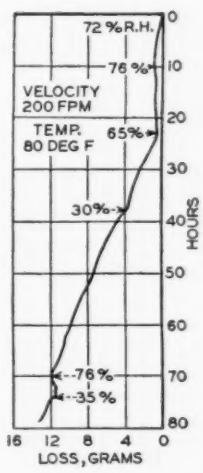

Fig. 10 (Right) Balance Record of a Run at Constant Dry Bulb and Varying Humidities

in many classes of materials should be susceptible of treatment by the use of salt solutions.

A curve of general interest taken from the recording balance is shown in Fig. 10. This was a miscellaneous run completed with the intention of investigating the correctness of the theory of regain as applied to drying. The theory is substantiated by this result.

In general the results obtained on experimental samples are not sufficient in number to enable analyses to be made. A new improved equipment is now in operation in which these results will be checked, and new ones obtained.

The results given herein were used to assist in the design of a commercial drier, now in operation for about 6 months.

Heat Transfer to Falling-Water Films

By W. H. McADAMS,[1] T. B. DREW,[2] and G. S. BAYS, JR.[3]

Data are presented in this paper for heating water as it flows by gravity in turbulent motion down the inner walls of vertical copper pipes, ranging in height from 0.41 to 6.1 ft. Heat balances check within 5 per cent and the temperature of the inlet water ranges from 38 to 146 F. The data are adequately correlated by the equation: $h = 120\Gamma^{1/3}$, where Γ ranges from 600 to 15,000 lb of water per hr per ft of width of stream. Steam-side and over-all coefficients are given. The rather inadequate data for streamline flow by gravity over nearly horizontal pipes (trombones) are reviewed.

Nomenclature

THE nomenclature which is used throughout this paper is given in the following list:

A = Area of heat-transfer surface, sq ft; A_i for inside, A_o for outside, A_{avg} for wall

C = Specific heat of liquid, Btu per lb per deg F

D = Diameter, ft; D_i for inside, D_o for outside

g_L = Local acceleration due to gravity, approximately 4.18×10^8 ft per hr per hr

h = Individual coefficient between tube surface and water layer, Btu per hr per sq ft per deg F; h_w for inside with turbulent flow, based on logarithmic-mean temperature difference; $h_{a.m.}$ for outside, with streamline flow, based on arithmetic-mean temperature difference

h_{ST} = Individual coefficient between steam and outer wall, Btu per hr per sq ft per deg F, based on saturation temperature of steam and length mean temperature of wall on steam side

k = Thermal conductivity, Btu per hr per sq ft per unit temperature gradient, deg F per ft

L = Distance, ft; L for thickness of tube wall; L_H for height of heating surface; for vertical tubes, L_H is the height; for horizontal tubes, $L_H = \pi D_o/2$

q = Rate of heat transfer, Btu per hr

Re = Reynolds' number $= 4\Gamma/\mu$; Re_m is based on μ_m, Re_f on μ_f

t = Temperature, deg F; t_1 for entering liquid; t_2 for exit; t_p for mean temperature of the surface of the pipe; t_{ST} for steam

U_i = Over-all coefficient of heat transfer, Btu per hr per sq ft of inside surface per deg F logarithmic-mean over-all difference from steam to water

w = Water rate, lb per hr leaving the tube

x = Length of horizontal tube, ft

Γ = Water rate from tube per unit width of stream, lb per hr per ft; for vertical, $\Gamma = w/\pi D_i$; for horizontal, $\Gamma = w/2x$

(Δt) = Temperature difference, deg F; $(\Delta t)_o$, over-all from steam to water; $(\Delta t)_{ST}$, on the steam side; $(\Delta t)_p$, through the pipe wall; $(\Delta t)_i$, on the inside

μ = Absolute viscosity, lb per ft per hr; $\mu_m = (\mu_1 + \mu_2)/2$; μ_f at film temperature; μ_a is taken at $(t_1 + t_2)/2$; μ_s is taken at t_p

π = 3.1416

ρ = Density, lb per cu ft

Introduction

The vertical shell-and-tube condenser, used widely in the refrigeration industry, is cooled by layers of water flowing by gravity down the inner walls of the tubes. Published information from several sources (1, 2, 3)[4] report over-all coefficients of heat transfer from condensing ammonia to water in such apparatus. No corresponding individual heat-transfer coefficients were available, and the work described in this paper was undertaken to fill this need.

Apparatus and Procedure

Three single-tube vertical falling-film heaters were constructed, each being heated by steam condensing on the outer wall of the tube. The three heaters have been described in an article (4), giving results for streamline flow of hydrocarbon oils. Table 1 summarizes the essential dimensions.

TABLE 1 NOTES ON VERTICAL APPARATUS

Heater no.	1	2	3
Heated length, L_H, ft	2.00	0.407	6.08
Inside diam of test section, in.	2.50	1.50	2.50
Outside diam of test section, in.	2.88	2.25	2.88
Metal for wall	Copper	Copper	Copper
Metal on steam side	Chrome plate	Chrome plate	Copper
Promoter on steam side	Oleic acid	Oleic acid	Benzyl mercaptan
Bakelite calming section, ft	0.50	0.75	0.75
Number of pipe-wall couples	10[a]	None[b]	10[c]
Jacket material	Steel	Pyrex glass	Copper-plated steel
Inside diam of jacket, in.	5.05	8	6.07
Filtered steam	Yes	No	Yes

[a] In heater No. 1 the five pairs of pipe-wall thermocouples were 1, 5.25, 12.25, 19.25, and 23.5 in. from the top of the heated section.

[b] In order to determine the average steam-side coefficient, a plot was made of $1/U_i$ vs. $1/\Gamma^{0.3}$, which gave h_{ST} of 10,000.

[c] In heater No. 3 the five pairs of pipe-wall couples were 2 7/16, 18 7/16, 34 7/16, 50 7/16, and 66 7/16 in. from the top of the heated pipe.

The saturation temperature of the steam was used in calculating the logarithmic-mean over-all temperature difference from steam to water $(\Delta t)_o$. The mean temperature of the outer surface of the tube was obtained by graphically averaging the ten temperatures over the length of the tube. The saturation temperature of the steam, less the mean temperature of the tube, gave the mean temperature difference $(\Delta t)_{ST}$ from steam to the outer wall. The mean temperature drop $(\Delta t)_p$ through the copper wall was calculated from q, k, L, and A_{avg}. The mean temperature difference $(\Delta t)_i$ between the inner wall and the cooling water was taken equal to $(\Delta t)_o - (\Delta t)_{ST} - (\Delta t)_p$. The heat balances checked within 5 per cent and the rate of heat transfer q was based on the water rate and the measured temperature

rise.[5] The following coefficients were calculated and are shown in the tables of data and results

$$U_i = \frac{q}{(A_i)(\Delta t)_o} = \frac{\text{Btu}}{(\text{hr})(\text{sq ft inside})(\text{deg F})}$$

$$h_{ST} = \frac{q}{(A_o)(\Delta t)_{ST}} = \frac{\text{Btu}}{(\text{hr})(\text{sq ft outside})(\text{deg F})}$$

$$h = \frac{q}{(A_i)(\Delta t)_i} = \frac{\text{Btu}}{(\text{hr})(\text{sq ft inside})(\text{deg F})}$$

Tables 2, 3, and 4 show the data and results for one third of the runs, omitting duplicate runs which checked runs included in the tables.

Water-Side Coefficients in Vertical Tubes

It is clear from a study of the data that the water-side coefficient increases with increase in Γ, the water rate per unit width. Except for the runs[6] in which Re_f was less than 2100, the data for all three vertical heaters are plotted on logarithmic paper in Fig. 1 with h as ordinates versus Γ as abscissas. The average line AB corresponds to the equation

$$h = 120\Gamma^{1/3} \quad \ldots\ldots [1]$$

All the data of Fig. 1 lie between the two dotted lines laid off for deviations in h of ± 18 per cent. For the longest tube, the runs with preheated water of series VII, shown by the triangles of Fig. 1, agree reasonably well with those where the water entered without preheat, series I–VI, shown by the circles. It was difficult to employ values of Γ greater than 22,000 due to a tendency of part of the water to arc across the weir and flow down the center of the tube, instead of flowing in a layer down the wall. It is possible that the insertion of a plug in the core of the water feed pipe would have prevented this. From the plot of h versus Γ for turbulent flow, it is concluded that heated length had no substantial effect upon h in the range from 0.41 to 6.1 ft.

Table 3 shows runs in which the temperature of the inlet water was varied substantially while Γ was held constant at various values. Examination shows that h increased somewhat with increase in the inlet temperature of the water. Table 3 shows Re_f based on μ_f and Re_m based on $\mu_m = (\mu_1 + \mu_2)/2$. The ratio $h/\Gamma^{1/3}$ was plotted against both μ_f and μ_m. In neither case was the per cent variation large for $h/\Gamma^{1/3}$, μ_f, and μ_m; the plot involving μ_m gave a somewhat better line than that with μ_f, and indicated

[5] Condensate was not measured for heater No. 2.

that $h/\Gamma^{1/3}$ varied inversely as $\mu_m^{1/3}$. Consequently the data of Fig. 1 for all three heaters were plotted on logarithmic paper in Fig. 2 as h versus Re_m, and a line CD having a slope of one third was drawn, giving the relation

$$h = 95 Re_m^{1/3} \quad [2]$$

The bulk of the data lie between the two dotted lines which are laid off for deviations of ±20 per cent in h. Although the use of Re_m instead of Γ somewhat improved the correlation of the data for the shortest tube, the high-temperature runs for the longest tube, shown by triangles, show a deviation of nearly 30 per cent, whereas the same data in Fig. 1 did not deviate from the average line by more than 12 per cent. The correlation of Fig. 1 is preferred to that in Fig. 2.

OVER-ALL COEFFICIENTS

Heater No. 2 was also operated with an upflow of water so that the water filled the pipe. The corresponding over-all coefficients are shown in Fig. 3, compared with the data for downflow in layer form. In the range of Γ common to both types of

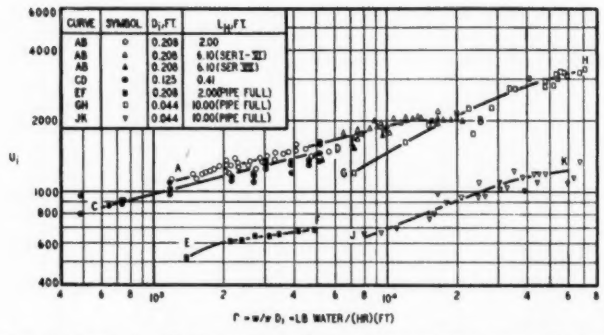

FIG. 3 OVER-ALL COEFFICIENTS FROM STEAM TO WATER FOR THREE VERTICAL FALLING-FILM HEATERS, COMPARED WITH DATA FOR TWO VERTICAL TUBES, RUNNING FULL

(The vertical falling-film heater *AB* gives over-all coefficients 2.2 times those *EF* for the same pipe running full; dropwise condensation on chrome plate, promoted with oleic acid, was used in both cases. For the 10-ft length of standard ½-in. copper pipe running full [Ref. 6], the use of dropwise condensation on chrome plate, promoted with oleic acid *GH* gave over-all coefficients over twice those obtained *JK* without added promoter.* For curves *GH* and *JK*, a value of Γ of 10,000 corresponds to a velocity of 4.06 ft per sec.)

flow (Γ ranging from 1700 to 5000) the falling-film arrangement gave over-all coefficients 2.2 times those for upflow. This increase is due to the fact that the water velocity, for a given water rate, is higher for flow in film form.

STEAM-SIDE COEFFICIENTS

Abstracts of the steam-side coefficients for heaters Nos. 1 and 3 have appeared earlier (5, 6). Tables 2 and 4 show the results. The range of the values of h_{ST} for all three heaters is summarized in Table 5.

HORIZONTAL PIPES—WATER-SIDE COEFFICIENTS

Data (7, 8) for the gravity flow of water over nearly horizontal pipes lie in the region of streamline flow. For these runs it was assumed that half the water flows down each side of the pipe, and hence Γ was taken as equal to $w/2x$, where $w/2$ is the water rate for each stream, and x is the length of the pipe. As for vertical pipes, Re_m was taken as $4\Gamma/\mu$. Since the references (7, 8) did not give the water temperatures, it was necessary to base the coefficients for the horizontal pipes on the arithmetic-mean temperature difference, the type of mean customarily arbitrarily used for runs in streamline flow. Except at the low values of Γ, the resulting coefficients $h_{a.m.}$, are not far different from those which would have been obtained using the logarithmic-mean temperature difference.

For a given Γ, the data for streamline flow over horizontal pipes indicate that $h_{a.m.}$ is an inverse function of the height of the heating surface, $\pi D_o/2$. In the range of the data, for a given Γ, $h_{a.m.}$ varied approximately as $D_o^{-1/3}$; for a given D_o, $h_{a.m.}$ varied approximately as $\Gamma^{1/3}$, for values of Γ ranging from 150 to 400. As shown by Fig. 4, for values of Γ/D_o of 600 and more, the data for horizontal pipes may be approximated within ±25 per cent by the equation

$$h_{a.m.} = 65\left(\frac{w}{2xD_o}\right)^{1/3} = 65\left(\frac{\Gamma}{D_o}\right)^{1/3} \quad \ldots\ldots [3]$$

If the diameter were very large or Γ were very small, the water would be heated to substantially the temperature of the wall, and the final temperature difference, $t_p - t_2$ would approach zero. For the case of negligible evaporation, by definition

$$h_{a.m.} = \frac{(2\Gamma x)(C)(t_2 - t_1)}{\left(\pi D_o x\right)\left(t_p - \frac{t_1 + t_2}{2}\right)} \quad \ldots\ldots [4]$$

The corresponding limit, for $t_p = t_2$ is

$$h_{a.m.} = \frac{4C}{\pi}\left(\frac{\Gamma}{D_o}\right) \quad \ldots\ldots [5]$$

Equation [5] is plotted as the line *AB* on Fig. 4. If there were no evaporation, all points would have to lie to the right of *AB* approaching it asymptotically as Γ/D_o is decreased. At low water rates, the points on Fig. 4 are seen to lie to the left of *AB*, possibly indicating substantial evaporation.[7]

Data (7) for the three horizontal pipes fall within ±25 per cent of the following semitheoretical equation based on stream-

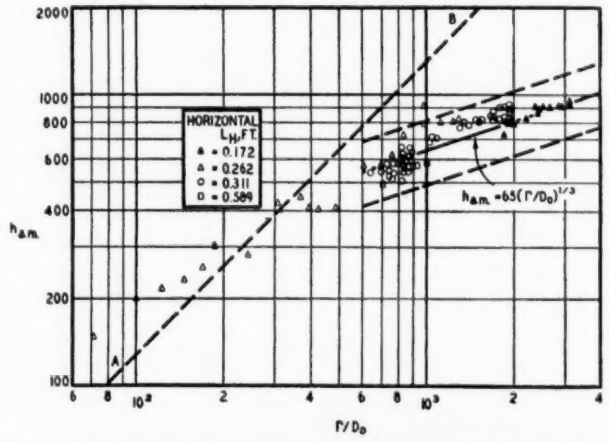

FIG. 4 WATER-SIDE COEFFICIENTS FOR HORIZONTAL (TROMBONE) HEATERS, PLOTTED AS $h_{a.m.}$ VERSUS (Γ/D_o)

(The dotted line *AB* represents the limiting case where the exit water is heated to wall temperature without evaporation, Equation [5]. In the range of Γ/D_o from 600 to 3000, the coefficients for the various sizes of pipe are roughly correlated by the equation $h_{a.m.} = 65\ (\Gamma/D_o)^{1/3}$.)

line flow of oils down the inner walls of the three vertical heaters (4)

$$\frac{h_{a.m.}}{k}\left(\frac{L_H k \mu_a^{1/3}}{C\rho^{4/3} g_L^{2/3}}\right)^{1/3} = 0.67\left(\frac{\mu_a}{\mu_p}\right)^{0.25}\left(\frac{4\Gamma}{\mu_a}\right)^{1/3} \quad \ldots\ldots [6]$$

This relation requires that $h_{a.m.}$ vary inversely as the one-third power of L_H, as shown in Fig. 4. The effect of viscosity on $h_{a.m.}$, predicted by Equation [6], is directly as $\mu_a^{0.025}/\mu_p^{0.25}$. Since in the water runs μ_p varied but little, no substantial effect of viscosity would be expected, and none was found (7, 8) for the water flowing over horizontal pipes. However, Equation [6] predicts that $h_{a.m.}$ varies directly as $\Gamma^{1/3}$, as was found to be the case for the oils, but the data for water on horizontal pipes show that $h_{a.m.}$ varies approximately as $\Gamma^{1/3}$, for Γ above 100. This increased percentage effect of Γ in the streamline region may be due to the presence of ripples in the water layer. The "horizontal" pipes (7, 8) were slightly inclined to facilitate flow of condensate, and the inclination would give an axial component to the water velocity. One (8) of those observers noted ripples in the water layer

* However, as explained in reference 6, "mixed condensation" was obtained in run *JK* due to a small concentration of promoter normally present in the boiler steam used. Data for film-type condensation are given as curve *D*-I of Fig. 1 of reference 6.

[7] The values of $h_{a.m.}$ were apparently based on the condensate rates. Although the rate of flow of effluent water was measured, it is not clear whether Γ was based on the rate of discharge of water or upon the mean of the rates of water feed and discharge. The rise in water temperature was not published, nor was the per cent evaporated given.

and found that the thickness of the water film at the side of the tube varied widely with position along the length.

Summary

Although predictions can be made most closely by using the plots of h versus Γ, and of $h_{a.m.}$ versus Γ/D_o, the following equations are recommended for approximate purposes:

For turbulent flow of water in layer form down vertical tubes, Γ ranging from 600–15,000 lb per hr per ft of stream width

$$h = 120\Gamma^{1/3}$$

with a deviation in h of ±18 per cent.

For the streamline flow of water over nearly horizontal tubes, Γ/D_o ranging from 600 to 3000

$$h_{a.m.} = 65\left(\frac{\Gamma}{D_o}\right)^{1/3}$$

with a deviation in $h_{a.m.}$ of ±25 per cent.

Discussion

N. C. Ebaugh.[8] The writer would like the authors to answer the following questions:

1 What provision was made in the experimental apparatus for determining the quality or the superheat of the entering steam or, in other words, how was the enthalpy of the entering steam measured? The accuracy of the results has not been questioned since the heat balances were reported to check within 5 per cent. This is merely a request for additional information on the experimental procedure for problems of this type.

2 The over-all coefficient of heat transfer, when dropwise condensation was not promoted appears to be rather high when compared with other available data. Would the authors care to comment on the possible reasons for these high figures?

Authors' Closure

In reply to Professor Ebaugh's first question: High-pressure steam (at pressures usually ranging from 200 to 300 lb gage) from a well-drained line was reduced in pressure through a series of two regulators, giving superheated steam, the temperature and pressure of which were measured at a section just ahead of the jacket on the test section. The saturation temperature of the steam, corresponding to the pressure in the jacket, was used for computing temperature difference, and the enthalpy of the superheated steam was used in the heat balance.

The second question refers to the results (6) shown by curve *JK*, Fig. 3 of the paper. In the preprint, the subtitle to Fig. 3 failed to bring out the fact that a small amount of oleic acid was unavoidably present in the boiler steam used, although this was clearly stated (6). This defect in the subtitle of Fig. 3 was brought out in oral discussion, and the subtitle was revised at that time. The results of curve *GH* of Fig. 3 were obtained when using additional oleic acid above that normally present.

Curve *D-I* of Fig. 1 (6) gives results for a 6-ft × $^5/_8$-in-outside-diam vertical tube of Admiralty metal, operated where it was possible to employ atmospheric-pressure steam sufficiently pure to obtain film condensation, giving U_i of 500 at 6.3 fps.

Temperature Distribution and Sources in the Conventional Railway Journal Box

By E. S. PEARCE,[1] INDIANAPOLIS, IND.

The author presents the results of an investigation on heat distribution in a conventional journal-box assembly, in the process, outlining the exact test procedure followed. He concludes that the control of heat sources is the first step in avoiding limiting effects of temperature rise in the assembly, and that the condition of the waste, the oil used, and the bearing are the basic factors in controlling these sources.

THE purpose of this paper is to set forth certain data illustrative of the distribution of heat generated in the conventional railway journal-box assembly. These data have been collected collaterally with an extended investigation of heat causes or sources and their control in journal-bearing operation on railroad rolling stock. In a sense, this is an uninterrupted continuation of research and development work described in a previous paper by the author.[2]

The same plant and equipment, as described in that paper, were used for these tests, the amplification of equipment being the application of some 53 thermocouples to a $5^1/_2 \times 10$-in. journal box and contained parts. Fig. 1 shows the box in place on the test plant. Fig. 2 shows diagrammatically the exact location of all the thermocouples and their numerical designation. Fig. 3 shows the method of attachment of thermocouples and their specific location in the bearing and wedge. Fig. 4 is a diagram of the internal arrangement of a thermocouple. Fig. 5 shows the location of the thermocouples in the bearing surface to obtain oil-film temperatures. These are thermocouples Nos. 7, 8, 9, 10, 11, and 12, Fig. 2.

Test Procedure

The preparation for these tests consisted of packing the journal box in the conventional manner with a good grade of wool packing, saturated with oil in the ratio of $3^1/_4$ lb of oil per lb of waste. The car oil used was of a standard brand, having a viscosity of 45 sec Saybolt at 210 F. The combined quantity of waste and oil weighed 8 lb, consisting of $1^7/_8$ lb of waste and $6^1/_8$ lb of oil. Conventional standard Association of American Railroads (A.A.R.) $5^1/_2 \times 10$-in. journal bearings, broached to insure a fixed width of crown, were used. All tests were conducted under a fixed total load of 20,000 lb, giving a unit loading of 890 lb per sq in. of projected actual bearing area.

Tests were run at operating speeds of 20, 40, and 60 mph, equivalent to 268, 536, and 804 ft per min journal surface speed, with rpm of 186, 372, and 558, respectively. A 7-hr continuous run was made at each respective speed, at which time all temperatures recorded were at their stabilized maximum. These temperatures are shown in Fig. 6. Atmospheric temperatures were maintained within practical limits at approximately those of high summer temperatures. Tests were duplicated under conditions of still air and under conditions of moving air, the velocity of the air being proportional to speed, and blowing against one side of the box in the conventional manner obtaining with the journal box under actual service.

For reference purposes, tests were run with the journal submerged in an oil bath to a depth of 1 in., indicated in Fig. 2 as "oil bath only," such tests being designated by this term. The same cycle was used as with the conventional waste pack. A sample comparison, in terms of temperature rise above atmospheric temperature, is shown in Fig. 6 for the temperature at each of the 53 thermocouple locations, as shown by Fig. 2. The temperatures shown in Fig. 6 represent in each case the maximum temperatures obtained after 7 hr continuous running at each respective speed under high atmospheric temperatures.

In general, the center of the journal has the highest temperature; the bearing has the next highest temperature; then, the oil film between the two; and then, the wedge on top of the bearing. The packing temperature is lower than the wedge and lower than the oil film. The temperature of the top of the box is lower than the wedge and the waste pack.

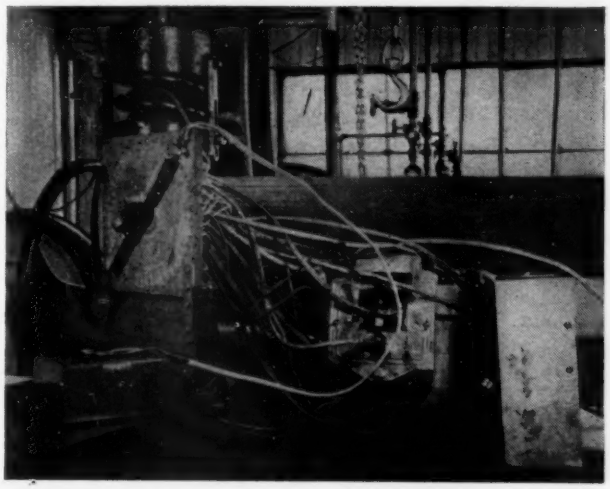

Fig. 1 Box in Place on Test Plant

The comparative temperatures, shown in Fig. 6, are not a measure of the relative proportion of friction losses between perfect bath lubrication and waste-pack lubrication. They have no significance in this respect at all. At 20 mph, the difference in friction loss between bath lubrication and the waste pack was 3.25 per cent; and at 40 mph it was 1.06 per cent, bath lubrication having the lowest loss. At 60 mph, the difference was 1.6 per cent, the waste pack having the lowest loss. No difference in friction could be expected between the two methods of lubrication, due to the fact that the bearing surfaces were receiving all the oil necessary for successful operation and all other conditions were the same.

(SVI-45 sec oil; atmospheric temperature constant at 50 F; cotton waste at 3.25 to 1 saturation; still air.)

Operation in still air and perfect flood lubrication have no practical application in the operation of railroad equipment. It is shown here only to reflect the insulating effect of the waste pack and the effect of air flow against the journal box. Railroad journals to operate at all are immediately subject to air movement. Flood, or bath lubrication, of railroad journals has many mechanical and operating limitations. Due to the fact that railroad journals operate under wide fluctuations of temperature, the insulating effect of waste might be considered an aid to lubrication in its influence on oil viscosity, which would otherwise be controlled by rapid temperature changes, as would exist with flood lubrication. The data reflecting the effect of flood lubrication in still air are to a degree representative of the operating conditions encountered in power-consuming or generating units of a stationary nature.

EFFECT OF VISCOSITY AND CLEANLINESS OF LUBRICATING OIL ON JOURNAL-BOX TEMPERATURES

One common factor which influences the amount of heat generated in a journal-box assembly is the viscosity and cleanliness of the lubricating oil. To illustrate this, Fig. 7 reflects the temperature of the center of the journal under no load and without a bearing, comparing the temperature effect of new oils of 45 sec and 60 sec viscosity at 210 F, dirty oil as removed from service with a viscosity of 61 sec, and this same oil after cleaning with a viscosity of 54 sec at 210 F.

The effect of the bearing under load, as a source of increased journal temperature, is not a factor. It will be seen from Fig. 8 that the bearing serves to reduce the operating temperature of the journal by the fact that it aids materially in the dissipation of heat. This is because it provides the principal path for the transfer of the generated heat to the walls of the journal box. This obtains, however, under the condition of clean journal-box packing and with a bearing in proper mechanical condition. Dirty packing and/or a bearing in improper mechanical condition may be a limiting factor in operation by adding to the heat normally generated in excess above that possible of dissipation through the bearing. The modification of the conventional bearing to compensate further for the effects of temperature and to augment its heat-dissipating capacity has produced outstanding improvements in the actual service operation of bearings.

In Fig. 8 is also shown the temperature of the center of the journal as affected by clean dry waste, and with clean oil-saturated packing, without a bearing or load. Dry packing, or packing with a reduced oil content, approaches the temperature effect of the dry waste shown in proportion to the oil deficiency, which would be further augmented by increasing the dirt content of the packing, as reflected by the combined evidence of Figs. 7 and 8. In actual operation this condition is a source of heating, which is due to the effects of service, producing undersaturated dirty packing.

CONCLUSION

Obviously, the control of heat sources is the first step in avoiding the limiting effects of excessive temperature rise in the conventional journal-box assembly. The conditions of the waste, the oil, and the bearing are the basic factors in controlling temperature sources. There is no economic substitute for clean journal-box packing properly saturated. The proper conditioning of bearings at the time of initial installation, and their modification in design to compensate for the effects of temperature, increase the factor of dependable operation. The extensive reduction to practice of these fundamental principles by several railroads has amply demonstrated their value.

Discussion

G. [illegible] CARELITZ.[3] This comparison of temperatures recorded under several modes of operation and at various locations in the test bearing is rather interesting. In the waste-packed bearing, the temperatures of the journal and brass are considerably higher than those observed with the oil bath, but the wall temperatures are appreciably lower. In other words, the temperatures are more even in the case of the oil bath, while the temperature gradient from journal to wall is much steeper in the waste-packed bearing. This, no doubt, is caused by the oil thrown by the shaft from the bath onto the walls. The oil splash acts effectively in carrying heat from the journal and bearing to the walls. On the other hand, the heat generated in the oil film must travel in the waste-packed bearing by way of the brass, wedge, and bearing top to the bearing walls for final dissipation into the surrounding atmosphere by convection.

The temperature of the oil film was considerably higher in the case of the waste-packed bearing, the respective average temperature rise being 147 deg and 88 deg for waste packing and oil bath (60 mph, still air). The viscosity of the oil was, therefore, considerably higher with the oil bath, and the friction was correspondingly higher. This accounts for the higher wall temperature with the oil bath. The respective average wall-temperature rise was approximately 71 deg and 59 deg, indicating that the losses in the oil-bath bearing were some 20 per cent higher than in the waste-packed. This is at variance with the estimates given by the author. It would be of interest to know how the friction was measured, and to investigate the discrepancy.

The same general condition has developed in the experiments with moving air. However, in the absence of data on the character of draft and its velocity, no comparison can be drawn between the operation in still and in moving air.

Several years ago, the writer, while carrying on work with waste-packed bearings, also had occasion to measure the temperature at the center of the journal by means of a thermometer inserted in the journal. At that time, the temperature was found to be also the highest in the bearing. The heat transfer along the shaft is inappreciable because the heat conductivity of steel is rather low, and the temperature gradient along the shaft is small, due to the presence of a hot supporting bearing in the close neighborhood of the test journal. The center temperature of the journal is, therefore, fairly close to the average temperature of the oil film.

A further analysis of the data published by the author, with a full utilization of the test records and observations, can give a most interesting study in the heat transfer in a railway bearing. This would form a notable contribution to the general subject of temperature distribution in bearings.

C. B. SMITH.[4] The conclusions in this paper merit the careful consideration of all interested in reducing the number of hot boxes occurring on passenger and freight trains.

The comparison of the high temperatures in charts, Figs. 6 and 8, indicates the significance of the journal bearing as a path for the dissipation of heat and directs attention to the proper relation to each other of the surfaces of the journal and of the bearing. Another chart might well have been included in the paper, showing a comparison of temperatures of the bearing with those at the center of the journal. This would illustrate more clearly the data shown in Figs. 6 and 8.

The heat-generating effect of dirty oil and the reduction in

temperatures attained after cleaning the dirty oil are impressively revealed in Fig. 7, even when no bearing and, hence, no load is involved.

The effect of dry or undersaturated packing in causing temperature increases ranges from 14 to 26 per cent, as shown in Fig. 8. This justifies free oiling of journal boxes when restoring cars to service which have been idle for a long period, especially in extremely hot weather. Fig. 6 clearly shows that the journal runs hotter than the bearing and emphasizes the maintenance of the best lubricating medium between the journal and the bearing, thus minimizing the heat transferred to the lead lining of the bearing.

The conclusion that the cleanliness of journal packing is economically important should impress those who favor the longer periods between repacking of journal boxes with clean, renovated packing waste.

The Boston & Maine Railroad has made some studies of the relation between the occurrences of hot boxes in freight-train service and the elapsed time between packing renewals. The hot boxes in freight trains on that railroad occur in cases where packing has been in service from 8 to 9 months. Figs. 9 and 10 of this discussion show that beyond 10 months elapsed time, the hot boxes occur at an increasing rate up to 15 months elapsed time and, thereafter, rapidly up to 18 months. A reduction of the repacking period to 9 or 10 months should show justifiable results.

Author's Closure

In the comment by Dr. Karelitz on frictional losses at 60 mph, comparing bath lubrication with waste-pack lubrication, since all conditions were the same on the entire test unit, except the absence of waste in one case and its presence in the other, total input in kilowatts per hour for each of the three 7-hour runs is a true basis of comparison for the determination of frictional losses with the following result:

60 Miles per hr, 7 hr, 20,000 lb load	Average kilowatts per hour — Test run — No. 1	No. 2	No. 3
With oil bath	2.59	2.58	2.61
With waste pack	2.59	2.74	2.70

Obviously the same amount of frictional heat must have been created in both cases. The fact that it was distributed differently to the walls of the box is a phenomenon which has no significance in establishing the quantity at the source.

The points brought out by Mr. Smith are particularly interesting, since they demonstrate that the results of the laboratory findings can be and are reproduced and their effect measured in terms of actual service. To illustrate more clearly, as Mr. Smith points out, the data shown in Figs. 6 and 8, Fig. 11 is included showing the comparison of temperatures of the bearing with those at the center of the journal, for the purpose of giving the effect of oils of approximately the same viscosity; but in the one case clean oil and in the other case dirty oil was used. These charts, taken particularly in connection with Figs. 9 and 10 shown by Mr. Smith, reflect in practical operation the effect of an accumulation of dirt in car-journal oil as it affects journal temperatures.

Purchase and Use of Fuel

By E. WADSWORTH STONE,[1] THOMPSONVILLE, CONN.

In this paper, the author discusses the location of industry, sources of its fuel supply, available competing fuels and their relative cost, the purchaser's combustion equipment, the method and efficiency of conversion, all of which are factors influencing the cost of power and the fuel necessary to produce it. The history of fuel production, supply, regulation and use, and the substantial improvement in combustion equipment during the last twenty years afford an interesting commentary upon the complicated problem of fuel purchase and supply.

FUEL represents potential energy for release in the form of heat, and its purchase and use involve many interrelated factors.

Consumers evaluate fuel according to the recoverable heat when this is converted in their own equipment and for their own use. Consumer interest will vary to the extent that certainty of fuel supply and fuel cost are important factors in their own production problem.

Producers, to continue in business, must realize in the aggregate their true actual cost of fuel production, preparation, and sale. Producers must also accurately appraise markets, consumer needs, and available conversion equipment in the preparation and merchandising of their fuels successfully to meet competition.

Consuming markets seldom are located at or adjacent to the sources of supply. The cost of transportation, definitely established for whatever means employed, therefore constitutes a necessary, measurable, and usually a major factor in the delivered fuel cost.

The cost of production, distribution, and utilization thus determines the character and extent of the fuel markets, price levels, and the relative values of competing fuels available in any common consuming market.

Regulation, either state or federal, provided it properly recognizes the public, producer, and consumer interests, and fair existing competitive opportunities, may prove helpful. But regulation which ignores the effects of changing economic conditions and disregards the ordinary flow of fuel, in response to normal supply and demand under normal conditions of free and open competition, may cause a shift of markets and a permanent dislocation of production and consumption sufficient to offset any immediate temporary or localized gain.

Integrated valuations of fuel by producer and by consumer, measured one against the other, will determine its fair average value. Any abnormal or arbitrary departure therefrom will adversely affect the producers of fuel and the consuming markets they serve.

Location—Industry and Fuel Supply

This country's growth, commencing at the Atlantic seaboard, has largely been toward the West and Northwest, with industry's movement and location generally determined by the availability of raw materials, consuming markets, and convenient means for the distribution of manufactured products.

Fortunately, acceptable fuels were usually accessible. Fortunately too, excepting a few industries like steel and glass, fuel constitutes but a minor portion of the raw-material requirement. Moreover, the development of power represents but a small, although increasing, part of the cost of production, due to the continued advance in the cost of manual labor. Transportation factors governing commodity movement were also favorable toward the convenient supply of fuels.

Initially, industry, particularly in New England, was located to make use of available water power. Increasing power requirements later necessitated the installation of steam relay stations and, eventually, the use of purchased power.

The gradual movement of industry westward, and its convenient location along rivers, lakes, railroads, and other available means of transportation, has brought about a corresponding redistribution of industrial-fuel markets and, likewise, shifts in the centers of population and domestic-fuel markets.

In each instance, the continued effort to secure lower costs of heat and power has stimulated the use of more efficient combustion equipment and lower grades and less expensive kinds of fuels.

From 1889 to 1929, energy for all uses increased approximately sixfold; from 1909 to 1929, industrial power requirements increased some twofold; and in the last 20 years, the use of electric energy has increased threefold. This increase in the use of power, particularly of electrical energy, has brought about the installation of many large generating stations in and near important industrial centers.

Extensive transmission systems have been provided to interconnect large steam-generating plants and the near-by hydrostations. In spite of this augmented flexibility of generation and supply of electrical energy, the relatively limited storage facilities at the source and at consumers' plants require continued and even greater dependence upon the transportation systems for high-speed service, reliability, and continuity of fuel supply.

Frequently, reference is made to the location of large generating stations at the mine or other source of fuel supply, but the fuel-transportation factor may be offset by the lack of condensing water at the mine and the economics of electrical-energy transmission. Bituminous coal has been and undoubtedly will continue to be the principal source of steam and electrical energy. Competing fuels and hydropower are making substantial increases, although seasonal variations in the latter may necessitate steam relay stations. Calculated at the prevailing fuel rate for electrical energy, the percentage of hydropower to the total energy consumption has approximated 3 to 4 per cent (1, 3)[2] since 1899.

Competing Fuels

Coal deposits, with minor exceptions, are conveniently accessible to all consuming markets. On the other hand, oil is produced principally in the states of California, Oklahoma, and Texas, and to a lesser degree in several other states. The producing areas for natural gas roughly coincide with those for oil.

Bituminous coal, fuel oil, and natural gas not only compete with each other in those markets easily reached or favorably situated, but with domestic anthracite in the East and with manufactured

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

gas and coke in many industrial centers throughout the United States.

New England is a good example of a competitive fuel market. Imported fuels are a negligible factor, but the production of hydropower and the use of fuel oil, anthracite, and bituminous coal, together with the by-product forms of manufactured gas and coke, present to both the industrial and domestic consumer a wide variety of fuels from which to choose.

The importation of oil, although frowned upon by producers of competing fuels, has the effect of preserving our country's rather limited oil reserves. On the other hand, the importation of foreign coal, particularly anthracite along the Atlantic seaboard, does detract from the potential markets for solid fuel, of which there is available several thousand years' supply.

Energy Consumption

TABLE 1 TOTAL ENERGY SUPPLY—ALL FUELS AND WATER POWER[a] (1, 3)

Year	Annual energy supply, Btu (trillions)	Coal equivalent[b] in million tons
1909	14284	545
1918	21706	830
1929	25421	972
1937	24183	921

[a] Refer also to Figs. 1 and 2.
[b] 26.2 million Btu per ton of bituminous coal.

The total annual supply of energy from mineral fuels and water power (at the prevailing central-station heat equivalent) closely approximates 25,000 trillion Btu. As now proportioned, this may be expressed in terms given in Table 2.

Approximately 70 per cent of the total bituminous-coal tonnage is produced in the eastern or Appalachian fields, 18 per cent in the middle-western fields (minimum price areas (2, 10) Nos. 1 and 2, respectively), and the balance in varied and scattered amounts in the South and in the Rocky Mountain and northwestern states.

TABLE 2 ESTIMATED ANNUAL NORMAL PRODUCTION

Bituminous coal	440 to 480 million tons
Anthracite	50 to 60 million tons
Petroleum	1280 to 1300 million bbl
Natural gas	2450000 million cu ft
Hydropower	45000 million kwhr

Note: Coke and manufactured gas involve the consumption of other primary forms of fuel and are not included.

The annual consumption of bituminous coal in the market areas east of the Mississippi River, for industrial and domestic uses, excluding export, railroad, and bunker fuel, approximates $^3/_4$ of the total tonnage of the United States, apportioned (4) as shown in Table 3.

TABLE 3 ANNUAL CONSUMPTION OF BITUMINOUS COAL IN EAST

	Million tons
New England States	17
New York State	23
Pennsylvania, West Virginia, and other North Atlantic States	75
Other states south of the Ohio and east of the Mississippi Rivers	42
States north of the Ohio and east of the Mississippi Rivers	162

Substantially all the anthracite is produced in eastern Pennsylvania and consumed in the North Atlantic States.

The principal consumption of fuel and gas oil is in the producing and adjacent areas and those markets conveniently

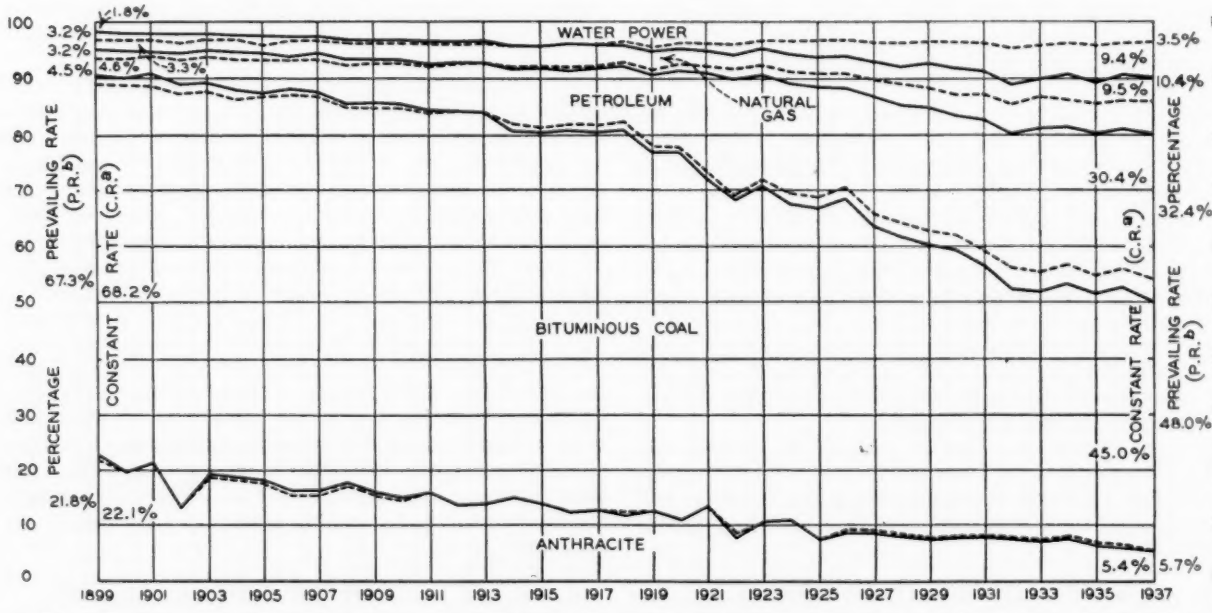

Fig. 1 Percentage of Total Btu Equivalent Contributed by Anthracite, Bituminous Coal, Petroleum, Natural Gas, and Water Power in the United States, 1899–1937

(From supplement to Weekly Coal Report No. 1084 of The National Bituminous Coal Commission.)

Notes on Fig. 1

[a] C.R. Water power at constant rate;———— 1913 rate, 4.02 lb per kwhr
[b] P.R. Water power at prevailing rate; – – – – – – 1918 rate, 3.36 lb per kwhr; 1937 rate, 1.42 lb per kwhr

Unit heat values used

Kind of fuel	Btu value
Anthracite	13600 per lb
Bituminous coal	13100 per lb
Petroleum	6000000 per bbl
Natural gas	1075 per cu ft

Water power equivalent (C.R.) is based on the year 1913 or mid-point of years compiled (1889–1937) and is the constant factor of 4.02 lb of coal per kwhr
Water power equivalent (P.R.) is based on the prevailing factor which varies from 7.05 lb of coal per kwhr in 1889 to 1.42 lb of coal per kwhr in 1937
When production of water power was not available, the horsepower equivalent was used, taken at 20 per cent capacity factor for manufacturing and mines and 40 per cent for utilities

reached via tidewater and pipe line. The total distribution (5) in 1937 approximated:

	Per cent
New England States	9
Middle Atlantic States	29
South Atlantic States	4
North Central States	14
South Central States	20
Rocky Mountain States	1
Pacific Coast States	23
Total	100

The consumption of natural gas likewise is generally confined to the producing areas, except where accessible by pipe line, with the total distribution (5) 1937 divided as follows:

	Per cent
California	14
Louisiana	13
Oklahoma	12
Texas	36
West Virginia	6
Other states	19
Total	100

In 1937, there was produced from fuels 77,348 million kwhr of electrical energy, and from water power, in competition with fuels, some 43,702 million kwhr, a total production of 121,050 million kwhr,[3] apportioned (6) as shown in Table 4.

[3] Approximately 128,000 million kwhr in 1939.

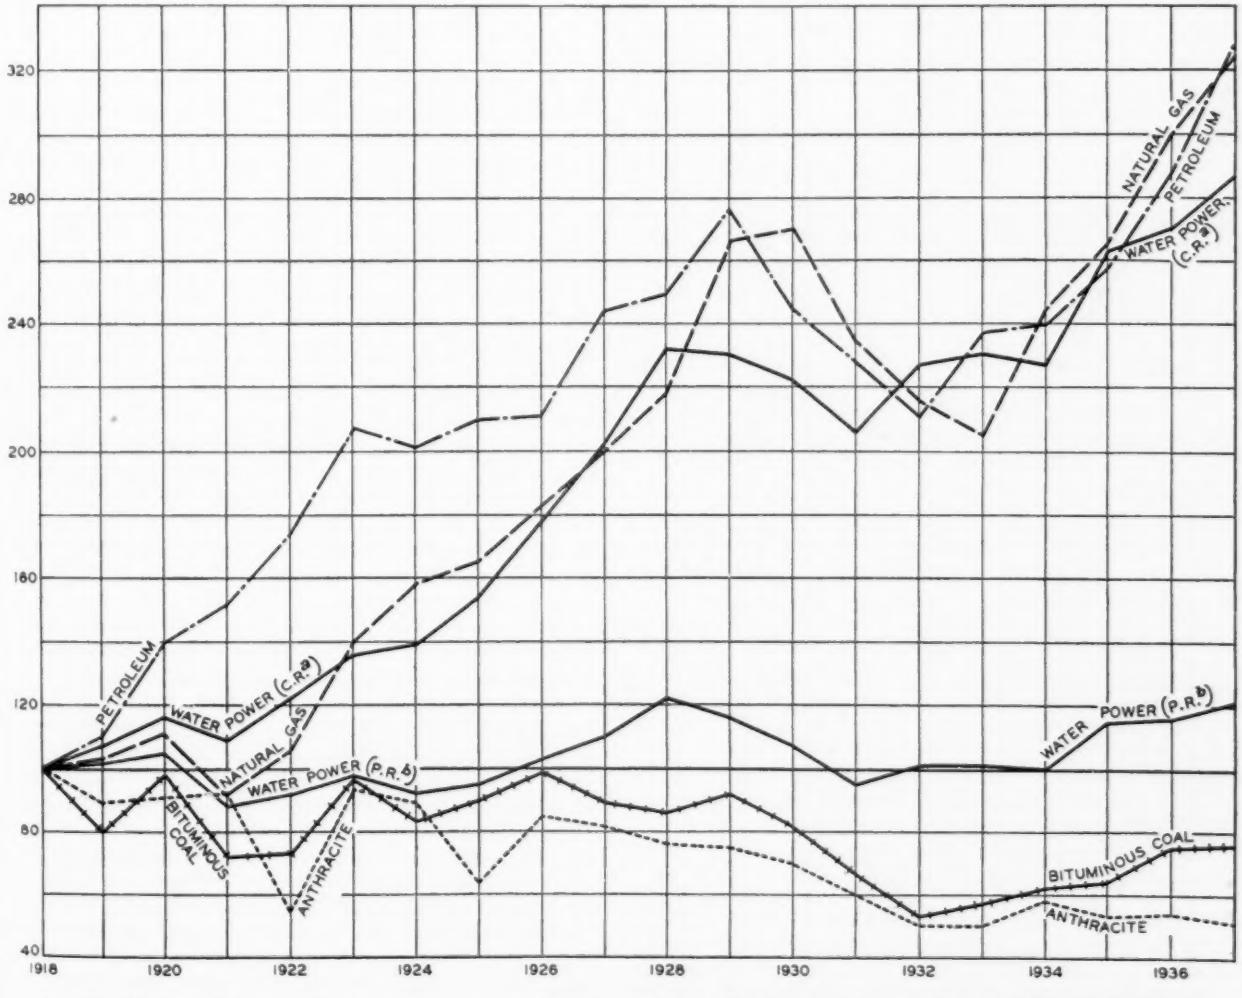

FIG. 2 RELATIVE RATE OF GROWTH OF ANTHRACITE, BITUMINOUS COAL, PETROLEUM, NATURAL GAS, AND WATER POWER IN THE UNITED STATES

Industrial	39	59
Hydropower		31
		683 to 733

Efficiency of Conversion

The improvement in efficiency of converting the potential energy of coal and other fuels into electrical, mechanical, or other useful forms of energy offers an interesting commentary upon the relatively constant total supply of energy from mineral fuels since 1918, except during the depression years of the 1920's and again in the 1930's. The following examples will illustrate this point:

The average number of pounds of coal required per 1000 gross ton-miles for freight service on steam railroads decreased from an average of 170 lb in 1919–1920 to 115[6] in 1938; a reduction of 32 per cent (4, 5, 7).

During the same period, the pounds per passenger-train car-mile decreased from 18.5 lb to 14.9;[7] an improvement of 19½ per cent (4, 5, 7).

In 1918, the production of a gross ton of pig iron required the use of the equivalent of some 3577 lb of coal, whereas, in 1938 this amounted to but 2865 lb; an improvement of nearly 20 per cent (4, 5).

The improvement in the efficiency of production of electrical energy is even more marked. It is reported that in 1889 the average consumption of coal was 7.5 lb per kwhr. This requirement (1, 4, 5, 6, 8, 11) was reduced in

1902 to 6.4 lb per kwhr
1912 to 4.5 lb per kwhr
1919 to 3.22 lb per kwhr
1920 to 3.04 lb per kwhr
1929 to 1.69 lb per kwhr
1938 to 1.41 lb per kwhr

The reduction since 1919 approximates 56 per cent.

Several central stations are now producing electrical energy for 0.75 lb of coal per kwhr, approximately ½ the 1938 average for the entire United States. Many factors have encouraged this improvement in efficiency and undoubtedly will continue to do so, although perhaps not to the extent possible in the past.

Equipment and Changes

The record is replete with coal analyses, boiler- and power-equipment tests, specifications and descriptions in general and in detail, including design, construction, and operation of modern steam-generating stations for the utilization of solid, liquid, or gaseous fuels, singly and in combination, and need not be further amplified in this paper.

Considerable thought has been given to the storage of fuel, its delivery to the furnace, the method of firing, combustion control, the removal of waste, desirable fuel characteristics, boiler design, operating pressures, capacities, and the rate of heat release. Much study has been devoted to size and arrangement of combustion space; gas velocities, to secure maximum rate of heat transfer; furnace temperatures; the use of waterwalls and special refractories to withstand the higher prevailing furnace temperatures; the use of alloy steels and welded construction; pulverizer design and the use of watercooled stokers.

Heretofore, the quantity of ash and of sulphur and the ash-fusion temperatures appeared to be limiting factors in the use of certain types of combustion equipment. Methods for continuous or intermittent ash removal, either in the dry or plastic state, have been improved. We know more about what actually takes place in the combustion of fuel and the behavior of ash on refractory and boiler surfaces. This has indicated that the slagging characteristics of a coal may be dependent upon the fusion temperatures of its component parts rather than an average of all, and that Fe_2O_3, lime, and other components of ash definitely influence slag formation. All this has helped to make possible the combustion of high ash pulverized coal with ash-softening temperatures as low as 2300 F, in a dry-bottom furnace, and, conversely, the use of high-fusion coals with ash-softening temperatures as high as 2550 F, in wet-bottom furnaces, the furnace temperatures in either case being controlling factors.

These numerous experiments, studies, and investigations, individually and collectively, constitute an important contribution to the use, operation, and efficiency of modern steam-generation equipment, and encourage still further improvement. The ex-

[4] Approximately 40 million kw at the end of 1939.
[5] 26,200,000 Btu per net ton.
[6] 112 in 1939.
[7] 14.8 in 1939.

perience and results obtained on the larger units have been and can be applied, with perhaps less refinement, to the smaller and simpler combustion units for industrial use, or for the modification and more efficient utilization of existing equipment.

Large utility and industrial consumers of fuel employ technicians to check fuels and power-plant operation carefully and frequently. To the small consumer, who may question the economic justification of such a check, there are now available fuel technicians and an extensive array of operating data. The larger producers of fuel maintain, for the convenience of their customers, technical staffs thoroughly acquainted with their fuels and frequently experienced in actual plant operation. The National Association of Purchasing Agents (9) has also reminded its membership of the more important factors influencing the use of fuels.

Heretofore, initial cost has frequently been permitted to influence the installation and use of steam-generating equipment, often to the extent of restricting it to a single or a limited number of types or grades or sizes of fuel.

There appears to be a growing realization among equipment manufacturers and, likewise, among the users of all kinds of fuel that, with very little additional effort and expense, steam-generating equipment, having a much wider range of fuel utilization, can now be manufactured and installed.

If this be a correct interpretation of the trend, this increase in the adaptability and range of use of fuel-burning equipment will enable the consumer, in spite of the tendency to regulate both price and source of supply, to purchase fuel at a low average unit cost and effect the same or even greater efficiencies of conversion than have heretofore prevailed.

Likewise, manufacturers may, at little added cost, modify their combustion equipment to make possible the burning of solid, liquid, or gaseous fuel, and the high- and low-grade fuels of any type with substantially equal efficiency.

Thus, the consumer will be enabled to take greater advantage of the potential and changing fuel markets and available methods of transportation, and in his purchases can be governed to a larger degree by the actual fuel value measured by the delivered fuel cost per million Btu.

Market Trends[1]

Natural gas has been marketed in ever-increasing quantity since 1921, similarly fuel oil, with the increased consumption more pronounced for domestic heating than for other uses. At the same time, there has been a definite trend downward in the use of both anthracite and bituminous coal, this trend being more pronounced since 1926.

Throughout the last 20 years, steam-generated electrical energy has increased threefold, with but slight increase in the use of fuel, due to improved efficiency in fuel utilization. Hydro-generated electrical energy has increased in substantially the same proportion, but, if evaluated at the prevailing rate for steam-generated energy, the coal displacement appears to show relatively small change since 1918.

Except for the periods during and immediately following the World War, and during strikes and other abnormal times, all bituminous coal has averaged to realize at the mine between $1.75 and $2 (5) per net ton.

The realization at the mine for Pennsylvania anthracite appears to have declined steadily from an average of $5.35 in 1931 (5) to nearly $4 in 1937. The downward change, which was greater for domestic sizes, was somewhat offset by a gradual increase in the realization for industrial and steam sizes.

If we take the tidewater price of bunker C fuel oil at New York, the average price per barrel for the years 1933 to 1939, inclusive, has ranged from approximately $1 to $1.30 (5), with the actual price, of course, depending somewhat upon the local market conditions, the quantities involved, and subject to greater fluctuation than that of other fuels.

The average annual realization for natural gas, on the other hand, has ranged within relatively narrow limits, from approximately 21½ cents to 24¾ cents per thousand cubic feet at point of consumption for the years 1925 to 1938 (5), inclusive. Although the figure for all natural gas has remained substantially constant, the average for industrial use during the same period appears to have declined from a high of nearly 13 cents to a low of 9.7 cents, whereas, the corresponding rates for domestic consumption appear to have increased from a low of 56 cents to a high of some 69 cents per thousand cubic feet.

These figures, unless otherwise stated, are merely averages for the entire United States. They do not indicate the relative prices at any particular market or destination, where the different transportation costs will substantially modify the actual delivered prices for the available fuels.

The better- and not the lower-grade fuels move to the more distant markets, where transportation is important. From time to time, strikes, changing business conditions, temporary shortages of supply, and other varying factors may serve to modify consumer preference and the relative prices of competing fuels, but the general parallelism between the costs of the different types of fuel (solid, liquid, and gaseous) appears to continue.

Recently, producers of bituminous coal have given more attention to the screening, sizing, cleaning, and possible dust treatment of their coals, the better to meet changes in market conditions and in combustion equipment, realizing that thereby they can substantially improve their opportunities to hold and possibly extend existing markets.

The use of the finer sizes of slack and double-screened coals, respectively, for the industrial and domestic trade has substantially increased. Slack coals, formerly a drug on the market, selling at ridiculously low prices, have encouraged the introduction of pulverized-fuel equipment. The introduction of domestic stokers has made possible and convenient the use of smaller and less expensive double-screened sizes of coal, tending to reduce the supply of slacks available for industrial use.

The price differentials between the so-called "prepared" or double-screened coals, on the one hand, and slack coals, on the other, tend to diminish, with the mean or weighted average approaching but not reaching the mine-run figure. This diminishing differential as to size, coupled with corresponding differentials as to grade, has accelerated the price leveling-out process, as indicated by the generally greater increase proposed under the new price schedules for slacks and industrial coals than for the large double-screened and domestic sizes.

Transportation

Freight rates are not always proportional to the distance traveled, in fact those for long hauls often are relatively lower, to enable newer and more distantly located coal fields to compete in the larger consuming markets with the older near-by fields.

The cost of transporting a ton of coal via rail averaged, for the entire United States, an amount equal to or greater than the average cost of the fuel itself. This cost ranged from $2.15 to $2.27 per net ton during the years 1929 to 1938, inclusive, with the actual transportation charge to many consuming markets several times the actual fuel cost f.o.b. cars at the mine. Approximately 24 per cent of the bituminous-coal production is water-borne wholly or partly via lake, river, or tidewater, and 7 per cent is moved by truck from the mine to near-by destinations and usually at less than rail rates.

[1] Refer to Figs. 1 and 2.

Transportation cost, reliability of the carrier or carrier system, and the continuity of supply are important factors when coal or fuel oil are considered.

The increasing availability of natural gas has encouraged the extension of pipe lines so that now it may be so conveyed thousands of miles from the source of supply to the ultimate consumer.

Anthracite destined for eastern markets generally moves via rail, or rail and tidewater, with a small portion moving via truck.

Selection and Evaluation of Fuel

Purchasers of fuel are anxious to familiarize themselves with the limitations of their own equipment, the operating man's viewpoint, and the characteristics of available fuels. They desire some readily understood measure of fuel evaluation and performance, first, to guide them in its selection and, subsequently, to check actual performance when the fuel is burned in their own plants.

A suitable measure of performance will facilitate comparison between plants and between competing fuels in the same plant, also the effect of variations in preparation and physical characteristics upon the efficiency of utilization.

A vast amount of detailed information and individual plant-operating experience has been accumulated and made available by the engineering profession and by producer and consumer organizations as to available fuels. Nevertheless, the major problem still remains.

A scientific approach to the purchase of fuel is possible. Frequently, however, the power or fuel portion of the total manufacturing cost is not sufficiently large to justify the extensive and detailed evaluation methods used by those who consume millions of tons annually. However, the many chemical and physical characteristics of fuels undoubtedly do have a marked bearing upon the selection of appropriate fuels and, having once determined the desired type or types, the field is considerably narrowed. It then becomes a matter of evaluating fuels on the basis of actual heat recovery rather than on a casual analysis of a salesman.

TABLE 7 SUGGESTED METHOD OF EVALUATING FUELS

	Coal per Ton				Per Barrel		Per M Cu.Ft.	
	Stoker		Pulverizer		Oil		Gas

**Total Unit Cost:		$6.36		$5.574		$1.369		$.138
Million B.T.U. absorbed per Ton or unit Fuel Cost:	22.2		22.8		5.2		.86	
Cost per Million B.T.U. absorbed:	$.287		$.244		$.263		$.162	

Notes: * Includes cost of coal pulverization or oil heating.
** Unit for comparison may be Net Ton (Coal), Barrel (Oil), 1,000 cu.ft. (Gas), or cost per Million B.T.U. Inclusion of fixed charges optional.
*** Includes induced draft fans.

Coal is now available in a greater variety of sizes and grades than is generally realized. The producers themselves have learned to better prepare, size, grade, and treat their coals; fuel oils have increased in specific gravity and heat content; refinery by-products and residues have become available; and the extension of natural-gas lines has brought this fuel into many otherwise inaccessible markets. Combustion equipment has been designed or modified to permit high rates of heat release and to burn not only one but several fuels with substantially equal facility. The fuel-selection problem thus has become increasingly complex.

The average consumer is manifestly somewhat bewildered by the kaleidoscopic changes in fuel prices, fuel markets, and factors affecting fuel production, distribution, and use. His interest in the evaluation of fuels leans toward a definite, tangible yardstick or measure of evaluation and a definite departure from the old rule-of-thumb method of purchase from "Smith" or "Brown," because the fireman thought it burned better or merely because the supplier had convinced the fireman that his coal shoveled better than that of his competitor.

The suggested method of evaluation is illustrated in Table 7 for coal, gas, and oil, and for stoker- and pulverized-fuel-fired boilers.

The variable factors, production, transportation, handling, and utilization, may be divided into two fundamental and essential groups as follows:

1 The complete cost of the fuel, including transportation and conversion, per ton, barrel, or million cubic feet.

2 The heat recovery expressed in convenient units, as, for example, million Btu per fuel unit.

Both of these in the average industrial plant may be readily and accurately determined. When compared, they provide a simple and substantially uniform and sufficiently accurate method of evaluation regardless of the fuel, the conversion equipment, the method of operation, plant location, or any other of the many factors which enter into or effect the utilization of fuel.

After the primary determinations, supplemented by a heat balance if desired, fuel evaluations are completed for representative fuels and the usual boiler ratings. Subsequent modification may be quickly approximated to determine the effect of changes in prices, transportation costs, and operating efficiencies. Thereafter, periodic tests and an analysis of the results over extended periods may suggest further changes in fuels and conversion equipment and make possible the widening of the range of fuel application. Thus, the management and operating staff are provided with a yardstick or standard of performance which can be easily and readily applied to a large or a small plant, and which includes all the essential fundamental factors. To illustrate, if we add the following items:

A The delivered cost of fuel, including storage and handling if necessary;

B Cost of handling the fuel into and through the conversion equipment;

C Ash- and waste-removal cost;

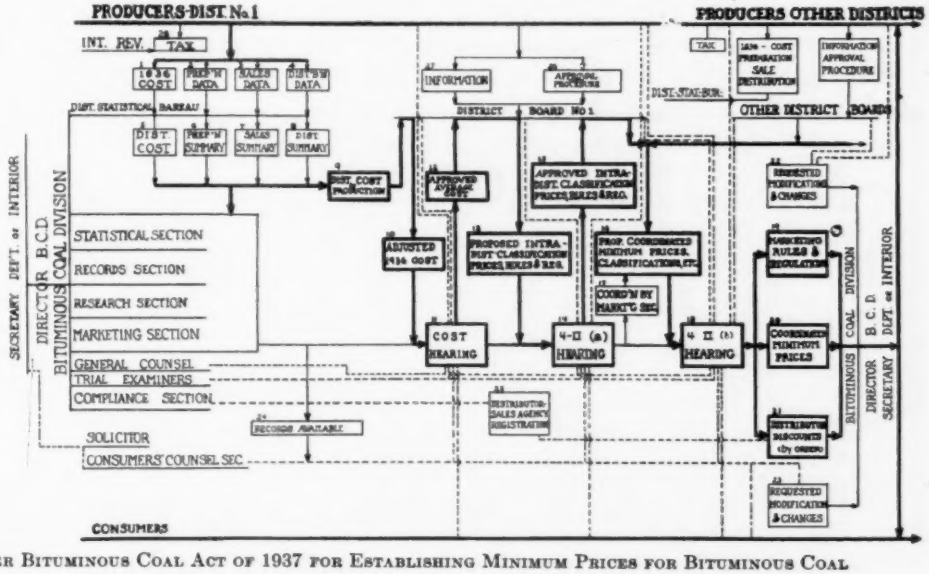
D Supervision, labor, maintenance, and other operating expense;

then we can readily determine, from these known and easily secured data, a unit cost for fuel delivered and consumed.

Actual heat recovery may be readily ascertained from the steam produced or an equivalent-use evaluation in other processes. The two predominating and major factors may then be

compared directly to determine the cost per million Btu actually recovered, i.e.

$$\frac{\text{Fuel cost}}{\text{Heat recovered}} = \text{Cost per million Btu recovered}$$



The three cost factors *B*, *C*, and *D*, are the average for the particular plant for the preceding year, weighted (plus or minus) to approximate empirically the probable increase or decrease, as the case may be, for handling the particular type, grade, or size of the fuel in question. The average cost assigned to *B*, *C*, and *D* is controlling and is a definite and known amount for any given plant. Such slight modification as may be required properly to weight these items for any particular fuel is a very small portion of the total cost of the delivered and converted fuel, in fact so small as not to be seriously questioned by either the seller or the consumer of the fuel, and usually small enough to be waived entirely in case of serious argument.

This method of evaluation includes the cumulative effect of many factors not otherwise distinguishable except through detailed analysis. Actual experience and use have shown that it affords a reasonably simple and accurate comparison of the energy-conversion cost for different plants, either large or small, or different usable fuels in the same plant, or even plants other than those used for the generation of steam.

To a particular producer 5 cents per bbl or 10 cents per ton differential in the fuel cost (f.o.b. source) may appear to be a substantial one, and may even mean the loss or gain of his market or customer. To the consumer, transportation is an added and an important element of expense; in fact, frequently, as in New England, transportation cost may average to be twice that of the fuel itself. Thus, small variations in fuel price, although seemingly of major importance to the producer, actually become a minor factor in the consumer's total cost, and particularly so if, for the fuels or the plants being compared, there is a marked difference in the percentage of heat actually recovered.

Minimum Prices For Bituminous Coal

There has been in progress during the last two years a series of investigations, collection of fundamental data, and hearings for the purpose of determining the weighted-average cost of production and establishing minimum prices for bituminous coal in accordance with the Bituminous Coal Act of 1937 (2). The Act authorizes separation of the coal fields of the United States into 23 producing districts and the grouping of these into 10 minimum-price areas. The Act requires that the production of

Fig. 3 Procedure Under Bituminous Coal Act of 1937 for Establishing Minimum Prices for Bituminous Coal

Producers' Data to District Statistical Bureau

(1) to (4) *Cost of production:* (1) Direct and indirect expenses plus cost of selling.
Preparation: (2) Kinds, qualities, sizes.
Sales: (3) Selling price, spot orders, invoices, credit memo.
Distribution: (4) Tonnage by kinds, sizes, grades, and use to each market area.

(5) to (9) *District Statistical Bureau to Division Statistical Section:* Summaries of 1936 cost (5), preparation (6), sales (7), and distribution (8) data for each District to statistical section of Bituminous Coal Division; District cost summary (9) to District Boards.

(10) *Adjustment 1936 production cost:* District Boards' recommendations to Division to reflect changes in wages, etc., since 1936.

(11) *Cost hearing:* Regrading determination weighted average cost of production for each District and price area.

(12) *Approved weighted average cost of production* authorized by Division as basis for proposing minimum prices for various kinds, qualities, and sizes of coal produced in each district.

(13) *Intra-district quality and price relationships* to reflect values of the kinds, qualities, and sizes of coal produced by each mine within the district as proposed by each District Board, together with their proposals as to marketing rules and regulations for the sale of coal.

(14) *4-II (a) Hearing:* Regarding proposed intra-district quality and price relationships and marketing rules and regulations.

(15) *Approved intra-district classifications and marketing rules and regulations.*

(16) and (17) *Coordinated minimum prices, coal classifications, marketing rules.* (16). Proposed as result of coordination by the several producing districts for each kind, quality, and size shipped by any of them, in competition into any and every market area, together with coordinated marketing rules and regulations.
In the event of failure of the districts to agree in whole or in part, the Bituminous Coal Division may complete and propose such coordinated minimum prices and marketing rules (17).

(18) *4-II (b) Hearing:* Regarding inter-district coordination, prices, and marketing rules proposed for the shipment of coals into common consuming markets.

(19) Marketing rules and regulations: } Promulgated by Secretary of the
(20) Prices—minimum and if necessary, maximum: } Department of the Interior upon recommendation of the
(21) Discounts to distributors: } Director of the Bituminous Coal Division.

(22) and (23) *Price modifications and changes* found necessary or advisable on the Division's own representations or on request from producer (22) or consumer (23) interests, and after suitable hearing, legal procedure, etc.

(24) Records are available to Consumers' Counsel on request.

(25) Distribution or sales agency, registrations.

(26) and (27) Rules: Procedure and relationship between District Board and producers (26) and necessary assistance and information (27).

(28) *Tax:* None on export shipments or those to federal, state, or municipal purchasers; 1 cent per ton on all other except that produced by noncode members, which shall be 19½ cents per ton.

any district shall realize, as nearly as may be, the weighted-average cost of production of the minimum-price area of which the district forms a part. It also provides for the establishment of Consumers' Counsel as a liaison agency between the Coal Division on the one hand and the consuming public on the other.

The Bituminous Coal Division of the Department of the Interior on July 1, 1939, took over the work of the former National Bituminous-Coal Commission, and since that time has carefully and painstakingly continued the procedure (Fig. 3) of establishing minimum prices, f.o.b. mine, for bituminous coal from all producing districts within the United States and for movement into the many consuming market areas (some 200) within its boundaries. The task proved to be a formidable one; in fact, the final minimum-price hearing, which in a measure comprised an open coordination meeting, has taken 6 months, with the accumulation of some 25,000 pages of testimony and over 1700 exhibits, many of which are replete with data of varied and complicated character. All of this, together with the fundamental data upon which the weighted-average-cost determinations have been predicated, comprises a more extensive accumulation of pertinent data with reference to the production, distribution, consumption, and values of bituminous coal than any heretofore assembled in the history of the industry, and of inestimable value to producers and consumers alike.

The magnitude of the problem and the difficulty of arriving at an equitable solution becomes all the more apparent when one realizes that it involves:

1 The determination of the cost of producing and selling coal.
2 The classification of all coals by size and by grade.
3 The cost of transportation.
4 The establishment of minimum prices for the various kinds, qualities, and sizes of coal, produced in the several districts, to reflect, as nearly as possible, their relative market values at points of delivery in each common consuming-market area.

In addition, the Bituminous Coal Division, in the absence of complete agreement between producing districts, found it necessary to undertake the work of final price coordination.

Production costs for all mines for the year 1936, adjusted to reflect subsequent changes in wages, etc., including a reasonable cost of selling, when summarized, were used to determine the weighted-average cost of production per net ton for each price area for all of the ascertainable tonnage produced therein.

Subject to public hearing and subsequent approval by the Coal Commission, each district board proposed a classification of its coals and differentials as to size and grade. Subsequently, as a part of coordination, the Coal Division determined the base coals of each producing district and related these to the base coals of the other producing districts in their common consuming markets. The remaining coals of each district were then differentially related to its own base coals within the same market.

Throughout, consideration was given to sizing and preparation of coal, methods of cleaning and treatment, coal analyses, and to the possibility of rearranging and regrouping sizes proposed for each producing district, to facilitate the relation of various coals,

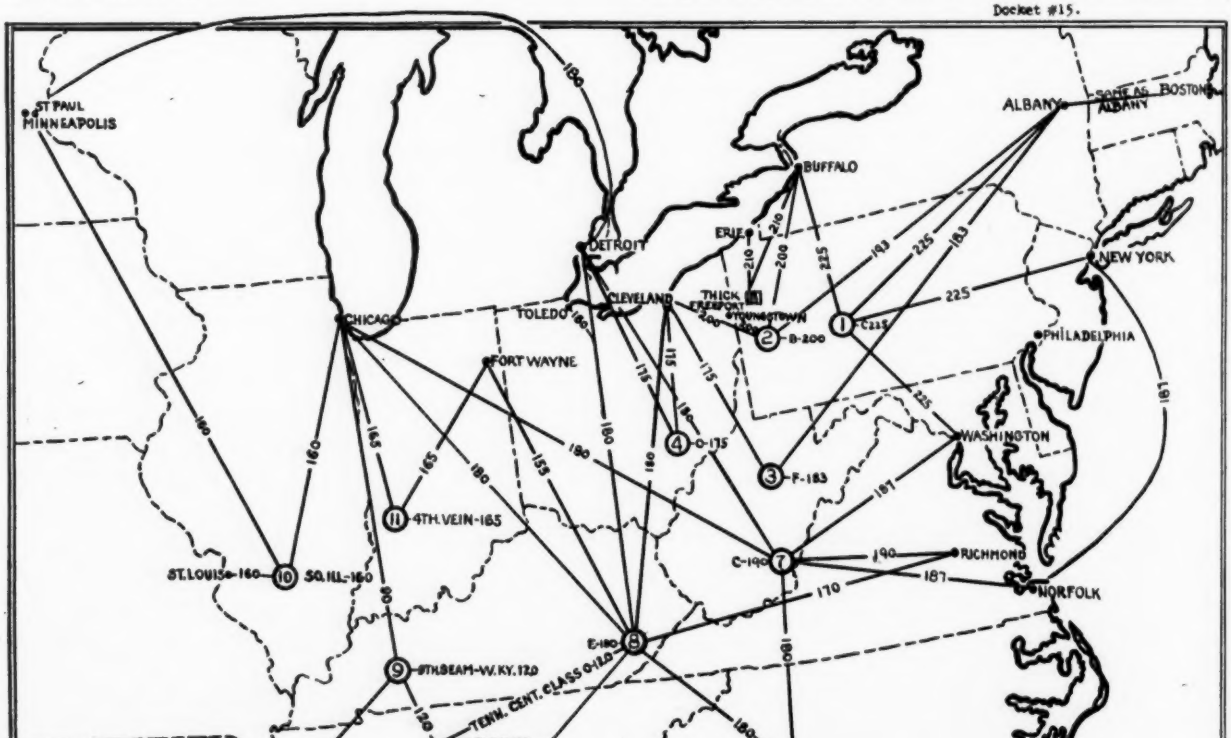

FIG. 4 PRICE RELATIONSHIPS F.O.B. MINE ON SCREENINGS FOR CERTAIN SELECTED DESTINATIONS

and simplify price structure for both producer and consumer.

Transportation tariffs are intricate in relationship and infinite in variety. Transportation cost constitutes a very definite and important factor in determining the f.o.b. mine prices of fuel. This is necessary if coals from the various sources are to compete with other fuels on a basis which will insure fair opportunities for the consumer to purchase and producers to distribute their coal in their natural markets without serious interruption or dislocation of tonnage.

In relating truly competitive coals, substantial freight differentials frequently were reduced by the absorption of a limited portion of such differential by the expedient of lowering the f.o.b. mine price of the coal or coals moving on the long freight rates. Coal for truck delivery was priced at the mine to effect the same delivered price as that for rail movement, an average trucking charge being used for this purpose.

An effort has been made to retain the advantages of low-cost water transportation in some market areas and for those consumers who are privileged to receive fuel on an "alongside" basis. Coal moving ex-dock, ex-river, or ex-lake has been coordinated with competing fuels moving all-rail into the same common consuming market.

TABLE 8 COST AND REALIZATION FOR VARIOUS PRODUCING DISTRICTS AND PRICE AREAS*

Price Area and District			Weighted Avg. Cost of Prod'n.	1937 Production (Net Tons)	Anticipated Realization	Difference: Realization and Cost
Minimum Price Area 1.						
(Eastern Pa.)	Dist.	#1	$2.3887	36,541,359	$2.1685	-$.2202
(Western Pa.)	"	#2	2.2140	65,299,792	2.0560	- .1580

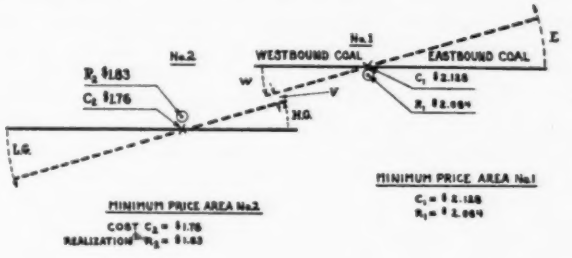
All Price Areas:			2.0884	408,100,769	2.0729	- .0155



* After recommended adjustments.

Under free and open competition, relative market values in each market area involved price differentials as to sizes and qualities for the coals of each producing district and the level of prices for that market.

Differentials in price are influenced by quality, size, size consist, treatment, use, chemical and physical structure, and the adaptability of a coal or coals to use, markets, transportation, and other factors.

The level of prices in any common consuming market is to a large degree determined by that market, its proximity to the producing field, and the extent to which competing fuels, whether they be gas, oil, other coals, or even hydropower, may affect the movement of bituminous coal into that market.

Fig. 4 is a reproduction of an exhibit (4) introduced by the Coal Division during the final price hearing. On this the Division has noted the principal markets, producing districts, and f.o.b. mine prices for competitive "base" steam coals for "certain selected destinations." This is included here by way of illustration, without in any way implying approval. It seemingly indicates an attempt so to coordinate coal prices as to avoid discrimination

V = VALUE DIFFERENCE, COORDINATION PRICES MIN. PRICE AREAS No.1 and No.2
E = INCREASE EASTBOUND
W = DECREASE WESTBOUND
H.G. = HIGH GRADE - PRICE AREA No.2 COAL
L.G. = LOW GRADE - PRICE AREA No.2 COAL

FIG. 5 COORDINATION BETWEEN MINIMUM PRICE AREAS NOS. 1 AND 2

between classes of consumers, market areas, and industrially competitive sections of the eastern United States.

The proposed prices involved consideration of both levels and differentials, and include all sizes and grades of coals, whether borne by rail, water, or truck, and for the following uses:

a Domestic
b Industrial
c By-product-coke manufacture
d Water-gas and producer-gas manufacture
e Railroad-locomotive fuel
f Vessel and bunker fuel.

The "minimum-price" fixing procedure has reached a point where the Bituminous Coal Division has been able to estimate the realization anticipated from the proposed minimum prices, based on the 1937 tonnage distribution. In some instances, proposed prices are lower and in others considerably higher than the present market, with the average realization exceeding that now prevailing. The anticipated realization, together with the corresponding weighted-average cost for each of the several producing districts and price areas, is included in Table 8 (10).

The weighted-average cost of production and corresponding realization for minimum-price areas Nos. 1 and 2 (comprising the Appalachian and middle-western producing fields, respectively), allowing for subsequent modifications suggested by the Marketing Division, are:

Price area	Weighted average cost of production	Estimated realization	Difference
No. 1	$2.1284	$2.0843	—$0.0441
No. 2	1.7622	1.8320	+ 0.0698

Price area No. 1 underrealizes and price area No. 2 overrealizes their respective costs of production. However, further approach of realization to cost is difficult in view of the Marketing Division's desire to coordinate the prices of those coals produced

within each of the two price areas where they compete in common consuming markets. This may be illustrated diagrammatically by Fig. 5, in which is shown the relative weighted-average production costs and anticipated realizations for price areas Nos. 1 and 2. It so happens that a substantial portion of the tonnage of the southern districts of price area No. 1 moves into the Middle West in competition with the coals of price area No. 2, produced within that consuming area, price area No. 1 coals in both domestic and steam sizes generally being superior in value.

If the relationships between the coals of price areas Nos. 1 and 2, as determined by the Division, are correct, it is obvious that the truly competitive coals from each area must be priced f.o.b. the mine to deliver at their proper relative market value. Such coordination may be illustrated by the indicated rotation of the desired price level or realization lines. The rotation of price area No. 1 line indicates a price decrease for its westbound coals and a corresponding increase of the remaining coals moving eastbound since, only in this manner or by a decrease in realization (R_1), can coordination of price area No. 1 and price area No. 2 coals be effected.

The higher level of prices of those coals of price area No. 2 which actually compete with the westbound coals of price area No. 1 further assist this coordination. However, it is obvious that, for each ton priced above cost, there is a corresponding ton priced below cost in order that price area No. 2 realization may be accomplished.

Actual anticipated realizations indicate that price area No. 1 will underrealize and price area No. 2 overrealize its cost. Therefore, if the coals of these two price areas have been properly related, any further narrowing of the delivered price differentials between their competing coals means an abnormal increase in price area No. 1 coals moving eastbound or an abnormal lowering of prices for the coals of price area No. 2, which are not truly competitive with those of price area No. 1.

Price area No. 2 values cannot approach a point where they are considered "dump" prices, and the eastbound coals of price area No. 1, in turn, cannot be substantially raised without at once throwing an additional abnormal burden upon eastern consuming markets. This would also result in further discrimination, as between the market areas involved and a transfer of the burden of realization to an even greater degree than is appropriate for those coals, principally slacks, moving into market areas comprising New England and the eastern seaboard, which have no alternative but to take the coals of price area No. 1 or turn to competing fuels or forms of energy, such as hydropower, oil, and, in some cases, natural gas. Such competition has already resulted in a substantial increase in the utilization of oil and gas, and a decreased use of bituminous coal and anthracite throughout the eastern markets.

If the relationships between the coals of price areas Nos. 1 and 2, as determined by the Division, are correct, and if a narrowing of the differentials between the competitive coals of these two price areas is attempted in their common consuming markets either by lowering the level of realization (R_1) of price area No. 1 or by raising the level of realization (R_2) of price area No. 2, then the underrealization of price area No. 1 and the overrealization of price area No. 2, with respect to their costs of production, are aggravated to a still greater degree.

Distribution figures indicate and market history confirms the movement, for steam raising or by-product purposes in competition with other price area No. 1 coals, of the bituminous coals of eastern Pennsylvania (district No. 1), western Pennsylvania (district No. 2), northern West Virginia (district No. 3), and the southern low-volatile coals (district No. 7) in substantial quantities into New England, New York State, and other portions of the Atlantic seaboard as far south as Baltimore and Washington.

The southern high-volatile coals of district No. 8 and the low-volatile coals of district No. 7, particularly in the double-screened or prepared sizes, move westward through the Great Lakes and the northwest territory for "alongside" or "ex-dock" delivery in competition with the coals from Indiana, Illinois, western Kentucky, and Iowa (districts Nos. 9, 10, 11, and 12, respectively, comprising minimum price area No. 2). Slack coals from districts Nos. 7 and 8 also move into the industrial markets of Ohio.

Cost per Million Btu

If the average analyses (4) for the several sizes and grades of coal be applied to the delivered prices corresponding to the minimum f.o.b. mine prices proposed by the Bituminous Coal Division, the fuel cost per million Btu delivered is found to range from 9 to 14 cents for the mine run, and 9 to approximately $13^1/_2$ cents for the slack sizes for those destinations and market areas located at or close to the producing districts of the Appalachian coal fields. The delivered slack cost for more distantly located markets may approach 20 cents per million Btu in the eastern markets, 21 cents in the South, 25 and even 30 cents in the Northwest for rail movement, and 15 cents for Great Lakes destinations and for water-borne fuel. The mine-run figure averages 1 to 5 cents higher than for slacks. In any market, the differential in unit delivered cost between the high- and the low-grade fuels is surprisingly small.

Transportation appears to affect the unit cost for steam coals in eastern markets to a greater degree than in southern markets. In the Middle West, rail-transportation charges, both short and cross-haul, and those for water-borne fuel, together with the physical characteristics of the fuel and its adaptability for long-haul movement, evidently combine to make for wide variations in cost per million Btu for apparently small change in actual heat content of the fuel.

A comparison of solid, liquid, and gaseous fuels in those markets where they are actually available and competitive indicates a delivered cost per million Btu of substantially like amounts during periods of free and open competition.

Government Regulation

The World-War period, with its abnormal demand for coal for the manufacture of steel and munitions, and for industry, fostered the opening of many mines and thereby increased the accessible supply. The increased fuel prices prevailing during that period encouraged more efficient utilization and the use of lower-grade and cheaper fuels. These trends continued after the war so that the large potential supply of fuel became a serious burden; the solid-fuel industry, particularly bituminous coal, became demoralized, and the less efficient and higher-cost mines were forced out of business. The closing of mines continued, but not rapidly enough to prevent further demoralization of the fuel industry. Competition was keen and prices were low. These conditions, together with the realization that (*a*) the more accessible eastern coal reserves faced earlier depletion; (*b*) actual fuel recovery warranted substantial improvement; (*c*) improved working conditions and wages were in order throughout the industry, initiated and encouraged governmental interest (11).

This governmental interest continued from the time of the Hammond Commission in 1922 to, and culminated in, the NRA regulated prices. These were established at a sufficiently high level to permit increased wages in the northern and southern fields together with a general unionization of both. The effort to stabilize conditions within the industry, then begun, has continued until the present time. There is now imminent Federal regulation of the industry through the establishment of minimum prices for bituminous coal throughout the United States as prescribed in the Coal Act of 1937 (2).

A recognition of the rather limited petroleum reserves, overproduction of crude oil, and other economic factors has also aroused considerable interest on the part of governmental agencies in an effort to regulate (12, 13) the supply and stabilize prices for both crude and fuel oil and for oil products.

For similar reasons, attention has been directed to the possible control of natural-gas pipe-line installations and a stabilization and regulation of prices for both industrial and domestic use.

At the same time, considerable governmental interest has been shown in the development of hydropower and in the competition of this form of energy with that generated through steam, using solid, liquid, or gaseous fuels.

Although not generally realized and appreciated, this tendency toward governmental regulation of fuel production and price appears to be rapidly approaching a concerted effort to formulate a directed and coordinated program (11) of governmental supervision and control of all our natural resources, including fuel and water power.

This governmental interest apparently involves control of production, allocation of quantity, and source of supply. Its purpose, presumably, is that of conserving our natural resources, preserving the better grades of fuel and those with limited reserves, and encouraging the use of available lower-grade fuels as well as their more efficient production or recovery.

Anthracite producers' efforts parallel those to establish minimum prices for bituminous coal in that field.

Conclusion

The location of industry with reference to its fuel supply, the available competing fuels, and their relative prices in the market, improvements in combustion equipment, and the increasing use of power, all combine to complicate the problem of purchase and efficient utilization of fuel.

The purchase and use of fuel is in a state of evolution, or flux, and the change has been accelerated to a marked degree by governmental effort to regulate both supply and price.

Fuel selection and evaluation is by no means simple. The consumer's efforts may well be directed toward a better understanding of his needs, a consideration of available information, and a knowledge of the contemplated conservation measures (11) and extensive procedure gradually being evolved for the control of both price and supply of our natural resources. A proper interpretation and appraisal of these several factors is of primary importance in the satisfactory solution of his fuelpurchase problem.

Producers have come to realize that the sale of fuel is essentially an engineering problem, and that fuel preparation, to meet market requirements, is as important as its physical and chemical characteristics. Many producers also realize that low rather than high minimum prices are preferable, and that the use of low-cost fuels will increase to the exclusion of those which may be priced higher without possessing a correspondingly greater potential heat value.

There has been suggested a yardstick, or measure, for evaluating fuels within and between plants and for various methods of conversion. A résumé of the procedure for determining the proposed prices for solid fuels is included, with reference to the possible effect of governmental regulation. Reference has also been made to the manner of proper fuel selection and the possibility of cooperation between the combustion-equipment manufacturer and the consumer, in order to make possible a wider choice and use of sizes, grades, and kinds of fuel, to the end that the consumer may more economically purchase and more advantageously utilize available fuels.

The evaluation of fuels represents:

1 An integrated opinion of the producers of fuels which enter a common consuming market.

2 The relative values of available fuels, as determined by the consumer on the basis of conversion in his own plant and equipment and under conditions which govern his actual power production.

The evaluation by both may vary over a considerable range. Nevertheless, the integration of all valuations in each instance, measured one against the other, becomes, as it were, a fair average value of the proper differentials between the various kinds, qualities, and sizes of fuels. The required realization, modified as may be by the price for competing fuels, will determine the final level of prices for a fuel in a common consuming market.

Discussion

H. K. Dean.[9] The last few years have brought about several changes in fuel-burning equipment and in boiler and furnace design. In so far as coal is concerned, progress in burning is definitely toward pulverized coal, burned in either slag-tap furnaces on the one hand or in dry-ash furnaces on the other. There is less tendency to design the intermediate type, many of which are still giving considerable trouble.

A great deal is yet to be learned regarding the characteristics of ash, since its behavior is different for different methods of burning. The standard ash-fusion-temperature determination has, in the past, been given as of a reducing atmosphere and there is a difference in the fusing temperature in an oxidizing atmosphere; as much as 400 deg with certain types of coal.

[9] Sales Engineer, The Babcock & Wilcox Company, Boston, Mass. Mem. A.S.M.E.

A wide range of fuel utilization may be had, particularly in burning fuels in suspension. A combination of pulverized coal, oil, and gas can be and has been burned successfully in either the slag-tap or dry-ash types of pulverized-coal furnace.

Changes in coal prices and marketing practices may alter the natural movement of fuels as it is now known. Therefore, there appears to be a greater necessity for full investigation and accurate knowledge of the available fuel supply by the purchaser, the engineer, and the manufacturer. Design characteristics of steam-generating equipment and over-all economics will probably place limitations on fuel purchases for some time to come. There will probably always be certain characteristic fuels which will give better over-all performance in certain types of steam-generating equipment.

A. W. Thorson.[10] In view of the proposed minimum prices for bituminous coal, everyone concerned with the purchase or utilization of this type of fuel is vitally interested in and should make an exhaustive study of this paper. Very little engineering information regarding the method of developing prices has been available to date. The paper gives detailed information as to the method of studying markets and production costs together with the correlation of the two to set up the price schedules. If and when these prices become effective, the value of this paper will become more and more apparent.

Has the author prepared a chart similar to that given in Fig. 4, but showing delivered prices at the selected destinations rather than f.o.b. mine prices? It would appear that such an exhibit would be of added value to coal consumers.

Author's Closure

Mr. Dean and Mr. Thorson in their discussions have touched upon two factors, transportation and conversion, which together with the initial fuel cost at its source of supply have a fundamental and important bearing upon available fuels, sources of supply, and the markets which they can economically serve.

As I have indicated, the cost of transporting a ton of bituminous coal by rail averaged, for the entire United States, an amount equal to or greater than the cost of production. Coal, depending upon the mine location and the market destination, may and often does move in whole or in part by other competing forms of transportation, that is, via lake, tidewater, river, and truck. Competition between carriers and, what is perhaps even more important, the actual transportation rate itself may have an important bearing upon the available sources of fuel supply. To a large extent the cost of transportation may and does determine the producer's ability to retain or extend his fuel market, and it is not unreasonable to expect that a reduction in transportation cost might well result in a substantial increase in gross revenue to the coal carrier.

The delivered cost per million Btu, other factors being equal, becomes the consumer's measure of purchased-fuel value, and of this transportation forms a substantial part, in fact in many consuming markets it amounts to several times the actual fuel cost f.o.b. cars at the mine.

Indications are that in many instances the minimum prices now proposed will be revised somewhat in the final price schedules, and that consideration is being given to the modification of transportation rates. For these reasons it would seem more appropriate to defer for the present a graphic illustration of typical delivered fuel prices, those in which the consumer is primarily interested.

In the past, steam-generating equipment generally has been geared to the available fuel supply, its characteristics, prices, and marketing practices. Considerable progress has been made, as Mr. Dean points out, in widening the range of fuel utilization and particularly where fuels are burned in suspension, both singly and in combination. While it is true that design characteristics of steam-generating equipment and over-all economics may place limitations on fuel purchases in many cases and for some time to come, progress in the design of steam-generating equipment, the technique of fuel burning, equipment maintenance, and ash or waste disposal has been sufficiently great in the last few years to indicate that steam-generating equipment having a much wider range of fuel utilization can now be manufactured and installed with very little additional effort and expense.

Thus, through improvements in transportation and utilization of fuel, will the consumer be enabled to take greater advantage of potential and changing fuel markets and be governed in his purchases to a greater degree by the actual fuel value as measured by the delivered cost per million Btu.

The producer, the carrier, the equipment manufacturer, and the consumer, each have a real interest in the contribution of the others in the fair evaluation, economical purchase, and advantageous utilization of available fuels.

The expressed interest of Messrs. Dean and Thorson, as well as that of many others, is encouraging and very much appreciated.

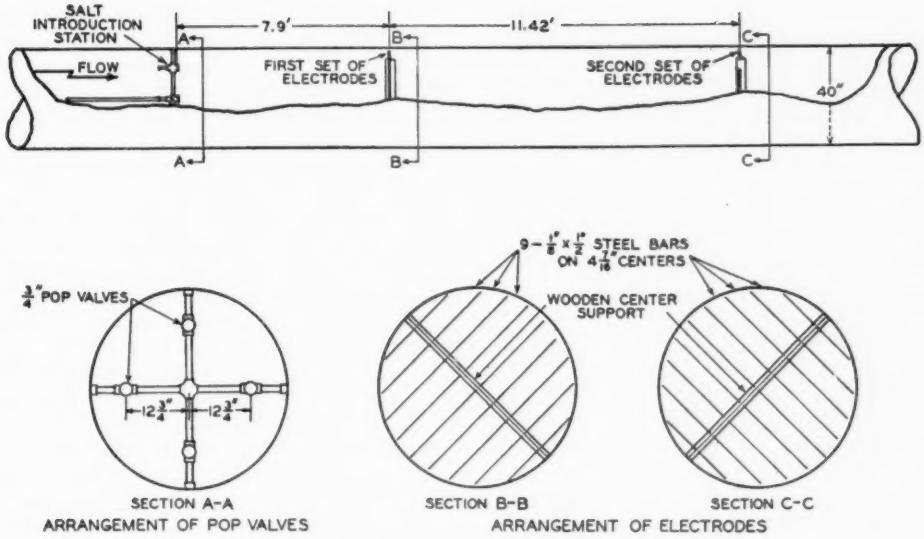

FIG. 1 TEST SECTION IN 40-IN. PIPE

Salt-Velocity Measurements at Low Velocities in Pipes

BY LESLIE J. HOOPER,[1] WORCESTER, MASS.

This paper describes tests made at the Alden Hydraulic Laboratory to determine the performance of the salt-velocity method at low velocities. Three series of tests were made: the first in a 40-in. pipe, the second in a 12-in. vertical pipe in which the test section and its approaches could be readily reversed, and the third in a horizontal 2-in. pipe. The tests show that for flow in a long straight pipe and for velocities lower than those normally found in practice, there exists a critical mixing velocity below which good mixing of the injected brine does not occur. An analysis of the results indicates some of the factors which affect the critical mixing velocity. Finally, it was found that the effect of gravity on the accuracy of the method, when applied to a vertical pipe, is negligible as long as proper mixing is secured.

THE salt-velocity method of water measurement has been primarily used for the measurement of discharge in the determination of pump and water-wheel efficiencies. In these applications, penstock velocities are usually of the order of one pipe diameter per second and no velocity limitations of the method were indicated in this experience. The object of this study was to investigate the sources of error at low velocities in the application of the salt-velocity method to long straight pipes.

DESCRIPTION OF APPARATUS

This investigation was conducted at the Alden Hydraulic Laboratory of the Worcester Polytechnic Institute and the tests were made during 1939 and early 1940.

A straight length of 40-in. pipe was selected for the test section, Fig. 1. Four $^3/_4$-in. pop injection valves were located at the introduction station. The first set of electrodes was located 7.9 ft downstream from the pop valves and the second set of electrodes located 11.42 ft beyond the first set. The brine was injected under 30 to 50 lb per sq in. excess pressure, and the discharge of the valves was controlled by a quick-acting lever valve in the brine supply line. The discharge of the 40-in. pipe passed through a 36 × 16-in. venturi meter, thence through a 100-hp water wheel and, finally, over an 8-ft suppressed weir in the tailrace. The venturi meter and the weir were both calibrated just before the tests by means of a 50,000-lb weighing tank.

The pop valves were built up from $^3/_4$-in. pipe fittings. Each valve had a spring-loaded flat disk operating against a stop. The valves required a pressure of about 5 lb per sq in. to open them. The excess-brine pressure of 30 to 50 lb per sq in. caused all the valves to be operated simultaneously and the spring-loaded disks kept brine leakage at a minimum between shots.

Each electrode in the 40-in. pipe was a grid, consisting of nine parallel $^1/_8 \times {}^1/_2$-in. steel bars, carried on a wooden streamlined center strut which was fixed across one diameter of the penstock, Fig. 1. These steel bars were placed edgewise to the flow to reduce their resistance and were arranged on 4 $^7/_{16}$-in. centers across the pipe, with the first and last bars 2 $^7/_{32}$ in. from the pipe wall. The bars were cut so as to leave an end clearance of $^1/_4$ in. The inside walls of all pipes tested were coated with insulating paint. Alternate bars were connected together and only one pair of leads was brought out from each electrode station.

In order to determine the effect of gravity on the heavier salt solution when injected into a pipe line, the apparatus which is illustrated in Fig. 2 was installed. The 12-in. vertical pipe with its test section and approaches was so arranged that it could be turned

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

end for end, thus reversing the effect of gravity on the flow.

The four pop valves were located 18 in. from the flange of the upstream elbow and the electrodes were located 3 ft 7 in. and 18 ft 7 in., respectively, from the pop valves. These injection valves were built of $^1/_4$-in. pipe fittings in the same manner as the $^3/_8$-in. valves described. The electrodes consisted of two

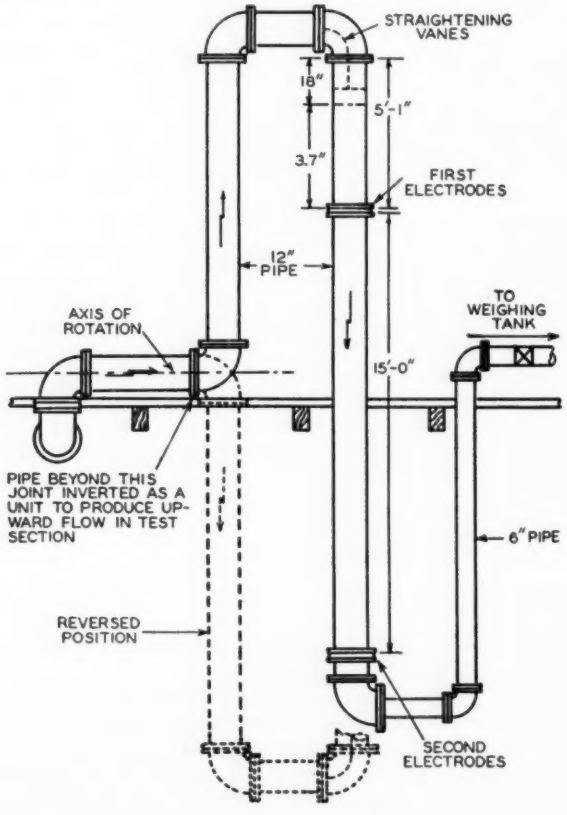

FIG. 2 TEST SECTION IN 12-IN. PIPE

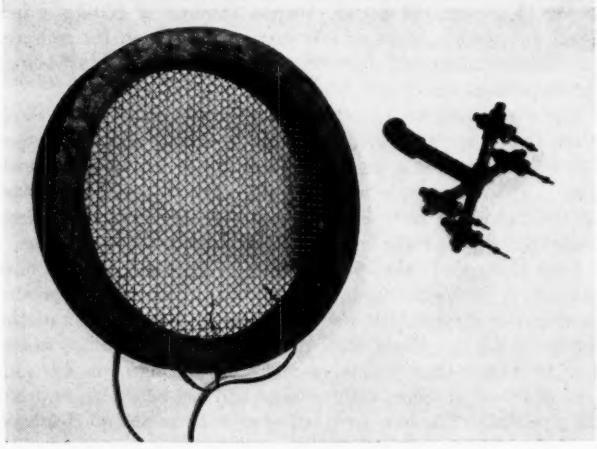

FIG. 3 POP VALVES AND ELECTRODE FOR 12-IN. PIPE

pieces of $^1/_5$-in. mesh galvanized-iron screen wire held between flanges and separated axially from each other $^3/_4$ in. The pop valves and electrodes are shown in Fig. 3. The discharge from the 12-in. pipe was measured directly in a 50,000-lb weighing tank.

The test section in the 2-in. line was located in a straight length of standard pipe. The brine was injected through a $^1/_4$-in. flush nipple located 4.61 ft downstream from a right-angle elbow. The distance from the introduction station to the first electrode was 2.39 ft and to the second electrode 10.48 ft. The electrodes consisted of $^1/_5$-in. mesh galvanized-iron screen wire similar to that used in the 12-in. pipe, except that the distance of separation was $^1/_8$ in. The discharge was measured in a 600-lb weighing tank. A Bristol 5-amp strip-chart ammeter was used to record the passage of the salt solution through the electrodes in the 40-in. and 12-in. line tests. A General Electric strip-chart recording polyphase wattmeter was used in the 2-in. line tests. The power supply for the electrode circuits was taken from a variable-voltage transformer. The electrodes were connected in parallel to the transformer with the recording instrument located in series in the common lead. A time record was made on the recording chart by a chronographic pen actuated from a calibrated timer.

The brine used in these tests was mixed to various specific gravities as determined by means of hydrometers. For most of the tests, solutions of common salt were used but dilute hydrochloric acid was used for the 1.02 specific-gravity tests in the 12-in. line. A hand force pump was used to inject the brine in the 12-in. and 2-in. pipe tests. The acid solution was injected under air pressure with the pop-valve operation controlled by a quick-acting valve.

The volume between the planes of the electrodes was determined by actual measurement of the diameter and length in the 40-in. pipe. Four diameter readings were taken at every foot along the test section together with 18 measurements of its length. From these measurements the test volume was computed.

In the 2-in. and 12-in. lines, the test section was blanked off and filled with water, which was then drained into a weighing tank. This measurement was repeated 8 times and the test volume was computed from the average weight and density of the water.

PROCEDURE

The procedure was essentially the same for all of the tests. The discharge was adjusted to a desired value and from 5 to 10 min were allowed to elapse to secure steady flow conditions. Then from 5 to 15 salt shots were recorded at the same time that the discharge was being measured by the check method. For the 40-in. line the venturi deflection and the head on the weir were read at intervals during each test. For the 2-in. and 12-in. lines, the discharge was measured with the weighing tank.

CALCULATIONS

The passage time for a salt shot was taken as the time in seconds between the centers of gravity of the two electrode curves. The volume of the pipe between the planes of the two electrodes divided by the average passage time of all the salt shots in a run gave the salt-velocity discharge.

The true discharge was that measured by the weighing tank for the 2-in. and 12-in. pipe tests or the average of the venturi and weir discharges for the 40-in. line test.

The difference between the true discharge and that of the salt-velocity measurement, expressed in per cent of the true discharge, was termed the error of the salt-velocity measurement.

The mean velocity was found by dividing the true discharge by the area of the pipe.

RESULTS OF TESTS

The results of these tests are shown in tabular and plotted form.

In a long pipe, where the normal flow pattern has been established, it is impracticable to introduce the salt solution uniformly by means of pop valves or any other known arrangement. In

this case, the turbulence existing in the pipe is relied upon to secure uniform mixing of the salt solution with the flowing water before the first electrode station is reached. With this in mind it might be supposed that good mixing would be secured as long as the flow in the pipe was in the turbulent range, as indicated by a Reynolds number of 2500 or more. However, it has been found by von Kármán and others that the turbulence existing in a pipe may be materially reduced by the presence of an unmixed solution either heavier or lighter than water.

To visualize this phenomenon, let us assume the worst case where a lighter liquid is overlying a heavier liquid and they are both traveling along a horizontal pipe together. For the present discussion, chemical or molecular diffusion may be neglected, since these diffusion velocities are negligible when compared to ordinary mixing velocities. If the two liquids are to be mixed, part of the light liquid must move down into the heavier liquid and a corresponding amount of the heavy liquid must be moved upward. Then work is done in submerging particles of light fluid in the heavier fluid and also in lifting the heavy particles into the lighter fluid. Clearly, in the example selected, the axial component of the fluid velocity has no effect upon the mixing

process and only the radial velocity components are effective in promoting mixture of the two liquids. It naturally follows that the work of mixing the two liquids is accomplished at the expense of the energy available in the radial components of flow. If the work required for mixing is less than the amount of energy available, then the mixing process goes forward rapidly. On the other hand, if the work required for mixing is greater than the turbulent energy present, the process continues until the energy available is used up and then, having reduced the crossflow, the mixing process is checked. Thus, in this second case, the presence of the heavier liquid tends to smother the crossflow in the pipe.

In the example selected, the mixing was accomplished by the radial components of flow but, in the more general case where there is a small isolated mass of heavier liquid, mixing can take place in all directions and it is more correct to say that the mixing process depends upon the energy available in the fluctuating components of the velocity.

From the foregoing, it would be expected that the change from good to poor mixing conditions would take place rapidly. That is, as soon as the heavier liquid starts mixing, its specific gravity is reduced so that the process continues more easily. However, if the heavier liquid is not diluted, it continues to smother the fluctuating component of flow.

The work of mixing is accomplished at the expense of the energy in the fluctuating component. The size of the average fluctuating component is usually expressed as a percentage of the average forward velocity and this is called percentage of turbulence. For instance, 10 per cent turbulence means that the average fluctuating component is $^1/_{10}$ of the average forward velocity at that point. Returning to the mixing process, when a given shot of salt solution is injected into a pipe, a certain amount of energy is required for mixing. Since the energy available for mixing varies as the cube of the fluctuating component and the fluctuating component is proportional to the forward velocity in a given pipe, it follows that the energy available for mixing varies as the cube of the forward velocity. Thus a small change in the forward velocity results in a large change in the energy available for mixing and it would be expected that the change from good to poor mixing conditions would take place suddenly. The test results show this to be true. The curves in Fig. 4 show small experimental or casual errors at high velocities which continue unchanged to some definite low velocity. Then there is a "break" in the error curve showing a sudden departure from the purely experimental type of error. The value of the velocity at the break in the error curve, which is the velocity required for good mixing, is termed the "critical mixing velocity."

FURTHER TESTS WITH BRINE AND HYDROCHLORIC-ACID SOLUTIONS

When brine is injected into water, the excess weight of the brine is proportional to the difference of the specific gravities of the brine and the water. Thus, brine of 1.10 specific gravity has 10 times more weight in water than brine of 1.01 specific gravity. The term "specific gravity minus one" is called the effective specific gravity during the remainder of this discussion.

Tests were then made to determine experimentally the effect of a change in the specific gravity of the injected brine upon the critical mixing velocity. This was done first in the 12-in. pipe and, subsequently, in the 2-in. pipe. In the 12-in. pipe test,

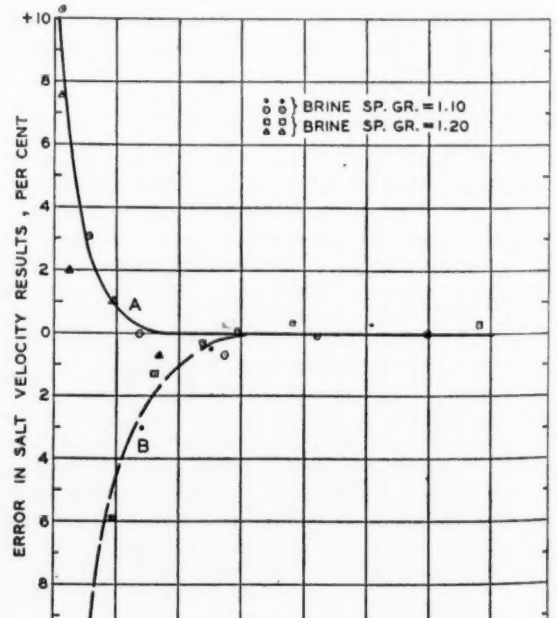

FIG. 5 TEST IN 12-IN. VERTICAL PIPE WITH BRINE SOLUTIONS
(*A*, downward flow; *B*, upward flow.)

brine of 1.2 and 1.1 specific gravity and dilute hydrochloric acid of 1.02 specific gravity were used. The results of the first two tests came out so close together that a single curve represents their average, Fig. 5. The test with the dilute acid, Fig. 6, indicated that the solution was mixed at a lower velocity in the case of upward flow but there was little change with the downward flow. Furthermore, these test points show much more scatter than in any of the other tests with brine. It was believed that the acid probably produced secondary chemical and, therefore, electrical effects at the electrodes which were zinc-covered, with the consequence that the results were not as reliable as the tests made with brine.

The results of tests with brines of 1.01 and 1.1 specific gravity are shown in Fig. 4. Selecting an arbitrary error of —1/2 per cent in the salt-velocity measurement, a velocity of about 0.94 fps is found with brine of 1.1 specific gravity and about 0.45 fps with brine of 1.01 specific gravity. These results are in substantial agreement with the mixing theory stated. On the one hand, the work done varies directly with the "effective specific gravity" of the solution being mixed, while on the other, the energy passing through a unit area in the pipe cross section varies as the cube

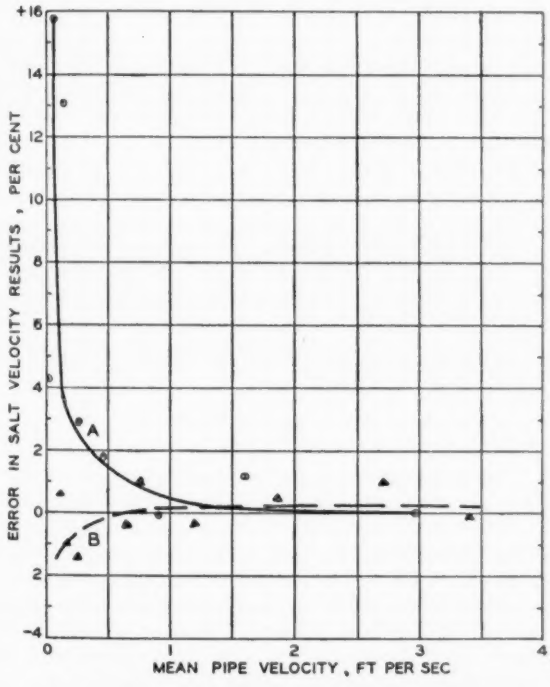

FIG. 6 TESTS IN 12-IN. VERTICAL PIPE WITH DILUTE HYDROCHLORIC ACID

(*A*, downward flow; *B*, upward flow; specific gravity 1.02.)

of the velocity. If the turbulent energy required is reduced to 1/10 of its previous value, the pipe velocity required to produce this energy is only reduced by $(0.1)^{1/3}$ or 0.465 of its previous value. This is practically the change in the critical mixing velocity found in the 2-in. line tests with a 10:1 change in the "effective specific gravity" of the injected salt solution.

The total work done in mixing is also proportional to the quantity of brine injected into a given volume of water flowing in a pipe. The power required for commercial recording instruments makes it difficult to secure sufficient electrode effect in small pipes and thus the quantity of brine is usually increased so that suitable curves will be obtained on the recording chart. For instance, in the 2-in. line tests with the weak brine of 1.01 specific gravity, the ratio of the brine to the discharge was nearly 20 times greater than in larger pipes. Therefore, the critical mixing velocities found in the 2-in. line tests are greater than those necessary in larger pipes with the same flow condition.

The laboratory tests do not indicate directly the effect of wall roughness upon the critical mixing velocity but an idea of its influence may be obtained from theoretical considerations. The previous discussion indicates that a definite value of the average fluctuating component was necessary to produce satisfactory mixing for a given flow condition. This value of the fluctuating component may be obtained with a low percentage of turbulence and a high forward velocity or with a high percentage of turbulence and a correspondingly lower forward velocity. The present theory of turbulence indicates that the percentage of turbulence at a point in a pipe is proportional to the wall roughness. Therefore, the greater the pipe roughness, the lower the pipe velocity necessary to provide good mixing.

EFFECT OF GRAVITY UPON INJECTED BRINE SOLUTIONS

The effect of the force of gravity upon the injected brine or the tendency of the brine to sink through vertically flowing water was studied in the 12-in. pipe tests. At very low velocities when proper mixing is not secured, the errors in the salt-velocity measurements indicate that the unmixed brine masses tend to slip through the flowing water under the influence of gravity. That is, when the flow is upward, the salt masses travel more slowly than the main body of water, resulting in a longer passage time and an indicated discharge which is too small. With downward flow, the brine tends to slip along faster than the water with a resulting discharge which is too large. But a study of the curves, Fig. 5, will show that, when there is proper mixing of the brine, there is no systematic error of the salt-velocity measurements. The importance of this fact cannot be overemphasized.

The test curves made with brine of 1.1 and 1.2 specific gravity in the 12-in. vertical pipe are not symmetrical with respect to the axis of zero error, the upward-flow tests showing a higher critical mixing velocity than the downward-flow tests. It is probable that, in the case of downward flow, the force of gravity, acting upon the unmixed brine masses, tends to give them a slightly increased velocity. This energy is dissipated in eddies and, hence, promotes the mixing process. Conversely, with upward flow, more energy must be supplied from the water flowing in the pipe to lift the unmixed brine in addition to mixing it.

APPLYING SALT-VELOCITY METHOD IN WATER-WHEEL INTAKE

In this discussion of tests at low velocities with the salt-velocity method, only the application of the method to a long straight pipe has been considered. This assumes that normal pipe flow exists at the point where the brine is injected and continues through the measuring section. It might be inferred from these tests that it would be impossible to apply the salt-velocity method in the intake of a large water wheel where pipe flow does not exist and, hence, where turbulence due to upstream wall roughness is lacking. But there are two very important differences to be taken into account when considering flow into an intake. Since pipe flow has not yet started, all of the water is moving forward with very nearly uniform velocity and, hence, the nonuniform distribution of the brine, as it leaves the pop valves, causes an insignificant timing error. On the other hand, turbulence is probably considerably greater than would normally be found at the entrance to a pipe due to the disturbing influence of the racks which are always present in a water-wheel installation. During 20 years of experience with this method, a large number of intake-test installations have been made. In not one of these instances was there any evidence of a lack of proper mixing of the brine, although in some cases the water velocity at

the injection station was below that indicated in these tests as being necessary for proper mixing. Thus, it is believed that the factors concerning the critical mixing velocity which have been discussed only apply to the measurement of flow in long straight pipes with very low velocities.

Summary

The following conclusions may be drawn from these salt-velocity measurements at low pipe velocities:

1 The low-velocity effects discussed in this paper are found at velocities below those normally encountered in practice.

2 The critical mixing velocity is a very definite limiting velocity below which proper mixing of the injected brine is not secured.

3 The force of gravity does not have any influence upon the accuracy of the salt-velocity measurement as long as the injected brine is readily mixed with the water flowing in the pipe.

Acknowledgment

The author gratefully acknowledges the assistance given by Dr. Th. von Kármán who suggested the mechanics of the mixing process and thereby contributed greatly to the value of this investigation.

Discussion

D. P. Barnes.[2] Referring to this and the paper[3] by O. H. Dodkin, it is begining to be recognized that, for the salt-velocity method to yield ideally correct results, it would be necessary that all the small elementary volumes of salt solution spend statistically equal periods of time in each of the different velocity zones from the center line to the outer radius in passing between electrode stations. This is to say that turbulent mixing should be continuous and complete transversely across the pipe throughout the passage. Any deviation from this continuous symmetry and uniformity of mixing would mean that part of the salt cloud must lag behind the mean flow, the center of gravity of the salt cloud, therefore, with it.

The natural tendency of a dense solution to settle downward and to underflow a lighter liquid as an integral body is now a well-established experimental fact. In the salt-velocity test, if this tendency is not completely countered by the turbulent mixing, it would be expected that in time the salt cloud would become progressively less symmetrical or less uniform with respect to the pipe.

In a sloping pipe, the effect of the tendency for the denser liquid to assume an asymmetrical distribution is compounded with the effect of the component of underflow in the downhill direction. In any case the asymmetry or nonuniformity alone would tend to produce a velocity reading smaller than the true mean, and this effect would be increased in the case of pumps with uphill flow or decreased in the case of turbines with downhill flow by the downhill component of the underflow.

The numerous field checks would appear to establish that the errors introduced by these tendencies are slight and, that where the method is used with full recognition of the possible sources of error and where a proper allowance is made for them, the results may be supposed accurate within perhaps 0.5 per cent, at least for downhill flow. This is a view to be accepted with caution, however, for bends, obstructions, steep slopes, low velocities, or abnormal velocity distributions in the penstocks must continue to introduce uncertainties wherever their effects are not subject to calibration. It would seem that each proposed application of the method should therefore be considered largely on its own merits.

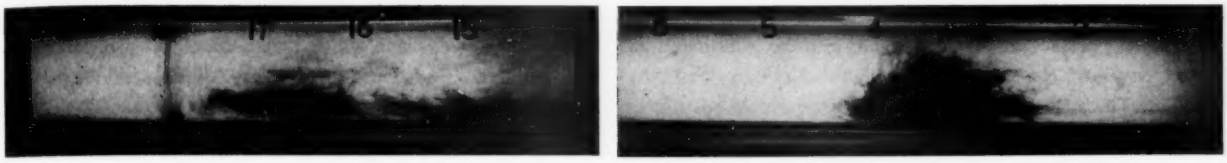
Andrew Fejer[4] and J. W. Daily.[5] During the last few years, it has become more and more desirable to determine large rates of flow with great accuracy. In the case of large-scale field tests the salt-velocity method has been found particularly suited for such measurements because of its simplicity and convenience in application. Very little is known, however, about the performance of the method at low velocities, and this paper furnishes useful experimental information in that range.

In connection with investigations conducted at the hydraulic-machinery laboratory of the California Institute of Technology on the design, operation, and testing of large-capacity pumps and especially in connection with the question of extrapolation of model results to prototype results, it has been of considerable interest for the Institute to subject the salt-velocity method to experimental study. The experimentation was assigned to the writers, who present the following summary of results with the approval of the laboratory directors.

Experimental Work

Following Dr. von Kármán's suggestion that a salt cloud would tend to settle downward in water due to its higher density whenever the turbulent forces were inadequate to keep the cloud in suspension, it was decided to obtain qualitative information about shape and character of salt clouds under different flow conditions. The tests undertaken were made in a straight, transparent, lucite pipe 20 ft long and $5^1/_2$ in. inside diam, mounted in such a way that it was possible to change its inclination from 0 to 13 deg. Solutions of sodium nitrate deeply colored with potassium permanganate were injected into the flow through pop valves under compressed-air pressure, and visual, photographic and cinematographic observations of the behavior of the cloud on its path through the pipe were made. Two types of injection nozzles were used, i.e., a single central pop valve in the pipe axis and a combination of six pop valves distributed uniformly over the cross section. Solutions of five different densities (1.2, 1.15, 1.10, 1.05, 1.025) were injected into flows of velocities, covering a range of 0.1 to 1.5 fps. This range corresponds to a range of 0.5 to 7.5 fps for geometrically similar flow in a pipe 10 ft in diam.

Discussion of Results



It was found that the salt cloud retained its symmetrical shape only at considerable flow velocities. This can happen only if the

energy of turbulent fluctuation is sufficient to overcome the differential-gravity forces. It may be considered that for a given setup the scale of the turbulence is independent of the rate of flow, while the magnitude of the turbulent-velocity fluctuations is proportional to the mean velocity of flow. This means that the energy of the turbulent fluctuations is proportional to the square of the velocity of flow. For this assumption, the ratio between the energy of turbulence and the work done by differential gravity forces may be expressed by a dimensionless quantity which contains in the numerator the square of the mean velocity and in the denominator the product of the effective gravity and a linear dimension of the setup (say the diameter of the pipe). This quantity, which has the form of a Froude number for a particular setup, is written

$$F = \frac{v^2}{Dg\left(\frac{\rho_2 - \rho_1}{\rho_1}\right)}$$

where v = mean velocity in fps; D = diam of pipe in ft; g = acceleration of gravity in fps^2; ρ_2 = mass density of cloud; ρ_1 = mass density of water; and product $g\left(\frac{\rho_2 - \rho_1}{\rho}\right)$ = effective gravity.

The value of the ratio at which the symmetrical form breaks down can be considered as the critical Froude number. Whenever the density of the injected solution is increased or the velocity of flow decreased so that the Froude number is smaller than the critical, a secondary or density-flow current is set up, the cloud sinks to the bottom of the pipe, and the assumption of the salt-velocity method that the average velocity of flow equals the average velocity of the cloud is no longer valid. Figs. 7 to 10 of this discussion[6] show typical salt clouds within a range of Froude numbers from 0.03 to 0.68. Figs. 8 and 10 show clouds corresponding to the critical Froude number which was found to be reasonably constant over the range of velocities and densities considered. For tests with the single nozzle $F_{crit} = 0.7$, and with the multiple nozzle $F_{crit} = 0.56$. The difference is due to the range in the scale of turbulence caused by the change in the geometry of the flow.

REMARKS ON THE FROUDE NUMBER

The Froude number just discussed should express the ratio of the inertia forces to the effective gravity forces acting on the cloud shortly after the effects of the injection have disappeared. As stated, the term ρ_2 should be the actual "initial cloud density." For practical use of the Froude-number criterion, it is necessary

[6] Figs. 7(*a*) to 10(*a*) show the clouds immediately after the injection, while Figs. 7(*b*) to 10(*b*) illustrate the same clouds some distance downstream. The numbers give the traveled distance from the injection nozzle in pipe diameters.

to correlate this initial density with the known density of the injected brine. Two simple assumptions can be considered as limiting cases:

1 The brine suffers no volume change between the instant of injection and the formation of the cloud; and

2 The injected brine is distributed immediately with a rate of dilution proportional to the velocity of flow.

As Figs. 7(*a*) to 10(*a*) indicate, the volume of the brine cloud does increase immediately after injection. On the other hand, the second assumption is not strictly valid. Rough measurements from photographic records show a definite tendency of the cloud size to decrease with increasing velocity of the main flow. This apparently is due to the fact that the penetration of the brine in the lateral direction decreases with increasing velocity. For high velocities, the cloud has an elongated shape with a small diameter while for small velocities the cloud has a large diameter even though of short axial length. It appears to the observer that because of these facts the two effects approximately balance each other. Consequently, the assumption of a constant "initial cloud size" seems reasonably justified. Since the density of the brine solution as injected is proportional to the "initial cloud density" for a constant injected volume and a constant initial cloud size, it was introduced into the expression for the Froude number.

It should be noted that the critical Froude number is not necessarily the same for different setups. The intensity and scale of turbulence can be different for various setups even in the case of geometric similarity. The type of the injection nozzles, the size of the injected volume, and the pressure used for the injection affect the initial cloud size. However, the experimental results mentioned show that, for a fairly wide range of injection conditions, the values of F_{crit} vary between narrow limits.

Conclusions

Both the author's work and the experiments noted in this discussion appear to indicate conclusively that salt clouds, as used in the salt-velocity method for rate-of-flow measurements, sink by virtue of the differential gravity forces into regions of lower velocities whenever the rate of flow and therewith the turbulent forces decrease beyond a certain minimum value. Below this velocity, which appears to be mainly dependent upon the Froude number of the test, it cannot be assumed that the cloud indicates the average velocity of flow.

It would be interesting to combine the author's method with the type of attack herein mentioned to determine whether the breakdown of the method, as shown by his experiments, coincides with the "critical Froude number" or whether additional sources of error counteract or accentuate the effect of the density currents.

R. T. Knapp.[7] These first published results on one of the auxiliary phenomena accompanying the salt-velocity method of water measurement are of value, especially, since it is possible that the effects of the density difference between the salt cloud and the water may form one of the basic limitations on the accuracy of the method.

The writer considers it rather unfortunate that the author restricted his measurements to horizontal and vertical pipes. The vertical pipe is not a typical case, since it represents a condition of equilibrium between the two fluids. It is true that this equilibrium is unstable, but it is probably very effective in the short time interval which exists in a salt-velocity measurement. Indeed, the existence of this equilibrium has been utilized by some Swedish investigators[8] in the development of a sedimentation type of particle-size analyzer in which a high-density suspension is superimposed upon a body of lower-density liquid. Thus, it seems that it would be unsafe to consider a vertical pipe as an extreme case of an inclined one and to use the results from the vertical flows to predict what would happen in the inclined pipe.

It should be remembered that the effect to be anticipated, as the result of the difference in density of the two flows, is basically a lateral one and not an axial one. In the horizontal or inclined pipe, the salt cloud tends to settle toward the lower side of the pipe, thus effectively lowering the average velocity of the solution. Of course, in the inclined pipe, there will be an axial component as well, which will tend to increase or decrease the velocity, depending upon the direction of flow. However, this axial component is probably of secondary importance.

In conclusion, the writer feels that this phenomenon is a very important one and hopes that the present paper represents only the beginning of the author's investigations on the subject.

M. A. Mason.[9] The suggestion that the possibilities and applicability of the Allen method might be defined by criteria relating the physical and hydraulic characteristics of a proposed test section[10] has been applied to pipe flow by the author, and it seems that at last the Allen method may be thoroughly studied in a logical manner, looking to the complete definition of its place in the art of water measurement.

The writer would, however, disagree with the author's choice of a criterion for good mixing. It is not believed that the "critical mixing velocity" is a sufficient definition of the hydraulic characteristics of a waterway to permit its use as a criterion of the mixing conditions in the test section. A moment's thought will show that, for a particular system in which normal pipe flow has been established, a critical velocity can be found which defines the mixing ability of the flow under the conditions existing. However, as stated by the author, "the percentage of turbulence at a point in a pipe is proportional to the wall roughness. Therefore, the greater the pipe roughness the lower the pipe velocity necessary to provide good mixing." It follows that the mean velocity of flow is not a satisfactory criterion of mixing, except for specified conditions which, in general, will apply only to the system used to evaluate the criterion.

A more important objection to the use of a velocity parameter as a criterion lies in the omission of a time element defining the period during which mixing is accomplished. To be of value in the application of the method, the mixing criterion must define, for a standard injection procedure, the minimum distance along the waterway required for the complete mixing of injected solution and water. Obviously the proposed velocity criterion does not furnish such information and, in fact, defines only the mixing ability of a flow under certain unique conditions.

From consideration of the mechanism of mixing and the character of turbulent flow, one may specify the probable components of a general criterion of mixing. The percentage of turbulence, i.e., the proportion of the forward velocity of flow present as fluctuating turbulence velocities in the flow, defines the ability of the stream to transport solution from the point of injection to other points in a cross section. If the turbulence is isotropic, then the percentage of turbulence is therefore a measure of the

rate of diffusion of the solution throughout a cross section due to turbulent mixing. The percentage of turbulence is certainly one of the components of the criterion, and includes not only the velocity, but also the roughness characteristics of the waterway.

Obviously, a size factor of the conduit must also be included in the criterion; for a closed channel the area, and for an open channel, either the wetted area or the hydraulic radius might be considered.

A third factor, time, must be included. Considering percentage turbulence as a measure of the spatial rate of transport of solution throughout the water, it is evident that a certain time must elapse for the transport of a salt particle from, say, the center of the conduit to the wall, or vice versa. The time factor might then be expressed as the ratio of water depth or pipe diameter to the radial component of the turbulence fluctuations. The fractional portion of the linear dimension to be employed in this expression will, of course, depend upon the injection pattern.

If a standard pattern of injection can be adopted the influence of injection procedure may be eliminated, and more important, the time factor may be very considerably reduced by the use of a well-distributed injection pattern.

Assuming the foregoing analysis to be applicable and letting u_t be the mean turbulence fluctuation; A the cross-sectional area of the channel; and T the time factor; the form of the mixing criterion might be

$$M = u_t AT \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

having the dimensions L^3 of a volume.

Because of the practical difficulty of measuring u_t, it may be desirable to substitute for u_t the expression[11] lv, where l is the Prandtl mixing length, and v is the kinematic viscosity of the water. Experiment alone will determine the most satisfactory term to be used as a measure of the turbulent diffusion, the suggestions given herein being intended principally to indicate the nature of the term.

The results of the author's tests to determine the effect of gravity on the operation of the salt-velocity method are a further corroboration of the writer's thesis[1] that turbulence in the stream is the chief factor governing the accuracy of the method.

E. A. Taylor.[12] The author has described a study which gives a laboratory answer to a salt-velocity question which has arisen several times in the field. This question was: "When salt is introduced into a penstock does the higher specific gravity of the salt solution drive the salt through the water and toward the bottom of the penstock, thus changing the time of passage of the salt solution through the test section, and introducing an error in salt-velocity measurements?"

At many of the high-head power plants, where salt-velocity tests have been made, the penstocks have very steep slopes and, at some of them, the penstocks approach the vertical for considerable distances. If this difference in the specific-gravity question were important, then the computations for turbine efficiency at those plants might be appreciably in error.

The results of the laboratory studies described by the author indicate that the effect of gravity on the salt-velocity method of water measurement is negligible, when proper salt mixing and distribution are secured.

In 1939, the salt-velocity method of water measurement was used in making efficiency tests on the Colorado River Aqueduct pumps for the Metropolitan Water District of Southern California. During those tests, a field answer was found to the specific-gravity question. The question was raised at the Iron Mountain Pumping Station and the district engineers agreed to turn that plant into a field laboratory to study the subject.

The regular salt-velocity test section, used for pump-efficiency tests at this plant, was 200 ft long, 100 ft from salt injection to the first set of electrodes, and another 100 ft to the second set of electrodes. For this specific-gravity study, two additional pairs of electrodes were installed in the 10-ft delivery pipe.

These additional electrodes were called spot electrodes and consisted of small steel plates, 4 in. square and spaced 2 in. apart. These spot electrodes were fastened 5 ft beyond the regular second set of electrodes, making the length of test section used for the spot electrodes 105 instead of 100 ft. One pair of spot electrodes was located at the top of the pipe and the other pair at the bottom. During the study, the ammeter connections were alternated, shot by shot, between the two sets of spot electrodes.

A total of 74 salt shots were made and computed in this study. Averaging the results of these shots showed that the passage time to the top spot electrodes was 0.04 sec less than the passage time to the bottom electrodes. This was regarded as a perfect check and a conclusive field answer to the gravity question.

As further assurance of the accuracy of the salt-velocity method of water measurement and confirming the belief that any specific-gravity error was too small to be seriously considered, two volumetric check tests have been made at Pacific Coast plants, one of them being a high-head plant with a steep slope in the penstock.

For those check tests, a 3-acre forebay, 20 ft deep, and a 10-acre reservoir, 10 ft deep, were used as basins for the volumetric measurements. The volumetric results checked salt velocity, by 0.75 per cent at one plant and by 0.5 per cent at the other plant. The latter was the high-head steep-penstock plant where any gravity effect would be expected to be most apparent.

The author's conclusion, from laboratory tests, that "for velocities lower than those normally found in practice, there exists a critical mixing velocity below which good mixing of the injected brine does not occur" is confirmed by some field tests recently made.

Field efficiency tests were made on the Colorado River Aqueduct pumps in May and June, 1939. At Intake, the first station tested, the discharge values for single pumps checked the discharges when two or three pumps were operating together.

At the second station tested, Gene, the results of the preliminary tests, comparing single- and multiple-pump discharges, did not check.

At all five Colorado River Aqueduct pumping stations, one 10-ft delivery pipe carries the discharge from the three pumps now installed at each station. When only one pump is operating, the velocity in the delivery pipe is comparatively slow, about 2 fps. The inside of these delivery pipes is coated with an enamel finish, as smooth as glazed porcelain, and there are no rivet heads or other projections into the inside of the pipe.

This combination of extremely smooth pipe and low velocities created a condition of low turbulence, too low for satisfactory salt mixing, during the passage of a shot. This accounted for the failure of the discharge values to check between single and multiple pumps.

To provide more turbulence, an artificial agitator, called a "turbulator" was installed beyond the salt-injection station. This so-called turbulator was a steel disk, 6 ft in diam, fastened in the center of the delivery pipe and normal to the axis of the pipe. This disk had an 18 × 24-in. hole in the center and was located 40 ft beyond the pop valves. The turbulator was used during the remainder of the pump tests and single-pump-discharge results checked the multiple-pump values.

No artificial turbulator was required at Intake, because the salt-injection station was just above the manifold where the three

[11] "Modern Developments in Fluid Dynamics," edited by S. Goldstein, Oxford University Press, New York, N. Y., 1938, chapter 5.

[12] Consulting Engineer, Worcester, Mass.

6-ft pipes enter the one 10-ft delivery pipe. The pop valves were only 25 ft beyond this manifold and the turbulence caused by the bends in the pipes was sufficient to last throughout the salt-velocity test section.

R. M. WATSON.[13] From information now available, it appears that, with normal pipe roughness, mean water velocities, reasonable test sections, and when handled by a competent test crew, the salt-velocity method for determining the rate of flow of water is consistently accurate within 0.5 per cent. The writer belives this to be the limit, at present with few exceptions, to which any evaluation should be made. This accuracy is quite comparable to that by which the other factors, pressure and power, which express the performance of hydraulic machinery, can be determined reliably in most commercial installations.

Among the many factors which affect the accuracy of the salt-velocity method are the velocity of flow and the degree of turbulence in the stream. As shown by the author, a certain minimum turbulence is necessary in order that the salt cloud will travel with the flow without slippage. Apparently this problem had not been encountered in the field until a recent installation which had an exceptional combination of low velocities and smooth pipe walls. Unexplainably low results indicated trouble which was traced to the absence of turbulence. Excessive deviation from the expected results was corrected by the introduction of a "turbulator," the purpose of which was to create high turbulence ahead of the salt-injection nozzles.

In view of the difficulties experienced in the initial tests, opportunity was taken to make a check of the effect of the low velocities at those stations at which pumps manufactured by the writer's company were installed. Each station consisted of three pumps, each pump discharging from a 6-ft pipe into a common 10-ft pipe. The salt-velocity test section was in this 10-ft line, with approximately 4 pipe diameters between the turbulator and the salt-injection nozzles; 10 pipe diameters between the injection valves and the first electrodes, and 10 diameters between the first and second electrodes. The 10-ft discharge pipe at the test section ran upward at an angle of about 25 deg with the horizontal.

The tests were made by the customer's crew of engineers. This test crew had had the experience of previous salt-velocity work, in addition to experience with the use of this method on nine other pumps in three stations at this same large development. In every case the same problem existed; that of measuring by the salt-velocity method the rate of flow with very low mean pipe velocities and with extremely smooth pipe walls. This same crew was present and assisted in the development of a satisfactory technique for the method under the same conditions of low velocities and smooth pipes prevailing at the first three stations, and was therefore well qualified to conduct similar tests under similar discharge-pipe conditions at the two stations in which the writer's pumps were installed.

Piezometer taps were placed at two sections of different areas in the suction cones of all three pumps. The reduction in areas was sufficient to give a differential reading of approximately 6 in. of mercury in the range of flows considered. These venturi meters were calibrated individually by salt-velocity tests made during the operation of each pump singly. The salt-velocity test section was in the 10-ft pipe common to all three pumps. Each pump was operated individually, then in pairs, and finally all three together. Salt-velocity determinations of the flow were made each time. These calibrations were used during the multipump runs to measure the flow delivered by the individual pumps. During the multipump run, the sum of the individual flows thus determined was compared with the total as measured by the salt-velocity method. The individual pump flows varied from approximately 180 cfs to 215 cfs, with corresponding mean pipe velocities varying between 2.3 fps and 2.7 fps. For two and three pumps operating together, the mean velocities in the test section were, respectively, 2 and 3 times the mean velocities in the test section during individual pump operation.

As a result of an analysis of the data by the writer, it appeared that the salt-velocity results obtained with the low mean pipe velocities, existing during the individual pump runs, were low by between 0.3 per cent and 0.6 per cent, as compared to the salt-velocity results obtained with the higher mean pipe velocities existing during the multipump runs. It is interesting to note that the laboratory results presented by the author confirmed the possibility, direction, and order of magnitude of this discrepancy. It is equally interesting to note that the discrepancy between the single-pump and multipump tests was within the 0.5 per cent accuracy obtainable with the salt-velocity method under normally favorable conditions. It was only the peculiar combination of circumstances present at this installation which warranted the attempt for even better accuracy.

In general, the difficulties experienced in the measurement of the flow by the salt-velocity method were traceable, as brought out in the paper, to insufficient turbulence to prevent an actual slippage and retardation of the salt cloud due to its greater density, particularly immediately after the injection. This resulted in an apparent rate of flow which was considerably less than the actual. Improvement was obtained by installing a turbulence-creating construction a short distance ahead of the injection valves. The trend, however, of any error from this effect was shown definitely in these field tests to be negative, as is indicated by the laboratory tests of the author.

Even with the artificially created turbulence, the analysis of the field tests on six of the pumps as made by the writer, indicated that some slippage did occur. In explanation, it is probable that the turbulence resulting from the constriction decreased sufficiently within the test section to permit some slippage of the slightly more dense salt cloud. Certainly such is possible if the rather high turbulent energy in the flow leaving the pump (although this energy would be in small-scale eddies), and the turbulence created at the junction of the 6- and 10-ft pipes during single-pump operation, decreases sufficiently before reaching the injection nozzles to cause the troubles noted.

In opposition to the results of the writer's analysis of field tests and checks and resulting conclusions, conditions at one of the other three stations of this project permitted a volumetric check of the salt-velocity results. By this check the salt-velocity results appeared approximately 0.5 per cent high, after installation of the turbulence-creating construction. However, the writer does not know the full details of this check, and cannot, therefore, attempt to analyze possible differences.

In connection with the field checks of the salt-velocity method, the writer wonders whether or not an examination has disclosed any common characteristics of settings, or other factors, which tend to give high results in some cases, and low results in others. Such an examination should help to predict the direction of any error and possibly ultimately to eliminate some of the causes.

With the increasing size of centrifugal pumps and an expanding knowledge of design, pump efficiencies have now reached and even exceeded 90 per cent. The pump designer is therefore no longer satisfied with the 1 per cent to 2 per cent over-all test accuracy which used to be acceptable. The ability to differentiate between the effects of small design changes requires increasing accuracy in the tests as the efficiency increases. Whereas, at 80 per cent pump efficiency an accuracy of 2 per cent is sufficient to detect

[13] Engineer, Centrifugal Pump Division, Worthington Pump and Machinery Corporation, Harrison, N. J.

really significant design differences, this accuracy should be better than 0.5 per cent when the efficiency approaches or exceeds 90 per cent.

Author's Closure

The discussion presented by Messrs. Fejer and Daily is of great interest to the author, especially the suggestion in connection with the Froude number. This number, however, cannot be used as a guide until more tests have been made to determine its critical limits and the factors affecting those limits, because it does not of itself completely define the flow conditions. Furthermore, in addition to the pipe velocity, pipe diameter, and brine specific gravity, which factors make up the Froude number, the roughness of the pipe wall has a direct bearing on the turbulence, as does also the viscosity of the fluid and the quantity of brine injected per second-foot of flow. Finally, there is a modifying factor introduced by the performance of the brine after being injected.

The first three points were mentioned in the paper, but the last may need further clarification. It has been shown by experiment that the same amount of salt solution, injected at a constant rate, provides practically a constant height of electrode curve over a wide range of velocities. Since the duration of the shot remains constant, it follows that for low velocities the salt is confined to a small volume of the penstock water and is distributed over a proportionally larger volume of penstock water at higher velocities. Thus the total energy for mixing becomes the product of the energy per pound and the quantity of water flowing. This indicates experimentally that the energy available for mixing varies approximately as the cube of the velocity rather than the square.

With these thoughts in mind, the critical Froude numbers are presented for those tests where complete information is available, as follows:

Test no.	Pipe diam, ft	Critical velocity, fps	Brine, specific gravity	Factor
1	0.17	0.45	1.10	3.70
2	0.17	0.94	1.10	1.61
3	1.00	0.90	1.10	0.25
4	3.33	0.67	1.06	0.07
5	10.00	2.50	1.18	0.11
Caltech	0.42	..	..	0.56–0.07

The results with the 2-in. pipe seem to be far out of line but it is known in test No. 1 that the quantity of brine introduced per second-foot of flow was nearly 20 times larger than usual. Dividing 3.7 by 20 gives 0.19, which brings the result more in line with the figures obtained for the larger pipes.

The values of critical Froude number obtained by actual salt-velocity measurements are about $^1/_6$ to $^1/_3$ the values given by Fejer and Daily and they extend over a rather wide band. At the start of these tests, all of the factors controlling the mixing process were not appreciated, so that some of the experimental information is approximate. This applies particularly to the amount of salt injected per second-foot of flow. It is hoped that some of these tests can be repeated at an early date so that an experimental verification of this Froude number may be obtained.

Referring to Mr. Mason's discussion, it was not the intention of the author to suggest the use of the "critical mixing velocity" itself as a criterion for good mixing. As stated in the paper, the mixing process is affected by (1) the amount of brine injected; (2) the specific gravity of the brine; (3) the roughness of the pipe wall; (4) the size of the pipe; and (5) the velocity of flow in the pipe. All of these terms affect the mixing process in the first power except the velocity factor which varies as the cube. Therefore, a change in the velocity is more significant than a change in any other factor. From this point of view, the term "critical mixing velocity" was used in a descriptive way and not as a sole criterion of performance.

Furthermore, Mr. Mason states that the time or mixing distance should appear in the mixing criterion. The mixing distance is a factor intimately connected with the design of the pop valves and their installation with respect to the first electrodes; from that point it is most important. But, it was pointed out in the paper that, if the mixing process starts, it will continue; however, if the injected brine smothers the turbulence, the brine falls to the lower part of the pipe and remains segregated. Under these conditions, doubling the mixing distance or time will not improve the mixing. It is believed, therefore, that time or distance should not be represented in the mixing criterion.

With regard to Mr. Watson's discussion, it may be true there actually existed a small error for the flows measured for the single-pump units. Three similar pumping plants were tested in the same fashion by engineers of Professor Allen's office. In each case, the average agreement of the sum of the single pumps, compared with two and three pumps operating together, was to 0.1 per cent. This does not mean that the over-all accuracy of the method is 0.1 per cent on a field test.

In conclusion, it is realized that the work reported in the paper has only been a start in the investigation of the salt-mixing process at low pipe velocities and the constructive discussions which have been offered are appreciated.

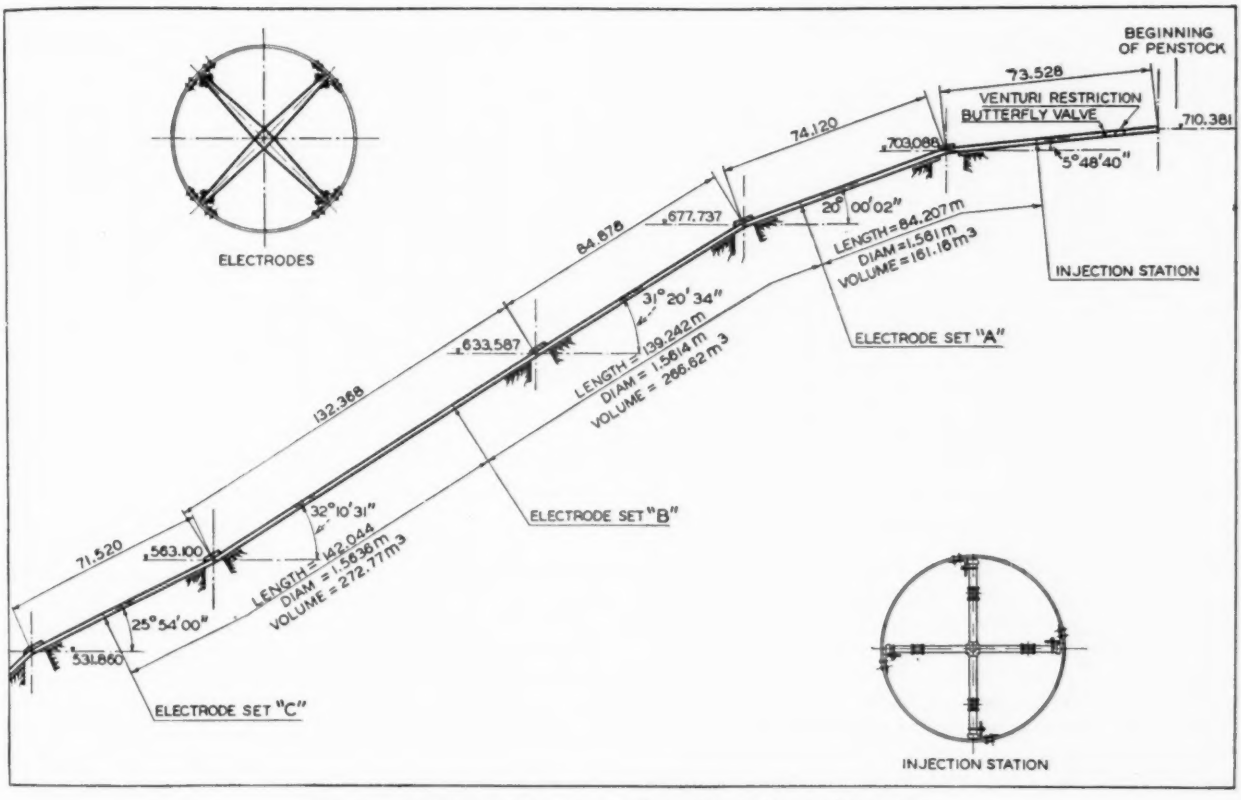

FIG. 1 SALT-VELOCITY LAYOUT AT UPPER END OF SERRA PENSTOCK

Field Checks of the Salt-Velocity Method

BY OSWALD H. DODKIN,[1] SÃO PAULO, BRAZIL

This paper gives the results of some tests made in Brazil on which verification of the reliability of the salt-velocity method of measuring discharge was obtained by cross checks with the method itself, by check tests with the Gibson pressure-time method, and by volumetric tests. These show a highly satisfactory agreement even in set-ups where the testing layout was far from ideal.

THE problem of measuring accurately the large discharges of modern hydraulic turbines is one that has engaged the efforts of many hydraulic engineers. About two decades ago the Gibson pressure-time method[2] and the Allen salt-velocity method[3] were introduced to the profession. Both possessed advantages of simplicity and ease of application as compared with some of the older methods. Laboratory tests and some field tests showed also a very promising degree of accuracy. Since then considerable experience has been obtained with these methods which in general has confirmed the early promises of accuracy of both methods.

Both the Gibson and salt-velocity methods have been used with success in the several plants of the companies subsidiary to the Brazilian Traction, Light and Power Company, Ltd., the former since 1926 and the latter since 1924. The purpose of this paper is to report verifications of both methods obtained in these tests. There will be given two tests in which the accuracy of the salt-velocity method is confirmed by itself with a different apparatus setup, two tests in which the results are confirmed by the Gibson method, and one in which its accuracy is confirmed by volumetric test.

SERRA UNIT 5

Unit 5 of the Serra plant of the São Paulo Tramway Light and Power Company, Ltd., is a double-overhung impulse turbine of which the nominal rating is 84,000 hp at 680 m (2230 ft) net head and 360 rpm; on test it can produce 92,300 hp at 674 m (2210 ft) head. It is fed by a penstock line approximately 1600 m (5250 ft) long with three diameters; 1565 mm (61.61 in.), 1463 mm (58.60 in.), and 1346 mm (52.99 in.). Fig. 1 shows in sketch form the upper end of this penstock and the location of the salt-velocity injection station and the three electrode sets used for testing the unit.

T = average time of salt-cloud passage.
Q = discharge, cu m per sec.
v = variation of discharge from corresponding discharge section A—C.

The injection station consisted of four 2-in. pop valves set in from the pipe wall 38 per cent of the pipe radius. Elementary electrodes were placed at the side of two of the pop valves to determine the time of the salt-solution injection.

Each electrode set consisted of two pairs of electrodes at right angles to each other, extending across the penstock to within $^1/_2$ in. of the penstock walls. These electrodes were bowed to have a center spacing 6.5 times that of the electrode ends.

The volume between the axes of the electrodes was determined from four measurements of diameter in each pipe, approximately one measurement for each 5 ft of penstock, and tape measurements of the lengths, due allowance being made in the volume for the bump joints and rivet heads, from the penstock manufacturer's drawings.

In testing the turbine, a total of 24 runs with an average of 5.6 salt shots per run was made. For each run six different determinations of the discharge were obtained, i.e., from the injection station X to electrode sets A, B, or C; from electrode set A to B, or to C; and from electrode set B to set C.

Table 1 shows the number of salt shots for each run, the time of salt passage for each run and electrode combination, the resulting discharges, and the variations of these discharges from those obtained from the combination of electrode sets A and C.

These variations have been analyzed by computing the probable variation of any one run for the several sections with the formula

$$r = \pm 0.6745 \sqrt{\frac{\Sigma v^2}{n-1}}$$

where r = probable error, per cent
v = variation, per cent
n = number of runs

The probable variations of one run, as percentages, are as follows:

Section	$X-A$	$X-B$	$X-C$	$A-B$	$B-C$
r	±0.47	±0.22	±0.10	±0.12	±0.12

This shows a high degree of consistency of the discharge measurements, the greatest probable deviation of one run being less than 0.5 per cent for section $X-A$ where the testing setup is the poorest. Examination of the variations shows no tendency for consistent positive or negative variations. In the case of section $X-A$, this tendency which is there the greatest, averages —0.07 per cent for the 24 runs, but is meaningless, since the probable deviation of the average is greater, being ±0.10 per cent.

A further indication of the small variation in the discharge is obtained from the calibration of the venturi restriction based on discharges determined in section $A-C$. The least-squares determination of a straight line fitting the observations gives $K = 7.807 + 0.0105\,Q$ in the formula $Q = K\sqrt{H}$, where

Q = discharge, cu m per sec
H = venturi differential head, m of water

The variations of the observations from this line show a probable variation of any one point of ±0.0148 or say ±0.19 per cent. Considering that this variation includes the errors of measuring the differential head by a U tube containing bromoform, as well as the errors of the discharge measurement, it is in line with the variations found in the discharge determinations of section $X-C$, $A-B$, or $B-C$.

Serra Units 3 and 7

Unit 7 of the Serra plant is essentially a duplicate of unit 5 previously described. Unit 3 is similar, but with slightly smaller penstock and nozzle diameters, having a rated output of 72,800 hp and an actual maximum of 78,100 hp. The penstocks for units 7 and 3, especially the upper end, and the salt-velocity setups as applied there, were similar to that for unit 5.

When unit 3 was installed and tested in 1936, its penstock was temporarily connected to the venturi restriction and butterfly valve intended for unit 7. Sixteen calibration runs were obtained giving an average of K in the equation $Q = K\sqrt{H}$ of 7.447 ± 0.006. The probable deviation of one run was r = ±0.32 per cent.

Later in 1939, the penstock of unit 3 was disconnected from this venturi and the penstock of unit 7 connected. The venturi was again calibrated during the tests of unit 7. Twenty-two calibration runs were obtained, giving an average value of K of 7.430 ± 0.005. The probable deviation of any one run was r = ±0.28 per cent.

In either case, the salt-velocity setup was similar to that for unit 5. The discharges were determined from electrode sets A and C. The differential heads were measured by U tubes containing bromoform. The data of these two calibrations are given in Table 2 and are plotted in Fig. 2.

In the case of unit 3, the location of the injection station was

only 11 m, 7 pipe diameters, below the butterfly valve and venturi restriction, as compared with 24 m, 15.5 pipe diameters, for unit 5. The distorted velocity distribution resulting from the venturi and butterfly valve upset the precision of the salt-velocity discharges determined from the injection station to the electrodes. Such determinations differed from those from electrode sets A to C by as much as —2 per cent for X to A decreasing to —0.35 per cent for X to C. The results between electrode sets A — B and B — C, when compared with those between electrode sets A — C, were satisfactory, the variations ranging from 0.59 per cent to zero, with a probable deviation for any one run of $r = \pm 0.21$ per cent.

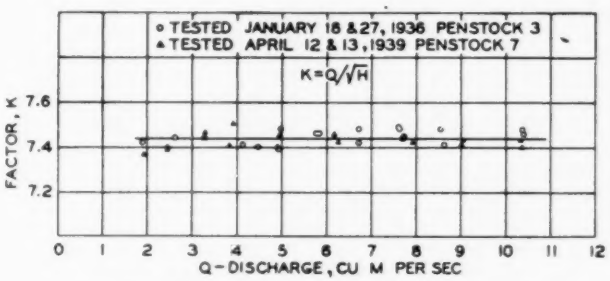

FIG. 2 CALIBRATIONS OF VENTURI; SERRA UNIT 7

The foregoing shows one point in the application of the salt-velocity method which must be emphasized. Where a high degree of accuracy is desired, the timing of the passage of the salt cloud in the waterway must be done between sets of electrodes extending across the entire waterway, not from the injection station to one electrode set, although with care in location of the injection station good results may be obtained thus, as shown by the tests on unit 5.

PARAHYBA UNIT 2

Unit 2 of the Parahyba plant of the Brazilian Hydro-Electric Company, Ltd., is a vertical reaction-type turbine, rated at 28,000 hp at 28.66 m (94 ft) net head or 32,500 hp at 31.7 m (104 ft) head and at 125 rpm. On test it exactly equals its rating.

Two complete efficiency tests were made on this unit December 19 and 21, 1927. On the first test, the discharges were determined

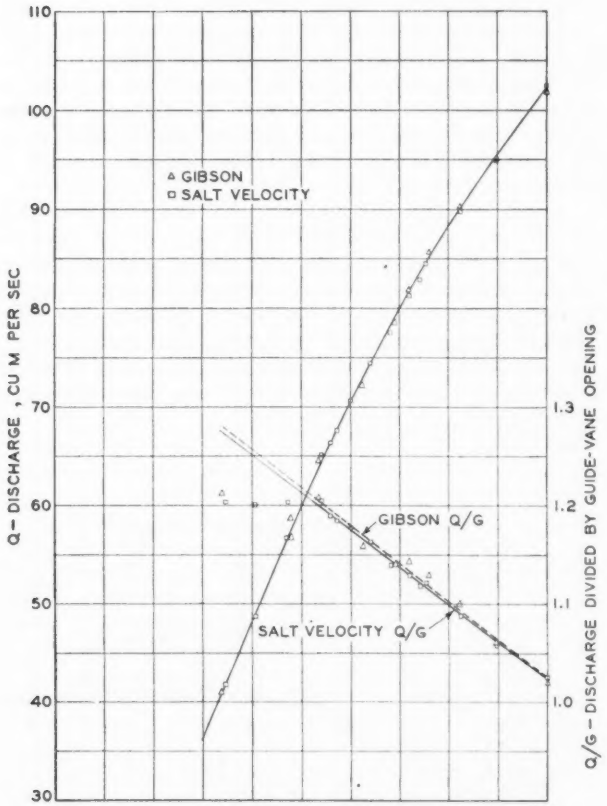

FIG. 4 TEST RESULTS; PARAHYBA UNIT 2

by the Gibson method applied differentially (10 runs). On the second test they were determined by the salt-velocity method (15 runs). Conditions of head, etc., were essentially identical on the two days.

Fig. 3 shows schematically the testing layout. Expressing the lengths in terms of the pipe diameter (average for the part concerned) the salt-velocity mixing length, introduction to upper electrode set, was 2.7 and the test length between electrode sets was 6.82. The length between the Gibson piezometers was 2.85. For the salt velocity, 12 pop valves were used at the stop-log plane. This gave one valve for each 40.5 sq ft of cross section at the injection station or one valve for each 24 sq ft of conduit section at the upper electrode set. The path from the highest pop valves to the upper electrode set was about 17 per cent longer than from lowest pop valves.

It was recognized from the start that, because of the short lengths relative to the diameter, and because the plane of the pop valves was not parallel to that of the upper electrodes, the testing setup was not ideal. Consequently, precautions were taken to insure good results with both methods. Great care was taken to adjust all pop valves for tightness up to 15 lb per sq in., and to have these open uniformly and at the same pressure. The electrodes were carefully shaped to have a center spacing 6.5 times the end spacing. The large electrode area and the natural conductivity of the water required an applied voltage of about 10 v. Consequently, large wires with carefully made joints were used in the electrode wiring.

For the Gibson method, all piping joints were carefully made for tightness. Also, during the performance of tests, the piping was flushed through completely between each run to eliminate any air and to insure that the temperature of the water in the piping was essentially that of the penstock water.

Table 3 presents the data obtained on these two tests. Fig. 4 shows the curve of discharge against guide-vane opening after transferring to a uniform net head of 28.66 m. In order to present graphically and clearly the variations between the discharge determinations by the two methods, and in an attempt to rectify the data for analysis by the method of least squares, each observed discharge at 28.66 m head has been divided by the corresponding guide-vane opening expressed in per cent. These quotients are likewise plotted in Fig. 4.

Examination of the plotting of these quotients shows that they may be approximately represented by straight lines from a gate opening of 53 per cent up to 100 per cent. The least-squares determination of the two equations of such lines gives

$$Q/G = 1.414 - 0.00390\,G$$ for the Gibson data

and

$$Q/G = 1.406 - 0.00385\,G$$ for the salt-velocity data

where

Q = discharge at 28.66 m head in cu m per sec

and

G = guide-vane opening in per cent.

The equation determined by the Gibson data in comparison with that determined by the salt-velocity data gives 0.42 per cent greater discharge at 53 per cent guide-vane opening (lower limit of applicability) and 0.29 per cent greater discharge at full guide-vane opening. The computed values of the probable variation of one run from the equations are $r = \pm 0.48$ per cent for the Gibson method and $r = \pm 0.22$ per cent for the salt-velocity method.

PARAHYBA UNIT 4

Unit 4 of the Parahyba plant is a vertical reaction-type turbine

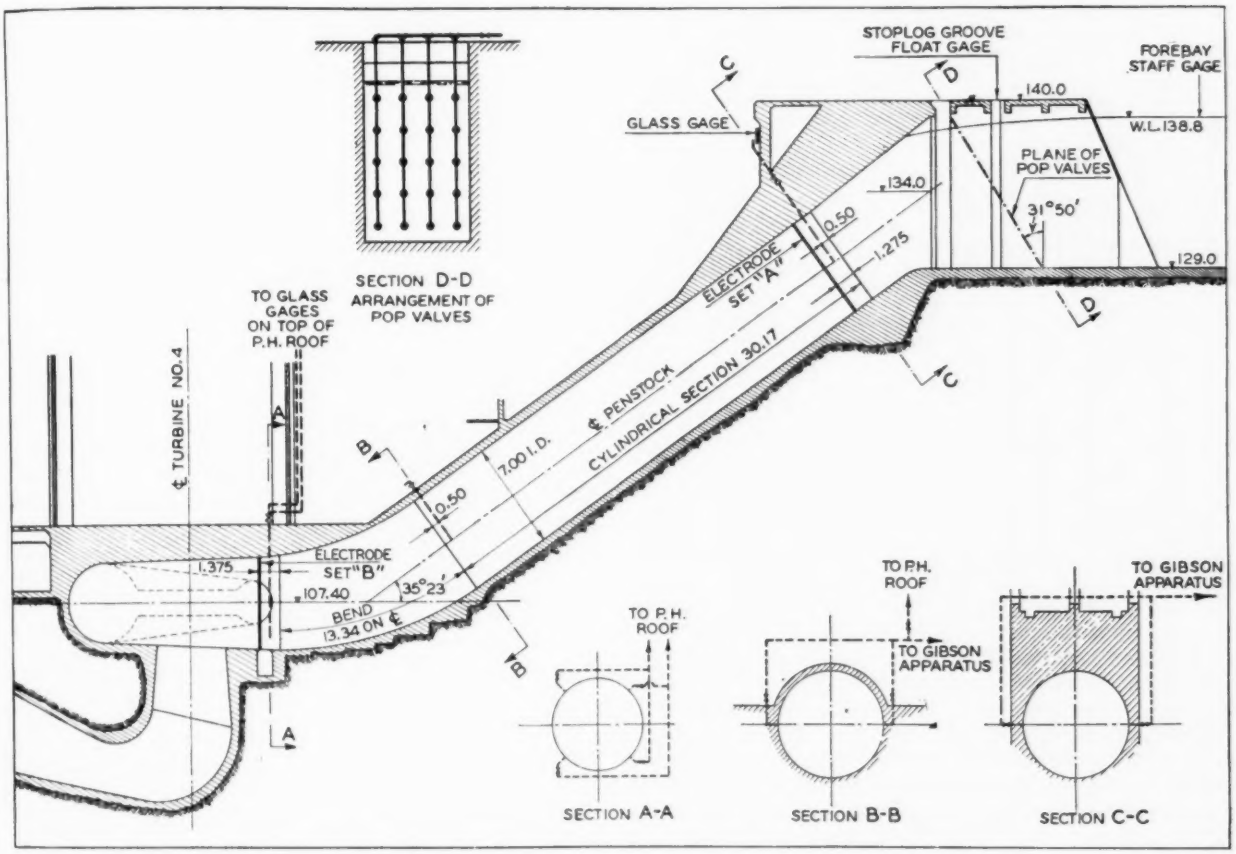

FIG. 5 TESTING LAYOUT, PARAHYBA UNIT 4

rated at 54,000 hp at 31.7 m (104 ft) net head and 115.4 rpm, with a discharge at maximum gate of over 5500 cfs; on test it can produce 57,190 hp at 31.7 m head.

A complete efficiency test of this unit was made in November, 1938. On this test, 28 runs were made using the salt-velocity method and, for 17 of these runs, the Gibson method was used at the end of the 10-min test run.

Fig. 5 shows schematically the testing layout which is generally similar to that for unit 2, except the pop-valve arrangement and the forebay water elevation at the time of the test. The lengths in terms of the pipe diameter are, salt-velocity mixing length 1.6, salt-velocity test length 6.4, and Gibson piezometer length 4.2.

For the salt-velocity method, 20 pop valves were used in a plane crossing the stop-log groove and closely parallel to the plane of the upper electrodes, thus making the paths from all valves of the injection station to the electrodes essentially equal. This gave one valve for each 35.5 sq ft of vertical cross section at the injection station or one valve for each 20.7 sq ft of conduit section at the upper electrode set. The same general precautions for insuring accuracy were followed with both methods as were used for unit 2.

Table 4 presents the data of this test. Fig. 6 shows the curve of discharge against guide-vane opening after transferring to a uniform net head of 31.7 m. As for unit 2, in order to present more clearly the variations of the discharge determinations and in an attempt to rectify the data for analysis by the method of least squares, each observed discharge at 31.7 m head has been divided by the corresponding guide-vane opening in millimeters. These quotients are likewise plotted in Fig. 6.

Examination of the plotting of these quotients shows that they may be approximately represented by straight lines over the range covered jointly by the Gibson and salt-velocity observations, that is, from 46 to 89 per cent guide-vane opening. Thus using all Gibson points and omitting the salt-velocity determinations of runs 1, 4 to 9, and 28, as being outside the range of joint observations, the least-squares determination of the two equations of such lines gives

$$Q/G = 0.5991 - 0.0004455\ G \text{ for the Gibson data}$$

and

$$Q/G = 0.6039 - 0.0004594\ G \text{ for the salt-velocity data}$$

where

Q = discharge at 31.7 m head in cu m per sec

and

G = guide-vane opening, mm.

The equation determined by the Gibson data in comparison with that determined by the salt-velocity data gives 0.42 per cent smaller discharge at 180 mm guide-vane opening (lower limit of applicability) and identical discharge at 345 mm guide-vane opening (upper limit of applicability). The computed values of the probable variation of one run from the equations are $r = \pm 0.0024$ or say ± 0.5 per cent for the Gibson method and $r = \pm 0.0031$ or say ± 0.6 per cent for the salt-velocity method.

SOROCABA UNIT 4

Unit 4 of the Sorocaba plant of the São Paulo Electric Company, Ltd., is a horizontal reaction-type turbine rated at 25,000 hp at 195 m (640 ft) net head at 600 rpm; on test it can produce 26,450 hp at 195 m head. Water is supplied to the unit by a penstock line about 656 m (2150 ft) long, having diameters of

1850 mm (72.83 in.), 1750 mm (68.90 in.), and 1650 mm (64.96 in.).

Fig. 7 shows schematically the layout of the plant from the lower end of the canal to the powerhouse, together with the profile of unit 4 penstock.

A complete turbine-efficiency test of the unit was made in January, 1926. Fourteen runs, measuring the discharge with the salt-velocity method were made. As shown in Fig. 7, the measurements of discharge were made between two sets of electrodes of the customary bowed type. The salt-injection station consisted of 4 pop valves set in from the pipe wall 39 per cent of the pipe radius and was generally similar to the Serra layout in Fig. 1.

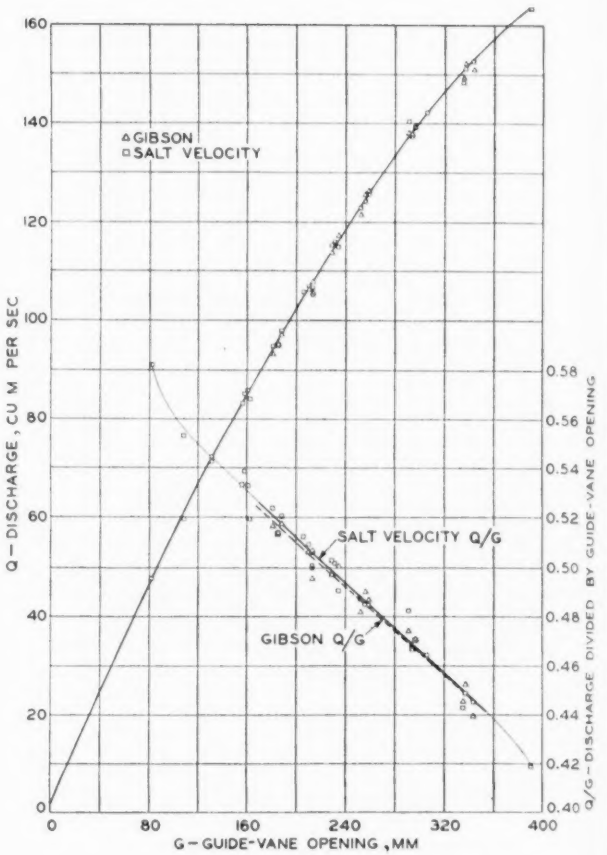

FIG. 6 TEST RESULTS; PARAHYBA UNIT 4

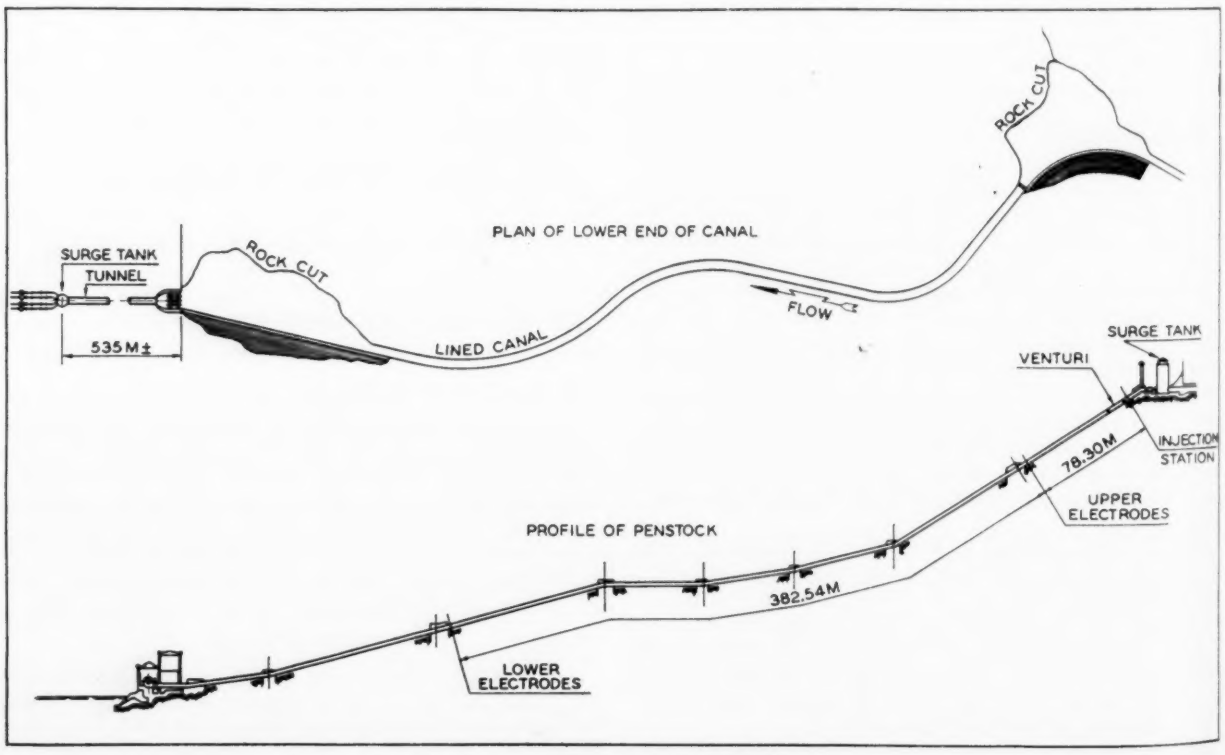

FIG. 7 TESTING LAYOUT; SOROCABA UNIT 4

The results of the test appeared entirely satisfactory, check points at identical gate openings showing a maximum difference of 0.2 per cent. However, the venturi meter, having full and throat diameters of 1850 and 1269 mm, respectively, showed a coefficient about 4.5 per cent lower than the usually expected value of 0.985.

As these tests were made in the early days of the companies' experience with the salt-velocity method, a volumetric check of the discharge was made as this was possible with the plant layout.

The volume of the canal forebay, and surge tank between three elevations, was determined by measurement of the areas. With all inflow shut off except a very small but measured inflow from a spring and no other outflow, this known volume was discharged through penstock 4 by bringing the unit from complete shutdown to a predetermined gate setting in about 2 min, holding this load constant for as long a period as the available water permitted, and shutting down the unit completely in about $1^1/_2$ min. The rate of discharge during the steady-load portion of the run was determined by deducting the percentage of water used during starting and stopping, determined on the basis of the previous constant-load tests from gate openings observed every 10 sec during changes of load. The water used in starting and stopping amounted to 16 per cent of the total on one test and 7 per cent on the other two tests. During the steady-load portion of each run, salt-velocity measurements were made.

TABLE 5 VOLUMETRIC CHECK OF SALT VELOCITY; SOROCABA UNIT 4

Item	Test 1	Test 2	Test 3
Initial level, m	804.688	804.584	804.638
Final level, m	803.858	801.645	801.535
Average area above 803.57, sq m	6130	5640	5700
Draft above 803.57, m	0.830	1.014	1.068
Average area below 803.57, sq m	....	3950	3940
Draft below 803.57, m	....	1.925	2.035
Volume, cu m	5088	13323	14106
Inflow from spring, cu m	20	27	22
Total water used on test, cu m	5108	13350	14128
Water used on steady load, per cent	84.15	93.20	92.70
Water used on steady load, cu m	4298	12442	13097
Time of steady load, sec	720	2100	1700
Average discharge—volumetric, cu m per sec	5.969	5.925	7.704
Average time salt velocity, sec	164.9	167.0	127.9
Average discharge—salt velocity, cu m per sec	5.967	5.892	7.694
Difference salt velocity—volumetric, per cent	—0.03	—0.56	—0.13

Table 5 presents the summary of these tests. It will be seen that the discharges determined volumetrically and from the salt-velocity method agree within 0.25 per cent average for the three tests. It is considered that the penstock volume for the salt-velocity and the canal volume for the volumetric check as determined had each a precision of about ±0.3 per cent. The test agreement is therefore as good as can be expected. At that time no greater refinement in testing results was attempted.

General Comment on Tests

From the period of obtaining the rights to use the salt-velocity and Gibson methods to date, all units of the principal plants of the companies associated under the Brazilian Traction, Light and Power Company, Ltd., have been tested by one or the other of these methods, with the exception of three units which are duplicates of machines tested. In some cases, the tests have been made indirectly by using the Gibson or salt-velocity method to calibrate a venturi restriction, using this calibrated restriction as a measuring device for several units. Eleven units have been directly tested with each method, a total of 16 tests with the salt-velocity and 15 tests with the Gibson method having been made. All of these tests have been satisfactory and, where doubts have occasionally been expressed, repeat tests and checks by other methods have confirmed the accuracy of the tests.

From the experience gained on these tests, the author suggests the following, but by no means comprehensive, precautions regarding the use of the two methods:

Salt-Velocity Method

1 If best results are desired, the timing of the passage of the salt cloud must be done between two sets of electrodes which represent the entire cross section of the waterway.

2 An adequate mixing length between the injection valves for the brine and the first set of electrodes is imperative for best results. The author does not feel competent to place a definite limit on this length, but suggests a lower limit of a length at least equal to the mean transverse dimension of the waterway and preferably at least twice this length. It appears also that the number of pop valves used should depend on this length rather than on the cross-sectional area of the waterway.

Gibson Method

1 The author has found that measuring the leakage with fully closed guide vanes may, at times, be the most troublesome feature of this method. In two cases it appeared conclusively that the leakage through the guide vanes did not vary as the square root of the head on the turbine, thus making it necessary to measure the leakage with the full head. No explanation of the discrepancies has been found, but they may be due, at least in part, to the variation in mechanical deflection of the guide vanes with varying applied pressure.

2 Besides the necessity of absolutely tight piezometer piping, the author considers it necessary to provide adequate provision for flushing the piping between tests to remove air and to maintain the penstock water temperatures if best results are to be obtained.

Acknowledgments

The author wishes to make acknowledgment to A. W. K. Billings, member of this Society, and vice-president of the Brazilian Traction, Light and Power Company, Ltd., for permission to use the companies' data, to C. P. Conrad and L. J. Hooper, also a member of this Society, who made the Sorocaba tests and to A. Santos, Jr., who made some of the many tests carried out by the companies and assisted in the performance of the others.

Discussion

M. A. Mason.[4] The writer had the opportunity, while studying in France as a Freeman scholar, to make an investigation of the possibilities of use of the salt-velocity method in open channels. It was found that previous studies had not resulted in the formulation of any logical conception of the physics of the method which would permit a definition of its limitations. An attempt was made, therefore, to define the limits of applicability of the method by a study of the basic principles governing its operation. The conclusion was reached that the chief requirement for accurate results is the attainment of proper mixing between the water and injected solution before the injected solution reaches the measuring section.[5] It is gratifying that the author arrives at an identical conclusion for the case of flow in pipes.

Concerning the magnitude of the "mixing length" required for accurate results, it was concluded from the writer's studies that this length was probably a function of the velocity of flow, the injection pattern, the form of the channel, the nature of the walls, and some time period. The author presents no evidence to

[5] "Contribution à l'Étude de la mesure des Débits d'Eau par la Méthode Allen," by M. A. Mason, Thesis, University of Grenoble, France; also *Révue Générale de l'Hydraulique*, No. 28, July-Aug., 1939.

justify the elimination of any of these factors and his conclusion that the "good mixing length" may be specified in terms of only a linear dimension of the conduit system does not seem to be justified.

Professor Hooper, in his paper on salt-velocity measurements of low-velocity flow[6] employs mean velocity of flow as a measure of the mixing of injected solution and water. It is probable that both criteria suggested are involved in the true criterion for good mixing and that neither is sufficient in itself.

Although no concrete evidence of the effect of electrode design is presented in this paper, the writer concurs in the first conclusion to the effect that the electrodes must suitably cover the entire cross section of the waterway. An analysis leading to this conclusion was included in the writer's paper.[6]

E. B. Strowger.[7] The author indicates that he has obtained a satisfactory agreement in the results of tests of two units by the salt-velocity method with those of the differential application of the Gibson method. The writer wishes to submit the results of other tests which show the consistent accuracy of the Gibson method.

Perhaps it should be pointed out that the Gibson method makes use of pressure-time diagrams of either the simple or the differential type. With simple diagrams, the changes of pressure at one piezometer section in the conduit are recorded while with differential diagrams the difference between the changes of pressure at two piezometer sections in the conduit are recorded. Indirect checks of the Gibson method can be made, therefore, when both simple and differential diagrams are used; in tests where two sets of simple diagrams are made, each utilizing a different length of penstock; in tests where two differential applications are made, each utilizing different lengths of pipe; and/or when tests are made using other comparisons.

Some of the material which will be presented herein has been published before but is being included for the purpose of assembling as much of this information in one place as is possible at this time.

Fig. 8 of this discussion shows the cross section of a 70,000-hp hydroelectric unit operating under a head of 217.5 ft. It also shows the piezometer sections used in testing this unit by the Gibson method. Simple diagrams were made on the unit, utilizing approximately 600 ft of penstock, extending from the forebay to the lower piezometer section and differential diagrams were made utilizing about 87 ft of the penstock as shown. The agreement between the two tests is indicated by the two sets of test points which fall on or close to the same power-discharge curve as shown in Fig. 9. The average divergence of the "differential points" from the line established by the "simple points" is within +0.2 per cent and the agreement between the two tests is accordingly within 0.2 per cent.

of test points indicate that a common power-discharge curve may readily be drawn.

Another example of two sets of simple diagrams taken on the same penstock is illustrated by the test on a 55,000-hp unit operating under a head of 312 ft, as shown by Figs. 12 and 14. With one set of diagrams approximately 310 ft of penstock was utilized and with the other set approximately 367 ft was used. The diagrams were made simultaneously, i.e., at one closure of the turbine gates, two diagrams were made. The two sets of test points shown by triangles in the one case and circles in the other were determined by two independent testing organizations using different apparatus and working independently.

The penstock shown in Fig. 15 was used for making two sets of differential diagrams, one set using 42.10 ft of length and the

other set a length of 79.54 ft. The power-discharge curve with the two sets of points is shown in Fig. 16.

Figs. 17, 18, and 19 show the results of testing three units by both the Allen and Gibson methods. The close agreement between the two measurements in each case is apparent.

Fig. 20 shows the coefficient curves of two 7 × 10-ft venturi meters built in the two penstocks of a hydroelectric station and tested by the Gibson method when the acceptance tests of the units were made. It shows the test points plotted as velocity against venturi coefficient. Figs. 21 and 22 show the test points plotted as discharge against manometer deflection on log paper indicating that, with this plotting, the relation between deflection and discharge is a straight line. The slope of the line is 2 and accordingly the discharge varies as the square root of the mercury deflection. This means that the coefficient for these venturis is constant for the range of velocity covered by the test.

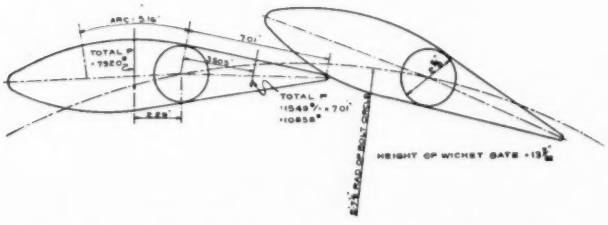

FIG. 23 COMPUTATION OF ANGULAR DEFLECTION OF TURBINE GATE STEM FOR LEAKAGE DETERMINATION

Table 6 of this discussion presents a list of comparative test results using the Gibson method in conjunction with other methods of water measurement as carried out at various places in Europe. The results of these comparisons have been published from time to time in the technical press. With the exception of the first tests at Heidenheim, which were not very good, all these results are within the practical limits of precision in the measurement of flowing water.

The author states he has found at times that measuring the leakage of the turbine with closed guide vanes was the most troublesome feature of the Gibson method and mentions two cases where the leakage did not vary as the square root of the head on the turbine. He suggests that the discrepancy, in part at least, was due to the mechanical deflection of the guide vanes with varying pressure. Since in many cases the turbine gate leakage must be determined under heads which are lower than the normal value and the experimental result must be stepped up to the full head, care must be exercised to see that proper adjustment of the orifice area is made in case deflection of the guide vane stems takes place. If this is done, the writer believes that the author will not consider the measurement as troublesome. Gate-leakage determinations usually can be made at several values of reduced head, especially if the fall in the pressure method of measuring the leakage is used, and the results may be plotted in the form of a leakage-head curve on log paper. If the orifice area changes with head, the relation so obtained is a curve rather than a straight line and may be extrapolated to the full head. The area correction is made in the process of extrapolating the curve.

Another method of determining whether an area correction is needed in stepping up the leakage to the full head is to compare the "squeeze" deflection of the wicket gates under full operating oil pressure with the calculated deflection of the wickets under full head conditions. If the squeeze deflection is greater than the deflection due to casing pressure, no area correction is necessary. An example of such a computation is shown in Fig. 23 for one of the units in a hydroelectric plant in New York State. At this plant the servometer piston travel is limited by a stop which is so placed that the wicket gates are closed with no squeeze when the wheel case is empty. The computed deflection of the guide vanes with full casing pressure was 0.093 in. resulting in an orifice area of 0.233 sq ft and a computed leakage of 28.6 cfs. The actual measured leakage per unit under full head as determined by a tailrace weir was 29.5 cfs. Other cases of leakage determination where the guide vane deflection is a factor in the determination could be cited, although with the method used in assembling and adjusting the gate mechanism of modern hydroelectric units, such deflection is seldom found to be appreciable.

It should be noted also that, as a practical matter, extreme care in measuring the leakage is not as a rule necessary. A relatively large error in the determination of the turbine-gate-leakage quantity affects the turbine efficiency by an insignificant amount. For example, on a recent test, a possible error in the leakage quantity of as much as 20 per cent of the total leakage represented less than 0.1 per cent in turbine efficiency at the point of maximum efficiency.

Unit Pressure, $P = 270 \times 0.434 \times 13.219 = 1549$ lb per in. of gate length

Moments around center line of stem.

Opening M in-lb $= 10{,}858.5$ lb $\times 3.505$ in. $= 38{,}059$

Closing M in-lb $= 7{,}920$ lb $\times 2.29$ in. $= 18{,}058$

Net M (opening) in-lb $= 20{,}001$

α = Angular deflection of stem (radians) $= \dfrac{l\,M}{E_s J}$

l = length of stem = 21.625 in.

M = moment

E_s = modulus of elasticity = 12,000,000

J = polar moment of inertia $= \dfrac{\pi d^4}{32}$

$$\alpha = \frac{21.625 \times 20{,}001}{12{,}000{,}000 \times 4.66} = 0.007735 \text{ radians}$$

Toe of gate moves, $7.01 \times 0.007735 = 0.05422$ in.

Heel of gate moves, $5.06 \times 0.007735 = 0.03914$ in.

Total opening $= 0.09336$ in.

Orifice opening top and bottom of wickets $= \dfrac{0.070}{12} \times 3.1416 \times 5.25 = 0.096$ sq ft

Orifice opening between wickets $= 16 \times 1.104 \times \dfrac{0.09336}{12} = 0.1374$ sq ft

Total orifice opening $= 0.096 + 0.1374 = 0.2334$ sq ft

Gate leakage under 270 ft head $= 0.2334 \times 8.02 \times \sqrt{270} \times 0.93 = 28.6$ cfs

Leakage per unit by tailrace weir = 29.5 cfs

EDWIN A. TAYLOR.[8] The results of three check tests at Sorocaba show that the salt velocity varied from volumetric by 0.03, 0.56, and 0.13 per cent, respectively. These results have a maximum spread for any one run of 0.5 per cent and an average difference between the two methods of 0.25 per cent.

The results of two check tests at Parahyba show that, for the wide range of the tests, salt-velocity and Gibson methods check within less than 0.1 per cent. For each unit, the two curves of discharge on gate opening coincide at full gate and differ only slightly at half gate.

[8] Consulting Engineer, Worcester, Mass.

A check test at Serra No. 5, comparing discharge results, using three different salt-velocity test sections, shows a maximum spread of less than 1 per cent, 0.5 per cent plus and minus. For the whole test, the average difference was less than 0.1 per cent. These comparative tests covered 24 runs and 130 salt-velocity shots. Similar check tests, with equally close comparative results, were made at Serra Nos. 3 and 7.

The writer has made a number of pump- and turbine-efficiency tests, using the salt-velocity method of water measurement. Several times the results by salt velocity have been checked by other engineers, using other methods of water measurement,

and frequently the salt-velocity results have been checked by the same method, using different test apparatus and test sections at the same plant.

Tables 7 and 8 show the results of fourteen such check tests on salt velocity, two by current meter, two by pitometer, two by Gibson, two by volumetric, and six by interchecking with various salt-velocity test sections.

Details of tests, apparatus, and procedure for the check tests in Tables 7 and 8 are omitted. The engineers conducting these tests were experienced in their lines and the tests were made in accordance with the latest accepted practice in each method.

A summary of the comparative results, shown in Table 7 of this discussion, indicates a close agreement between salt velocity and current meter, once in Germany and once in Pennsylvania. A comparison of the discharge values by pitometer in Germany and in New York and by Gibson in Quebec and in New York shows a close agreement with the salt-velocity values for discharge at the same plants.

A comparison of salt velocity with the five volumetric check runs in Table 7 shows the results have an average spread for all runs of 0.75 per cent and an average weighted difference for the five runs of 0.6 per cent.

While the values for average difference for the Pacific Coast volumetric checks are plus 0.6 per cent, the Brazilian volumetric checks show an average difference of minus 0.25 per cent.

The average mean difference, weighted for signs, for the eight check tests in Table 7 is +0.05 per cent.

In analyzing and comparing the results in Table 7, the spread and the deviation for runs should be given more weight than the average difference in values for the whole test. This average difference may mean very little alone. For instance, there could be a spread or run deviation in discharge values of 5 or even 10 per cent and the mean difference between methods for the whole test could still be zero. In that case, attaching much importance to the mean difference for the whole test becomes very significant of the accuracy of the method. This is important in field tests for pump and turbine efficiency because, in computing final results, curves are drawn to fit the test points and these curves do graphically what the average differences in Table 7 do arithmetically.

Table 8 of this discussion shows the results of six check tests at four different power plants, using various salt-velocity test sections. These test sections varied in length from 300 ft to 3.5 miles. The average spread for all runs shown in Table 8 was 0.33 per cent. The average mean difference, weighted for signs, for the six check tests shown in Table 8 is minus 0.06 per cent.

The mean difference for all the check tests shown in both Tables 7 and 8, which involve over 100 salt-velocity runs and 500 shots, is zero.

Author's Closure

Messrs. Strowger and Taylor have presented additional data showing verifications of the salt-velocity and Gibson methods. The assembly of such data is valuable in appraising the degree of accuracy which may be expected by these methods. Further testing results, where the agreement was less satisfactory, would also be valuable. Undoubtedly, attempts to extend the field of these methods have been responsible for the majority of tests where agreement was relatively poor. A record of these attempts, and of the experience gained in overcoming difficulties, is desirable.

To present one such case the following is submitted: Prior to the tests of Parahyba unit 4 described in the paper, preliminary tests were made on this unit with both salt-velocity and Gibson methods. The electrode setup for the salt velocity was the same as in the later tests. The injection station consisted, however, of only 12 pop valves placed in the vertical plane of the stop-log grooves. The form of the resulting curves was decidedly poor, each curve showing 3 peaks resulting from the unequal paths from the 3 horizontal rows of 4 pop valves each. The results differed from the final results given in the paper by an amount varying from 0 per cent at 180 mm guide-vane opening to +1.6 per cent at 345-mm guide-vane opening. The use of the salt-velocity method in this manner was an obvious but unwitting abuse. Notwithstanding, there is comfort in the relative closeness of agreement with the later tests made with an improved layout. The preliminary Gibson tests agree very closely with the final ones reported in the paper.

The suggestions given in the paper regarding mixing length resulted principally from thought on conditions of testing at the Parahyba plant. Mr. Mason, in his study[5] and in his discussion of this paper, and Professor Hooper, in his paper[6] have contributed further to this question. The determination of conditions providing a satisfactory mixing and distribution of the salt solution in the water channel between the injection valves and the upper electrodes would be a suitable laboratory study. It is apparent, however, that a requirement relating the number of injection valves to the cross-sectional area of the waterway is entirely inadequate without further stipulations. These probably should include factors for the channel dimensions, form, roughness, and possibly for the velocities expected. For ordinary commercial testing in hydroelectric plants the low velocity limits brought out by Professor Hooper are rarely, if ever, encountered.

The Viscosity of Superheated Steam

By G. A. HAWKINS,[1] H. L. SOLBERG,[2] and A. A. POTTER,[3] LAFAYETTE, IND.

After discussing the disagreement existing in viscosity data for superheated steam as reported by recent investigators, the authors report the results of a new determination of viscosity. A nickel capillary 103.2 ft long was used in this investigation. The differential head across the capillary was determined by radiographing the mercury levels in a steel-tube manometer. Data are reported for 60 calibration tests and for 61 tests on steam at pressures up to 1810 lb per sq in. abs and 1000 F. All of the tests were run under steady-flow conditions for a minimum period of 1 hr. Plank's equation has been modified to express the results over the entire range of pressures and temperatures covered by this investigation.

As a result of additional calibration tests made to determine the effect of curvature on the capillary constant, the results given in this paper supersede those presented at the Annual Meeting of the Society.

IN THE year 1925, Speyerer (1)[4] measured the viscosity of superheated steam by means of a capillary tube at pressures from 1 to 10 atm and at a maximum temperature of 658 F. In 1934, Schiller (2) published data on the viscosity of superheated steam as determined from the flow of steam through a nozzle. He obtained the relation for calculating the viscosity of steam in terms of that of water, by observing the velocity at which the discharge coefficient of a nozzle shows an abrupt increase for water and steam and then equating the two Reynolds numbers. Schiller's curves show one test point at 30 atm, four test points at 25 atm and other points at lower pressures with a maximum temperature of about 540 F. In 1935, the authors (3) published data on the viscosity of saturated and compressed water at temperatures up to the critical and on superheated steam at pressures up to 3500 lb per sq in. abs and temperatures up to 983 F. A modified form of the Lawaczeck (4) viscometer was used in which the time of fall of a metal cylinder in an accurately bored stainless-steel tube was recorded automatically. The results obtained by the authors (3) were in good agreement with those of Schiller and Speyerer.

In 1934, Schougayew (5) published data obtained by measuring the viscosity of steam in a Rankine capillary at pressures up to 93 atm and temperatures up to 400 C. He concluded that, within the limits of accuracy of his apparatus, viscosity was practically independent of pressure. In a discussion of the author's paper, Schougayew (6) presented a curve, showing the difference between the results for the viscosity of saturated steam, as plotted from the author's data, and similar results obtained in Russia by Schougayew and Sorokin.

In 1936, K. Sigwart (7) published data on the viscosity of water and steam as determined by a capillary tube. The results for the viscosity of water are in close agreement with those reported by the authors. However, the values for the viscosity of superheated steam differ widely from the results reported by the authors (3) and, in some cases, disagree by as much as 3 to 1.

A comparison of the results of several different determinations of the viscosity of steam is shown in Fig. 1. H. Speyerer (8) has recently published a discussion of the conflicting results which have been reported by the various investigators. The wide divergence in results has led to a careful examination of the work of Sigwart (7) as well as of the apparatus, the technique, and the results of the authors; also new determinations of the viscosity of superheated steam have been made and are reported in this paper.

Essentially, the method used by the authors in their earlier investigation was to measure the time of fall of a cylindrical body in an accurately bored cylinder containing a fluid of known viscosity and to measure the time of fall of the same body in the same cylinder containing water or steam under a known pressure and temperature. It is necessary that the flow of the fluid in the annular space between the falling body and the cylinder be in the viscous region. This flow was limited in the experiments to a maximum Reynolds number of 2100 based on the calibration data. The essential data required for a viscosity determination by this method are the density of the fluid under test, the density and viscosity of the calibration fluid, and the time of fall. It is not difficult to measure pressure and temperature and thus compute density with reasonable accuracy. The viscosity of the calibration fluids was taken from the International Critical Tables. The time of fall was recorded automatically on the strip chart of an Esterline-Angus recording milliammeter in a manner which eliminated the human element. It is believed that any errors introduced into the results were due not to errors in measuring pressure, temperature, or time, but to incorrect assumptions made in developing the theory of the Lawaczeck viscometer or due to failure to work with pure steam.

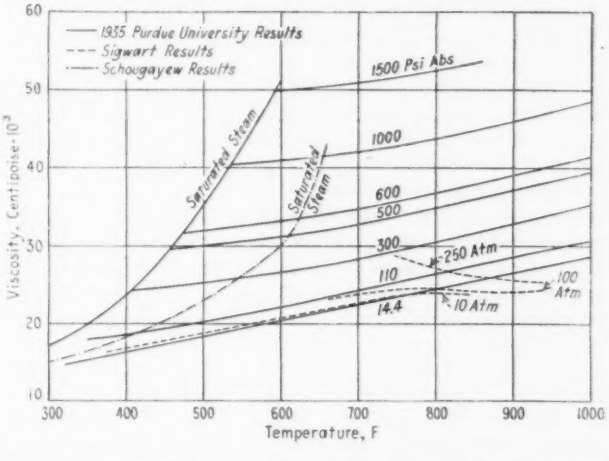

FIG. 1 VISCOSITY OF STEAM AS REPORTED BY RECENT INVESTIGATORS

In developing the theory of the Lawaczeck viscometer, the possibility of flow disturbances in the wake of the fall-body was not considered. Recent findings in the field of hydrodynamics

Contributed by the Special Research Committee on Critical Pressure Steam Boilers and presented at the Annual Meeting, December 4–8, 1939, Philadelphia, Pa., of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

indicate that such flow disturbances may exist. Considerable effort has been expended in a theoretical analysis of the problem of tail turbulence and the magnitude of the error due to the neglect of this factor. Up to date, a satisfactory solution of the problem has not been worked out which would permit a separation of the resistance to falling into viscous drag in the annular space around the fall-body and turbulence at the tail of the fall-body. Also, it may be that, under certain conditions, the motion of the fall-body is not translatory but vibratory.

Sigwart (7) used the capillary-tube method of measuring the viscosity of steam and water. Two capillary tubes were used, each about 14 in. long. The quartz capillary had an internal diameter of 0.375 mm, while the internal diameter of the platinum capillary was 0.547 mm. Steam was generated in a small boiler, superheated, passed through the capillary, throttled, condensed, and weighed. Sigwart states that a brown precipitate formed in the condensate after exposure to the atmosphere for some time. The differential pressure across the capillary was measured by means of a differential-pressure ring balance (9). Sigwart reports only one short table of original steam data. In this table, the maximum and minimum heads, due to the flow of steam in the capillary, were 0.247 and 0.184 in. Hg, respectively. It is obvious that the accuracy and sensitivity of the balance must be of a very high order if dependable results are to be obtained from such small heads.

The differential head, measured by the ring balance, was reported by Sigwart as being due to the equivalent of (*a*) flow through the capillary of the fluid leaving the system, and (*b*) flow of fluid from one leg of the manometer through the capillary and connecting tubing to the other leg of the manometer. The connections from the manometer to the capillary were mounted in a horizontal plane. It is obvious that, when measuring the viscosity of superheated steam, these manometer legs contained superheated steam of varying temperature, density, and viscosity; saturated steam and water of varying temperature, density, and viscosity. Based on certain assumptions, which did not include the variable physical state of the fluid in the manometer legs or the length of tubing occupied by the fluid in these various states, Sigwart derived an equation from which he estimated the time elapsed from the opening of the throttle valve on the discharge side of the capillary until the pressure drop, as measured by his balance, equaled at least 99 per cent of the head loss in the capillary. He then took the manometer reading at this time interval, computed a correction, and used this value to calculate the viscosity. Thus his readings were taken before a steady flow state had been established.

Requirements of a Capillary for Measuring the Viscosity of Superheated Steam

In order to check the results of their earlier investigation by a different method and to compare the new results with those of other investigators, the authors decided to use a capillary tube designed and operated in accordance with the following principles:

1 The capillary tube must have sufficient length to give a head which could be measured accurately.

2 The length of the capillary should be great enough so that the kinetic-energy correction at the ends would be negligible.

3 The tube should be made of noncorrosive material of sufficient strength to prevent distortion at the highest operating pressures and temperatures.

4 A uniform temperature must be maintained along the entire length of the capillary.

5 The manometer must be connected to the capillary in such a way that separation between the liquid and vapor phase of the fluid would be in the horizontal plane of the capillary.

6 In order to eliminate the human element, the manometer must be designed and operated to give a permanent photographic record of the head.

7 No readings should be taken until a steady flow state had been attained and the record of manometer readings must indicate the presence of a steady flow state for a test period of at least 1 hr.

8 The theoretical constant of the capillary should be checked at periodic intervals during the investigation and at the conclusion of the tests by the use of suitable fluids of known viscosity.

Description of Apparatus

In accordance with the above requirements, the capillary was made from 103.2 lin ft of 0.25-in. outside diam × 0.09294-in. inside diam seamless nickel tubing. The random lengths of tubing were connected into one continuous length of uniform internal diameter by facing each end square, butting it tightly against the end of the next piece in a snugly fitting nickel sleeve and welding the sleeve to the tube ends. Each joint was radiographed after welding to make sure that the ends of the tubes were in alignment and fitted against each other to form a smooth internal surface. The capillary was wound into a coil having a diameter of 2.5 ft, covered with a uniformly spaced electric-resistance-heater wire and thoroughly insulated. During the course of the investigation, the capillary was also wound into circle bends with a 1-ft radius, connected by straight runs about 12 ft long, and was later coiled on a 2-ft diam.

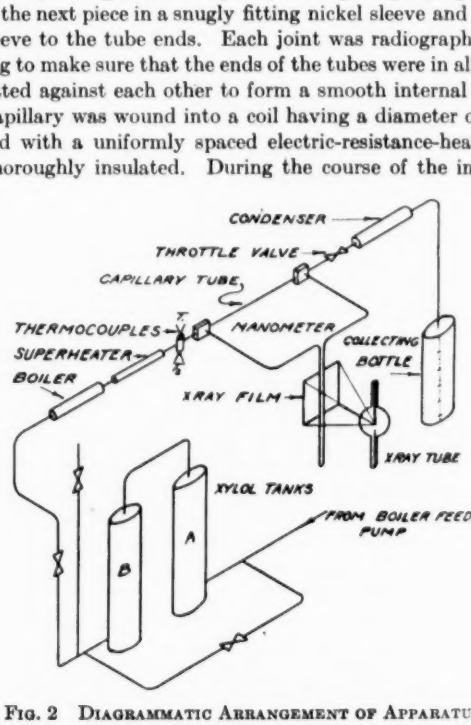

Fig. 2 Diagrammatic Arrangement of Apparatus

The manometer, made of two vertical legs of extra-heavy 1/4-in. iron-pipe-size, seamless steel tubing, was connected to the junction blocks at the ends of the capillary by tubing which was mounted in the horizontal plane of the ends of the capillary, in order to avoid any errors due to the variation in the level of the plane of separation of water and steam between the capillary and the manometer. The manometer was filled half full of mercury with water above the mercury level. Care had to be used to eliminate all air from the manometer legs and connections during the filling process. An X-ray tube was used to radiograph the mercury levels in the manometer and leave a permanent record on the film which was mounted in back of the tube as shown in Fig. 2. Heads up to 5.5 ft could be measured with this apparatus.

The boiler was supplied with deaerated distilled water by placing two tanks, *A* and *B* in Fig. 2, between the feed pump and the boiler. The tanks were connected by pipe at their upper ends

and were filled half full of xylol. This liquid will not mix with water nor contaminate it in any way at low temperatures. Before starting a test, boiling distilled water was supplied to the lower end of tank B and most of the xylol was transferred to tank A. Then during the test, the pressure from the boiler-feed pump was transferred to the feedwater through the xylol. In this way, only pure distilled water entered the boiler. During many of the tests, the xylol tanks were by-passed and the boiler was fed directly from the pump. The results were not affected by this change in the feedwater system.

The boiler consisted of a short length of double-extra-heavy 2-in. seamless steel pipe closed at each end by welding, set on an incline, and fired by a battery of Bunsen burners. Steam was superheated by placing an electric heater around a section of nickel tubing. The input to this heater was controlled automatically by a Wheelco Capacitrol and magnetic switch in order to maintain a constant steam temperature at the entrance to the capillary. Two calibrated thermocouples, welded into the bottom of wells, were placed opposite each other in a thermocouple block immediately ahead of the capillary (T_1 and T_2 in Fig. 2) in order to determine the steam temperature entering the capillary. Twenty thermocouples were provided for reading temperatures along the capillary, and the heater winding was adjusted to maintain a uniform temperature from end to end. The steam leaving the capillary was throttled, condensed in a copper coil, and weighed.

The Viscosity Equation for the Capillary

Poiseuille's law for viscous flow in a straight capillary, with allowance for kinetic-energy losses at entrance and exit, may be stated as follows

$$\mu = \frac{\pi r^4 \Delta P}{8Q(l+\lambda)} - \frac{M\rho Q}{8\pi(l+\lambda)} \quad [1]$$

where μ = viscosity
r = radius of capillary
ΔP = pressure difference between the ends of the capillary
Q = volume of flow per unit of time
l = length of capillary
M = a constant
ρ = density of the fluid
λ = a constant

For long straight capillary tubes in which the end kinetic-energy corrections may be neglected, the equation is reduced to the form

$$\Delta P = \frac{32\mu l V}{D^2} \quad [2]$$

where V = average velocity
D = diam of capillary

Equation [2] may be expressed as

$$\mu = 3.69682 \frac{D^4 h}{LWv} = C\frac{h}{wv} \quad [3]$$

where C = a constant depending upon the dimensions of the capillary
h = in. of mercury measured by the manometer under water
w = weight flow rate
v = specific volume

The theoretical constant C for a straight capillary of the diameter used in this investigation may be evaluated by substituting in Equation [2] the following units:

h = actual head loss as measured under water in in. on the radiograph
l = 103.2 ft
D = 0.09294 in.
w = weight flow rate in lb per sec
v = average specific volume in ft³ per lb
μ = viscosity in centipoises

Then $C = 26.7276 \times 10^{-7}$ or

$$\mu = \frac{26.7276 \times 10^{-7} h}{wv} \quad [4]$$

The capillary, 103.2 ft long, was first coiled on a 2.5-ft diam. Because of serious heater trouble, this arrangement was abandoned and the capillary was formed into circle bends having a 2-ft diam, connected by straight sections 12 ft long. Of the total length, 69.6 per cent was straight and 30.4 per cent curved to a 1-ft radius. This capillary arrangement has been called coil I in this report. Continued heater trouble made it necessary to obtain a new heater and to coil the entire capillary on a 2-ft diam, called coil II in this report.

For a bent capillary, the work of White (10) and Keulegan and Beij (11) indicates that at Reynolds' number above approximately 200, the effect of curvature increases the resistance to flow and the capillary constant then becomes a function of the Reynolds number and the ratio of the diameter of the capillary to the diameter of the coil. Equation [3] for the straight capillary may be modified to account for curvature by introducing a factor φ, for curvature resistance, or

$$\mu = 3.69682 \frac{D^4 h\varphi}{Lwv} = \frac{C\varphi h}{wv} \quad [5]$$

where φ is some function of the Reynolds number and the curvature of the capillary. For coil I, which is a combination of straight and curved sections

$$h = h_s + h_c \quad [6]$$

where h = total head loss in capillary
h_s = head loss in straight sections of capillary
h_c = head loss in the curved sections of the capillary

Substituting Equations [3] and [5] for the respective head losses in the straight and curved sections of the capillary gives

$$h = \frac{\mu wv}{C_s} + \frac{\mu wv}{C_c\varphi} = \mu wv\left(\frac{1}{C_s} + \frac{1}{C_c\varphi}\right) \quad [7]$$

where C_s and $C_c\varphi$ are the factors for the straight and curved lengths of the capillary.

Since $C = \dfrac{3.69682\ D^4}{L}$

then
$$h = \mu wv\left(\frac{1}{\frac{3.69682D^4}{L_s}} + \frac{1}{\frac{3.69682D^4\varphi}{L_c}}\right) \quad [8]$$

The total length of the capillary is 103.2 ft of which 69.6 per cent is straight and 30.4 per cent is curved or

$$L_s = 0.696L \text{ and } L_c = 0.304L$$

or
$$h = \mu wv\left(\frac{1}{\frac{3.69682D^4}{0.696L}} + \frac{1}{\frac{3.69682D^4\varphi}{0.304L}}\right) \quad [9]$$

or
$$h = \mu wv\left(\frac{0.696}{C} + \frac{0.304}{C_\varphi}\right) \quad [10]$$

where D = 0.09294 in.

or $$\mu = \frac{h}{wv} \frac{1}{\left(\frac{0.696}{C} + \frac{0.304}{C_\varphi}\right)} \quad \ldots\ldots\ldots [11]$$

For the straight capillary the value of $C = 26.7276 \times 10^{-7}$

or $$\mu = \frac{h}{wv} \left(\frac{1}{0.0260404 \times 10^7 + \frac{0.304}{C_\varphi}} \right) \quad \ldots\ldots [12]$$

where C_φ has the same value as in Equation [5] for a completely coiled capillary with the same coil diameter and total length as that used in a partly coiled capillary.

Test Procedure

With the throttle valve closed, the capillary was heated electrically to the desired uniform operating temperature and the pressure was raised in the boiler. By adjustment of the boiler and superheater input and the steam throttle valve, desired flow conditions were established in the capillary. All tests were 1 hr in length, as measured with a stop watch. The condensate was collected during this interval in a glass-stoppered bottle, the tare weight of which was known in advance, and weighed on an accurate balance at the conclusion of the test. Radiographs of

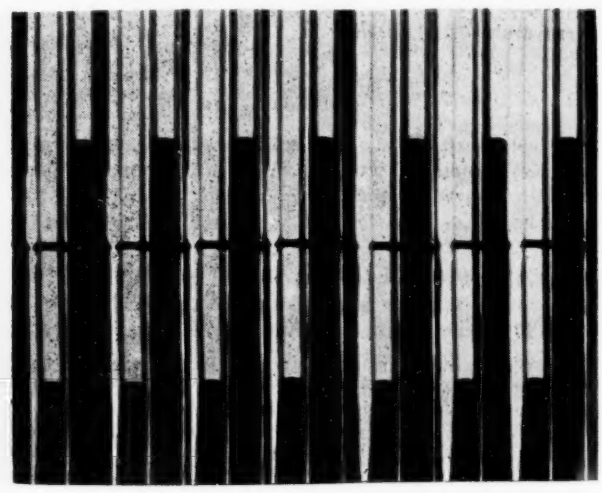

Fig. 3 Typical Radiograph From Acceptable Test

the manometer were taken prior to the start of the flow in order to check the manometer zero. During every 1-hr test, radiographs were taken at 10-min intervals with each exposure requiring from 20 to 30 sec. Fig. 3 shows a typical radiograph from a single acceptable test. Fig. 4 shows a radiograph from a test which was discarded because of unsteady flow conditions. If at any time during a 1-hr test, unsteady flow conditions were encountered, as evidenced by the cloudy meniscus in Fig. 4 or by variations in readings between individual exposures, the test was discarded.

Calibration of the Viscometer

Because of the difficulties encountered in measuring accurately the mean internal diameter of the capillary, the theoretical constant given in Equation [4] was checked by calibration tests. For this purpose nitrogen, dried in a calcium-chloride tower, and water were used for the calibrating fluids. Data for the viscosity of nitrogen were obtained from the International Critical Tables and the "Handbuch der Experimental Physik." Data for the viscosity of water were obtained from the International Critical Tables. The calibration tests for water were carried out strictly in accordance with the test procedure already described. In the nitrogen tests, the flow of the gas was measured by collecting it over water at atmospheric pressure in a burette. During a test about five 2500-cc samples were collected. If the times required for five 2500-cc samples to collect agreed within 1 per cent, the test was considered to be of sufficient length to insure accurate measurements.

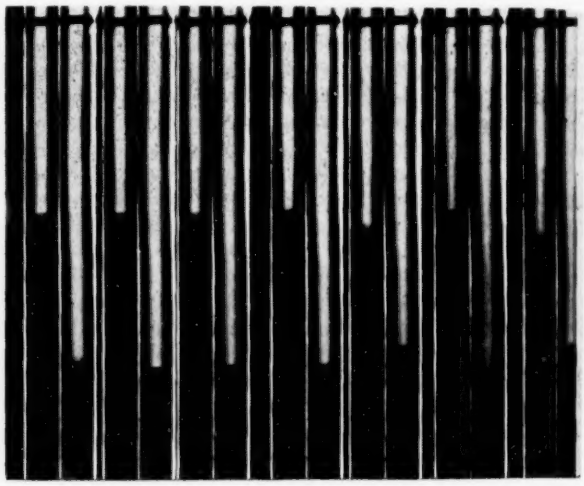

Fig. 4 Radiograph From Test Discarded Because of Unsteady Flow Conditions

Water-calibration data on coils I and II are given in Tables 1 and 2, respectively. Nitrogen-calibration tests on coil II are given in Table 3. The calibration data may be represented by the curves shown in Fig. 5. For a Reynolds number of less than 2000, the theoretical constant of a straight capillary is dependent upon its dimensions only and is 26.7276×10^{-7} for a capillary of the dimensions used in this experiment. For a Reynolds number of less than 180, the average of all data from Table 2 gives a value of 26.69×10^{-7} for the capillary constant. For a Reynolds number of more than 180, the constant must be modified for curvature as shown in Fig. 5 for coils I and II.

The general equation for the flow of a fluid in a pipe may be expressed as

$$h = \lambda \frac{l}{D} \frac{V^2}{2g}$$

where h = pressure difference between the ends of the pipe
g = acceleration of gravity
λ = friction coefficient

For the case of laminar flow in a straight pipe $\lambda = \frac{64}{Re}$. For a curved pipe, the friction coefficient λ is higher at a given Reynolds number than the corresponding value for a straight pipe. Fig. shows a plot of the friction coefficient against Reynolds' number for a straight capillary and for coil II. The solid curve labeled coil II is based upon the data of White (10) and all water-calibration tests are indicated by points.

Test Results

The viscosity of superheated steam was determined at pressures from 72.5 to 1810 lb per sq in. abs and at temperatures up to 1000 F. The essential data and results for the complete series of acceptable tests are given in Table 4. The results are plotted in Fig. 7.

At pressures above 1500 lb per sq in. abs, the high pressure drop through the throttle valve and the low specific volume of the steam made it virtually impossible to maintain steady flow conditions for a minimum test period of 1 hr. Inasmuch as the maintenance of a steady flow state for at least 1 hr, as evidenced by successive radiographic exposures of the manometer, was specified in advance as one of the criteria to be fulfilled before any test data would be accepted, no tests are reported in this paper for pressures above 1810 lb per sq in. abs.

In 1933, R. Plank (12) presented theoretical equations for the viscosity of gases and vapors. In the development, he showed that the thermodynamic equation of state may be expressed

$$P = \frac{RT}{v}\left(1 + a_1\frac{b}{v} + a_2\frac{b^2}{v^2} + \ldots.\right) \ldots\ldots\ [13]$$

By analogy, from this equation he states that

$$\mu = \mu_0\left(1 + A_1\frac{b}{v} + A_2\frac{b^2}{v^2} + \ldots.\right) \ldots\ldots\ldots [14]$$

This equation may be written

$$\mu = [A + B(t - C)]\left(1 + \frac{D}{v} + \frac{E}{v^2} + \ldots.\right) \ldots. [15]$$

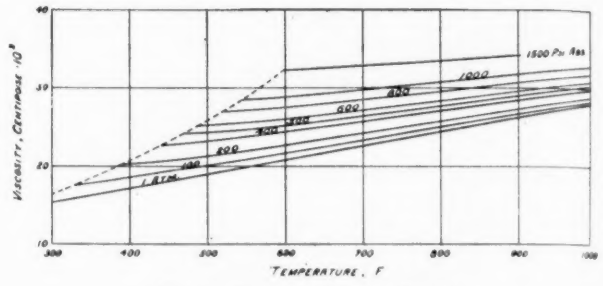

FIG. 7 THE VISCOSITY OF STEAM
(1939 Purdue University values.)

Equation [16] gives results which are in agreement with the smoothed values reported in this paper as shown in Table 5. Except for the 100-lb per sq in. abs pressures, the maximum deviation between the computed and smoothed results is 3 per cent. For the case of 100-lb per sq in. pressure the deviation is less than 3 per cent for temperatures ranging from 700 F to 1000 F but increases to 6.5 per cent at 400 F. The constants of Equation [16] are based upon the smoothed values reported in this paper for a maximum pressure of 1500 lb per sq in. abs, and it is probable that, at higher pressures, the variation in the specific volume of superheated steam is too complex to be expressed by the three terms of the equation.

Values of absolute viscosity have been obtained from Fig. 7 and tabulated in Table 6, together with the computed kinematic viscosity and several convenient conversion factors.

The viscosity data reported in this investigation are considerably lower at the high pressures than those presented by the authors in 1935. The higher 1935 values are probably due to end effects and wake turbulence of the fall body in the Lawaczeck viscometer.

ACKNOWLEDGMENTS

The authors are indebted to Mr. G. H. Van Hengel of The Detroit Edison Company for constructive criticisms and valuable assistance rendered in analyzing and interpreting the data of the investigation, particularly with reference to the effect of curvature

Discussion

E. F. Leib.[5] For the analytical representation of their data on the viscosity of superheated steam, the authors rely on Equation [14], as recommended by R. Plank. This equation has been derived from the kinetic theory of gases for the viscosity at high densities, where the space occupied by the molecules is of the order of magnitude of the gas volume, and the transfer of momentum occurs at collisions as well as between collisions. Definite values have been derived for all constants in Equation [14] and, due to their significance, these constants are essentially positive.[6] However, the constants in the authors' Equation [16] have nothing in common with these theoretical values and one constant is even negative. Therefore, the latter equation becomes purely empirical. The reason for the failure of Equation [14] is that, in the range investigated by the authors, the state of the vapor is that of moderate density, where the volume of the molecules is of minor importance, and the increase of the viscosity over the corresponding gas condition is mainly due to the forces of attraction between the molecules.

The viscosity of a vapor can, in first approximation, be obtained as follows: From the kinetic theory, we have the fundamental relation for the viscosity

$$\mu = {}^1/_3 \rho l^2 z \qquad [17]$$

where ρ = density, l = mean free path, z = number of collisions.

In the perfect gas condition

$$z = \frac{c_0}{l} \qquad [18]$$

whence the viscosity of the perfect gas, with $l = l_0$ is

$$\mu_0 = {}^1/_3 \rho c_0 l_0 \qquad [19]$$

where c_0 is the mean velocity of the molecules due to the thermal agitation.

The kinetic theory gives

$$c_0^2 = 3gRT \qquad [20]$$

and

$$l_0 = D \frac{v}{2b} \qquad [21]$$

where g = acceleration of gravity, R = gas constant, D = diameter of molecule, b = van der Waals' sphere of exclusion, v = specific volume. Thus, μ_0 depends only upon the temperature T.

Assume the density to be such that only binary encounters between the molecules occur. Consider a molecule midway between two collisions, where it will travel with the velocity c_0. While approaching the object of its next collision, it enters the field of attraction and experiences an acceleration. Thus, the velocity will be greater than c_0, and then, according to Equations [18] and [17] of this discussion, the number of collisions and hence the viscosity will be greater than in the gas condition.

To calculate this acceleration effect, we use a method similar to that by which Sutherland investigated the effect of the attraction on the mean free path. If $u(r)$ is the potential energy of a molecule with respect to another molecule in the distance r, the force of attraction is

$$F(r) = -\frac{du}{dr} \qquad [22]$$

Then the motion of a molecule subjected to this force is given by

$$F(r) = -m \frac{dc}{dt}$$

or

$$\frac{du}{dr} = m \frac{dc}{dt} \qquad [23]$$

where m = mass of the molecule, t = time.

Equation [23] can be written

$$dc \frac{dr}{dt} = \frac{1}{m} du$$

Since also

$$\frac{dr}{dt} = -c \qquad [24]$$

we have

$$2cdc = -\frac{2}{m} du$$

Integration gives the instantaneous velocity of the molecule

$$c^2 = -\frac{2u(r)}{m} + c_0^2 \qquad [25]$$

The time required to travel the distance dr is, from Equation [24]

$$dt = -\frac{dr}{c} = -\frac{dr}{\sqrt{-\frac{2u(r)}{m} + c_0^2}} \qquad [26]$$

Assume the potential energy u to decrease from a maximum ϵ with some inverse power of the distance r

[5] Combustion Engineering Company, Inc., New York, N. Y.

[6] "Mathematical Theory of Non-Uniform Gases," by S. Chapman and T. G. Cowling, Cambridge University Press, London, 1939, p. 288.

$$u = -\epsilon \left(\frac{D}{r}\right)^n \quad \ldots\ldots [27]$$

Then, from Equation [26]

$$dt = -\frac{dr}{c_0 \sqrt{\frac{2\epsilon}{mc_0^2}\left(\frac{D}{r}\right)^n + 1}}$$

where c_0 is given by Equation [20]. If we introduce

$$R = \frac{r}{D}$$

and

$$\Theta = \frac{2\epsilon}{3mgR}$$

we have

$$dt = -\frac{D}{c_0} \cdot \frac{dR}{\sqrt{\frac{\Theta}{T}\frac{1}{R^n} + 1}} \quad \ldots\ldots [28]$$

The kinetic theory gives for the mean free path at moderate densities

$$l = l_0 - \frac{D}{2} \quad \ldots\ldots [29]$$

Then the path from midway between collisions to the next collision is $\frac{l_0}{2} - \frac{D}{4}$. At collision, the distance between the centers of the molecules is D; consequently, we extend the integration from $r = D$ to $r = \frac{1}{2} l_0 + \frac{3}{4} D$, or from $R = 1$ to $R = \frac{1}{2}\frac{l_0}{D} + \frac{3}{4}$. Then we obtain from Equation [28] for the time elapsed between two collisions

$$t = \frac{2D}{c_0} \int_1^{\frac{1}{2}\frac{l_0}{D}+\frac{3}{4}} \frac{dR}{\sqrt{\frac{\Theta}{T}\frac{1}{R^n} + 1}} \quad \ldots\ldots [30]$$

while the number of collisions is given as

$$z = \frac{1}{t} \quad \ldots\ldots [31]$$

Equation [30] permits an exact integration for $n = 2$. Though the actual value of n may be greater, the error introduced by the choice $n = 2$ will be noticeable only at high densities, since it corresponds to a less rapid decrease of the potential energy with the distance between the molecules. Any value of n greater than unity is compatible with the equation of state for vapors, as derived by the writer from statistical methods, due to the particular type of molecular clusters chosen.[7]

The effect of this choice on the viscosity at moderate densities is negligible, and we obtain by integration of Equation [30], between the limits described, for $n = 2$

$$t = \frac{2D}{C_0}\left(\sqrt{\left(\frac{l_0}{2D} + \frac{3}{4}\right)^2 + \frac{\Theta}{T}} - \sqrt{1 + \frac{\Theta}{T}}\right)$$

and from Equation [31]

$$z = \frac{c_0/2D}{\sqrt{\left(\frac{l_0}{2D} + \frac{3}{4}\right)^2 + \frac{\Theta}{T}} - \sqrt{1 + \frac{\Theta}{T}}} \quad \ldots\ldots [32]$$

Substitution of Equation [21] into Equation [29] gives for the mean free path

$$l = D\left(\frac{v}{2b} - \frac{1}{2}\right) \quad \ldots\ldots [33]$$

If we now substitute Equations [32] and [33] into Equation [17], we obtain

$$\mu = \frac{1}{3}\rho c_0 D \frac{v}{2b}\left(1 - \frac{b}{v}\right) \frac{\frac{v}{4b} - \frac{1}{4}}{\sqrt{\left(\frac{v}{4b} + \frac{3}{4}\right)^2 + \frac{\Theta}{T}} - \sqrt{1 + \frac{\Theta}{T}}}$$

or, with the aid of Equations [19] and [21]

$$\mu = \mu_0 \frac{\frac{v}{4b}\left(1 - \frac{b}{v}\right)^2}{\sqrt{\left(\frac{v}{4b} + \frac{3}{4}\right)^2 + \frac{\Theta}{T}} - \sqrt{1 + \frac{\Theta}{T}}} \quad \ldots\ldots [34]$$

Equation [34] is the relation between the viscosity at moderate densities and the viscosity in the gas condition at the same temperature. The quantity b can be identified approximately with the smallest volume which the liquid substance can assume without being compressed; i.e., for H_2O, $b = \sim 0.0160$ cu ft per lb. The quantity Θ was taken as an average calculated from Equation [34] with the 1939 Purdue test data of the viscosity of steam and was obtained as

$$\Theta = 19{,}000 \text{ F}$$

With these constants, Equation [34] represents the test data with a deviation of a few per cent only. Due to the derivation from kinetic conceptions, this equation can be expected to represent the viscosity of steam far beyond the 1500-lb per sq in. limit reached in the 1939 Purdue experiments.

G. H. VAN HENGEL.[8] Recently, Russian results[9] have been published which differ with the results of the authors and other previous investigators. The many differing test results by all the various experimenters indicate the great difficulty in determining the viscosity of steam (8).[10] It seems that the capillary-tube method has inherent difficulties, some of which the writer will here review.

First let us consider the mechanical difficulties of the capillary. The authors have eliminated the complication of the entrance and exit losses of the capillary by taking a long capillary. This did away with the corrections investigated by Schiller.[11]

They introduced, however, some other problems, viz., the effect of the curvature of the coil and the problem of determining the tube diameter. Accurate determination of the diameter is a very important one as $\lambda = 25.103 \frac{\Delta p D^5}{W^2 v}$ for a length of 103.2 ft

and Re is inversely proportional to D, where λ = a dimensionless resistance coefficient, D = inside diameter in ft, W = weight flow rate in lb per sec, and v = specific volume in cu ft per lb.

The problem of the coil curvature has been investigated (10) and (11) but none had a coil of such a length or of such a heavy wall. Because it forms an oval cross section, the bending of a thick-wall tube may affect the tube diameter and cross-sectional area far more than previous investigators found.[12] This deformation reaches larger proportions at higher internal pressures, an indication of which can be found in an article by Dean.[13] This deformation may even affect the λ vs. Re curve for the coil.[14]

The determination of the inside diameter of the tube presented another problem with such a long coil. The inside diameter actually measured before the bending was 0.091 in. but the inside diameter after the bending could not be measured directly. The internal-volume determination with a liquid gave too large a diameter, due to the filling up of the connections between the different tube lengths. Gas-volume determination did not seem to offer higher accuracy.[15] Thus, finally, the tube diameter of 0.09294 in. was established by using White's formula[16] and the authors' 1940 calibration tests with water shown in Table 2 of the paper under the assumption of a round capillary. Deviations up to 5 per cent occurred for unknown reasons in the λ values.

In the paper, the influence of the temperature on the expansion of the nickel tube has been neglected, although this affects the computation of the viscosity by 3 per cent at the highest temperatures of 1000 F.

Another difficulty is brought out by Keulegan and Beij[17] that a little sag in a straight capillary contributes to large changes in friction coefficients. Here the coil was wound at random and was not at all the case of a coil in a horizontal plane.

The effect of the foregoing deviations, on which the viscosity calculation of steam is so vitally dependent, should have been established with the calibration test before the final steam tests could proceed.

But these mechanical deviations may not be the only items of great importance, because of other difficulties presented by thermodynamic problems. In the first place, among these is the effect of nonisothermal conditions in the viscous flow of incompressible fluids on the friction coefficient.[18,19] The slightest heat transmission will affect the parabolic velocity pattern considerably and thus influence the friction coefficient.

In the case of compressible fluids, there is added to the foregoing problem yet another one, i.e., the knowledge of the proper relationship between the pressure drop and the friction coefficient. This relationship will be different for the isothermal and adiabatic cases.[20]

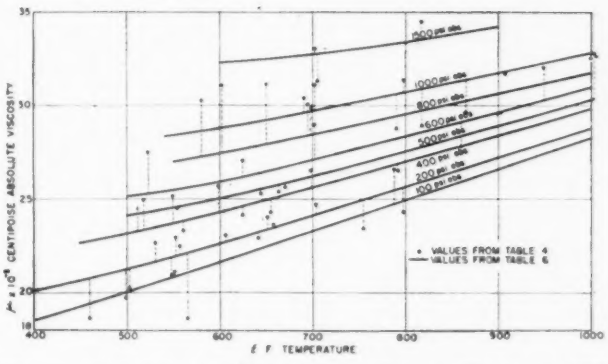

FIG. 8 COMPARISON OF PURDUE TEST VALUES WITH THE 1939 PURDUE SMOOTHED VALUES OF THE ABSOLUTE VISCOSITY OF STEAM

Perhaps one or more of these questions may play an important role in interpreting the results because, if the data of the authors' Table 4 were plotted in Fig. 7 of the paper, as in the case in the writer's curve Fig. 8, it will be noted that several points have a viscosity which deviates more than 10 per cent from the smoothed values given as curves in Fig. 7. This may be partly due to the two different coils that were used, but as long as that effect is not established other causes may exist.

Checking up Plank's formula results with the final smoothed values is only a matter of determining constants and is of no great importance in view of the deviation of the smoothed values from the actual test results. The smoothed values should therefore be used with great reservation.

For the reasons mentioned, the precise method of determining steam viscosities with capillaries must be more fully examined and developed before we can consider the values obtained as final.

Now that the authors are equipped with the experience of their published experiments, let us hope that they will once more go into this problem of fixing the values of the viscosity of steam. For pressure-drop calculations, the authors' values will be useful, but for calculations of nozzle flow, heat transfer, and the like, a higher accuracy is desirable.

F. G. KEYES.[21] Shortly after the publication of the measurements of steam viscosity by the authors (3) over a wide range of temperature and pressure (420 C:240 atm), a paper appeared by Sigwart,[22] reporting measurements considerably lower than those obtained by the American investigators. Recently the first investigators[23] have again measured the viscosity properties of water using the "capillary-flow" method of Poiseuille, whereas, the earlier results were obtained by observing the time of fall of a metal cylinder in a tube filled with steam. Both of these investigations were carried through with care and with the use of ingenious controls. The results are in substantial agreement, albeit the capillary-tube results do not extend over the wide pressure range reported upon in 1935. It is now established that the low results of Sigwart do not represent the true viscosity of steam.

The object of the present comment is to indicate that the entire ensemble of results by the authors may be simply correlated as a temperature function of the low-pressure viscosity of steam plus a function of the pressure only.

There are few data available for the viscosity properties of

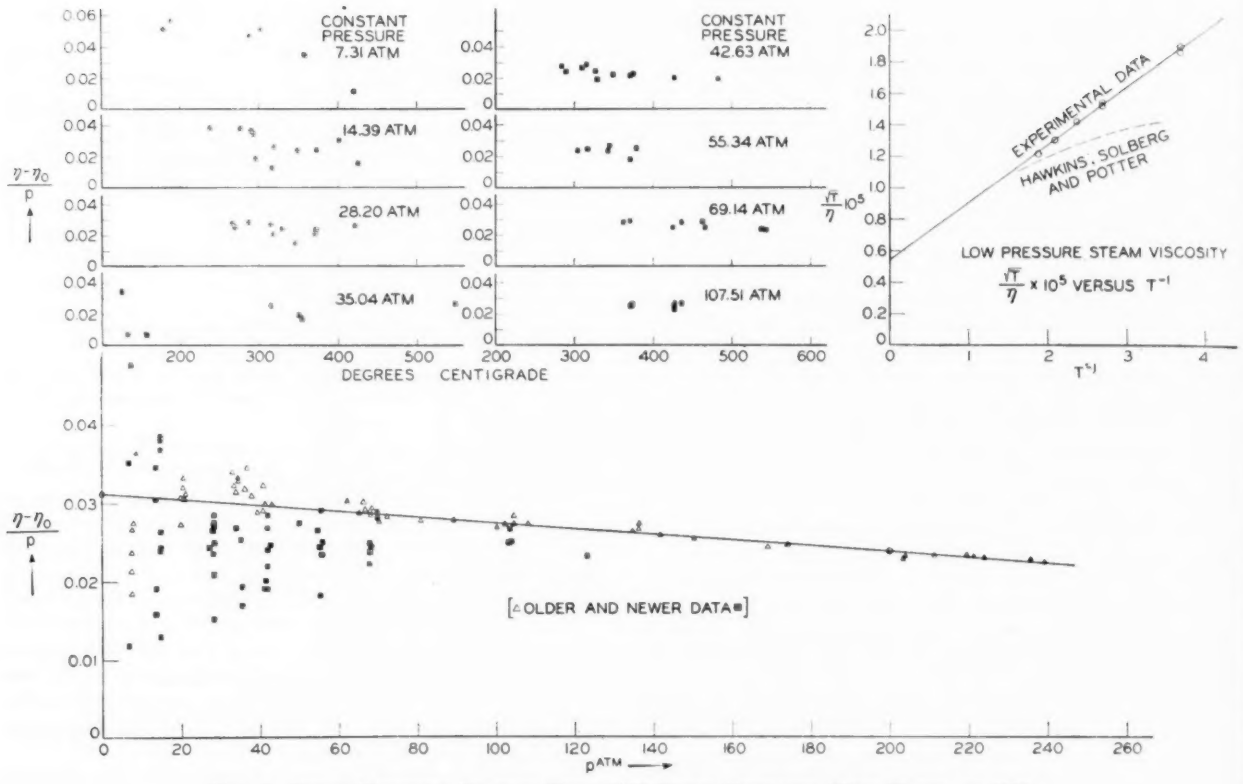

FIG. 9 STEAM VISCOSITY RESULTS FROM 1935 TESTS COMPARED WITH THOSE OF 1939

gases over any considerable pressure range[24] and the theory along classical lines has been mainly developed by Enskog[25] to a first approximation employing the van der Waals concept of the molecular field. The expression obtained for the viscosity η is

$$\eta = \eta_0 \left(\frac{1}{\vartheta} + 4/5\ b/v + 0.7614\ b^2\vartheta/v^2 \right)$$

η_0 is the viscosity as a function of temperatures at low (zero) pressure and $\vartheta = (1 + 5/8\ b/v + 0.2869\ b^2/v^2)$; the symbol b denoting the van der Waals quantity, 4 times the volume of the molecules. The formula was applied successfully to the data for CO_2.

From the computational point of view, a formula in the variables T and v is less convenient for engineering purposes than one in T and p. The writer accordingly attempted in a wholly empirical way to obtain such a formula and it appears that the following equation[26] represents the authors' results

$$\eta = \eta_0 + (0.03103 - 3.65 \times 10^{-5} p) p \times 10^{-4} \quad [35]$$

In Equation [35], the viscosity is expressed in poises and the pressure in atmospheres (14.696 lb-in.$^{-2}$). The quantity η_0 is the viscosity of steam for pressures approaching zero. The quantity η_0 can be represented by the following equation commonly referred to as the Sutherland formula

$$\eta_0 \text{ (poises)} = \frac{1.851 \times 10^{-5} (T)^{1/2}}{1 + 680.1\ T^{-1}} \quad [36]$$

The constants of Equation [36] were obtained by least-square procedure using all available low-pressure data.[27]

Equation [35] may be transformed to the form

$$Z = \frac{\eta - \eta_0}{p} = a + bp \quad [37]$$

It is clear that if Equation [35] is satisfactory, the function Z computed from the data should be linear in the pressure. Fig. 9 of this discussion shows the 1935 data which extend to 240 atm and indicates that the linear relationship is satisfied. There is moreover no detectable temperature influence left unaccounted for.

The new data lie in general below the older results but are confirmatory in general of the older measurements. The upper left portion of Fig. 9 shows the later data Z function plotted for constant pressures with temperature as the abscissas. There is no pronounced trend.

The upper right portion shows the data for low (zero) pressures plotted as follows: Equation [36] may be written in the form $\frac{T^{1/2}}{\eta_0} = \frac{1}{\alpha} + \frac{c}{\alpha} T^{-1}$. If the square root of the absolute temperature is divided by the viscosity, the quantity should vary linearly in reciprocal absolute temperature.[28]

The experimental data are seen to be adequately represented by the Sutherland formula of which the constants in Equation [36] were determined by least-square procedure. The dotted line represents in the same coordinates the low-temperature viscosi-

ties computed from the formula $(10.74 + 0.0178t)$ employed by the authors.

Summary

1 The authors' new viscosity data do not indicate that any change in the earlier viscosity Equation [35] is necessary.

2 Equation [35] reproduces the viscosity of steam in relation to all the authors' results within the limits of experimental error.

Comments

The foregoing discussion was prepared on the basis of the viscosity of steam data given in Table 6;[23] these results extend to about 123 atm. It is intended to show that the results are in tolerable agreement with the 1935 data obtained by a method different from that employed in 1939. The 1935 data extend to a pressure of 239 atm or nearly twice the range of the later results.

Recently, corrections have been applied to these data,[23] resulting in a considerable reduction in their magnitude. For example at 801 F and 123.2 atm, 3.83×10^{-4} poises is the corrected 1940 result obtained by correcting the December, 1939, datum, which is 5.34×10^{-4} poises; roughly 40 per cent greater. It is therefore clear, since the uncorrected 1939 results are in fair agreement with the 1935 results, that a serious error affects the 1935 data. The authors note this fact.

An examination of the new data using the form of Equation [35] indicates that the corrected data may be represented within the limits of accuracy. The formula is as follows

$$\eta = \eta_0 + (0.0151 - 5.9 \times 10^{-5} p^{\text{atm}}) p^{\text{atm}} \times 10^{-4} \ldots [38]$$

The formula for η_0 is the same, i.e., Equation [36].

If the viscosity of steam at 239 atm 788 F is computed using Equation [38], the number 2.67×10^{-4} is obtained. The 1935 result is however given as 7.30×10^{-4} which would imply that the Lawaczack method gave a result nearly 190 per cent greater than that which the capillary method might give. The extrapolation using Equation [38] to 239 atm (nearly twice the range upon which this equation is based) may of course be subject to great error.

R. C. H. Heck.[29] The object of this discussion is to set up an argument in terms of simple kinetic theory, for the necessary increase of gas viscosity with pressure and with temperature.

As to the detail of its mechanism, viscous action within a gas is distinctly different from that in a liquid. In the liquid, the shear stress of viscous resistance and the compressive stress of pressure reaction are both phenomena of molecular contact; but, in the gas, they are impact effects of molecules in free translatory motion. Of molecular motions and interactions in the liquid phase we have but vague concepts, knowledge (of over-all kind) coming wholly by observation and empirical determination. The free and simple motions of gas molecules can be reasoned in large degree; at least far enough to account for the major component of behavior that will yet require experiment for close determination.

First comes a brief outline of a part of the course of reasoning that leads to the gas equation $pv = RT$, taking the simplest case of a single gas with molecules all of the same mass m, having the mean velocity u. Imagine a cubic unit of gas enclosed by walls that are perfectly elastic and infinitely fine in structure, so as to be perfectly flat even to molecules. With n molecules in this cube and velocity u in terms of the edge of the cube as linear unit and per second, the number of impacts per second on the square side is $nu/2$. These impacts are in all directions, but the mean normal component velocity is $u/3$. Then it is as if a stream of fluid having the mass velocity $mnu/2$ were flowing squarely against the unit surface with velocity $u/3$ and momentum $mnu^2/6$. This stream is brought to zero velocity by impact and then completely reversed by elastic rebound; an action made possible by the mechanism of real molecular motion, to which the stream concept is merely an over-all equivalent. The effect of impact is now a unit pressure of the value

$$p = mnu^2/3 \ldots [39]$$

Since mn is the same as density ρ, the mass per unit of volume and equal to $1/v$, the relation becomes

$$p = \rho u^2/3 \quad pv = u^2/3 \ldots [40]$$

This pv is magnitudinally equal to $^2/_3$ of the kinetic energy of all the molecules in the unit of mass, but physically it is an inertia-force effect. The final step of making absolute temperature T proportional to u^2 goes beyond the needs of the present discussion. In a gas mixture, molecules of different mass m are put on an equal basis by the fact that mean energy $mu^2/2$ must be the same for all molecules at a given temperature.

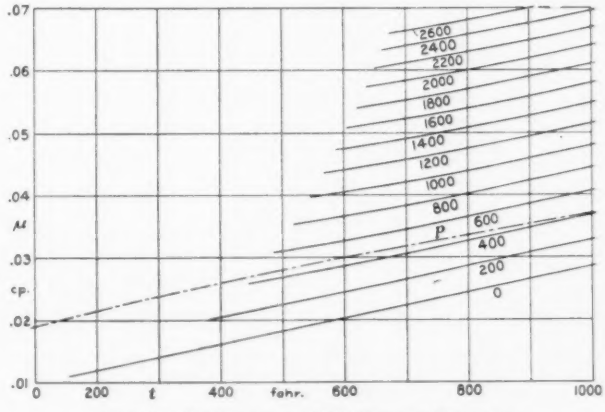

Fig. 10 Chart of the 1935 Purdue Results

Considering gas in motion, i.e., in mass motion, three forms of simple streamline flow are to be distinguished, as follows:

1 Ideal uniform flow, as in a "frictionless" straight channel, with progressive velocity V the same at all places in the current. Completely random molecular velocity continues to be distributed throughout the moving body of gas just as if this were standing still; and the total or absolute velocity of each molecule (with reference to the fixed channel) is the vector sum of the particular u within the current and the general V of the current.

2 Growing velocity of flow, as in current acceleration or jet formation, with V increasing and mean u decreasing as pressure falls. Flow velocity V is uniform over surfaces of like state across the current.

3 Viscous or "laminar" flow, in which V is constant along any line of flow but varies across the current. This is the kind of motion in which we are now interested.

In laminar flow, consider a surface of equal velocity V, which is a cylinder in either of the viscosimeters used at Purdue. This surface is now to be purely geometrical, offering no impedance to the passage of molecules. Across the surface, momentum is being carried at the rate $mnu^2/6$ figured for pressure effect. Also, across the surface (with dimension y in that direction) there is the velocity gradient dV/dy.

Next, consider the cross-stream of molecules from lower to higher V; these must be accelerated in the flow direction, hence, exert an inertia reaction against the higher-velocity stream.

[29] Research Professor of Mechanical Engineering, Rutgers University, New Brunswick, N. J. Mem. A.S.M.E.

Similarly, the cross-stream from higher to lower velocity must be retarded, with a forward pulling inertia effect. The two reactions combine to oppose relative motion of the parallel-flow streams; and the amount of this opposition, due to a deflection of momentum on account of gradient dV/dy, is proportional to the total momentum which manifests itself in pressure p. Since in any rate of streamline flow, velocity V will be very small relative to molecular u, viscosity is a very feeble force action in comparison with gas pressure.

In Fig. 10 of this discussion is shown a chart of absolute viscosity μ, interpolated from Figs. 9 and 10 of the 1935 paper (3). The stage of argument thus far reached, with the conclusion (partial) that μ should be proportional to V, would require that the constant-pressure lines be horizontal and that they be equally spaced vertically. It becomes necessary then to perceive some further influence which will account for the actual behavior seen in Fig. 10 of this discussion; and this is found in the matter of mean length of path of molecule between impacts. The modifying effect of path length is argued thus:

With rise of pressure along the isotherm, the increase of density ρ shortens the mean path; with a shorter path across the flow direction or in the direction of velocity gradient, there is smaller change of the V component of the total molecule velocity; and therefore the increment of μ with p lessens as the pressure is higher.

Along a p-constant line, smaller density with higher temperature lengthens the path of the molecule, hence there is greater change of momentum in the direction V, and μ rises with the temperature.

In Fig. 10 the dot-and-dash curve is the handbook curve of μ for air, at or near atmospheric pressure.

From the simple reasoning thus completed it is not possible to make a quantitative prediction; it is explanatory rather than determinative; and a theory of full quantitative capability would be far more elaborately mathematical. Also, for steam as a superheated vapor or a gas near to saturation, there is the further influence of departure from ideal-gas behavior.

[An additional discussion of the paper, as presented in preprint form at the 1939 Annual Meeting of the Society, was received from J. R. Finniecome of Manchester, England. Since revisions were made in the original paper, it has been impossible to communicate these to him in order that he might have the opportunity to revise his discussion. Therefore, it is with regret that it has been found necessary to omit his contribution at this time. EDITOR.]

AUTHORS' CLOSURE

The discussions of Messrs. Lieb and Keyes are very interesting because different types of equations are developed which closely represent the smoothed values presented in the paper. Dr. Lieb's equation, based on the kinetic theory, should permit extrapolation of the results to pressures much higher than the upper limit of the experimental data reported by the authors.

Mr. Van Hengel has contributed a very thorough and valuable discussion of the difficulties encountered in measuring viscosity by means of a capillary tube. His remarks should be of great assistance to any person interested in experimental work in this field.

Possible deformation of the cross-sectional area of the capillary on bending to a one-foot radius is one of the mechanical difficulties mentioned by Mr. Van Hengel. Five sections have been cut from the capillary coil, the ends have been polished perpendicular to the coil tangent, and enlarged photographs have been made of the tube cross section at a magnification of 100 diameters. The photographs do not show evidence of deformation of the circular cross section at any of the five sections investigated.

Mr. Van Hengel discusses the difficulty of accurately measuring the internal diameter of the capillary and points out that the fifth power of the diameter appears in the general flow equation of Blasius. The constants in the authors' Equations [4], [5], and [12] and the calibration data of Fig. 5 are based on a particular numerical value of the diameter. If the actual diameter of the capillary remains constant and the same value for the diameter is used in all computations involving both calibration and test runs, the final values for the viscosity of steam as computed by the method of the authors are independent of the numerical value used for the diameter.

Mr. Van Hengel mentions the effect of temperature on the diameter of the capillary. This has been considered in computing the Reynolds numbers used in connection with Fig. 5, but its effect upon the curves in Fig. 5 has been neglected. Thus a partial correction has been made and errors due to neglect of expansion of the capillary at high temperatures are considerably less than those indicated by Mr. Van Hengel in his discussion. The use of the general Blasius equation with friction coefficients in the form shown in Fig. 6 would have made the correction for expansion simple and complete but the final results would have depended upon the fifth power of the diameter of the capillary. To summarize, then, the method of computation used by the authors gives viscosity data which are independent of the numerical value assigned to the diameter of the capillary if this diameter is constant, but complete corrections for changes in the actual diameter with temperature, while small, are nevertheless almost impossible to make. The method preferred by Mr. Van Hengel of using the Blasius equation makes it possible to correct completely for changes in capillary diameter with temperature, but the numerical value of the diameter to the fifth power enters directly into the results at all temperatures and therefore necessitates a precise determination of the diameter.

In conclusion, the authors wish to thank all of those who have presented oral or written discussions for their interest, comments and constructive criticisms.

Steam-Turbine Blading

By R. C. ALLEN,[1] MILWAUKEE, WIS.

This paper reviews the blading-design practice associated with modern high-pressure high-temperature steam turbines. The design problems encountered in the development of partial-admission impulse blading for topping units are described, as well as the current engineering practice employed in the manufacture of such blading. The stress analysis used in the construction of full-admission blading is reviewed. The design procedure adopted for high-tip-speed last-row blading and the natural limits in capacity imposed on 3600-rpm turbine construction are also discussed. Materials for turbine blading are considered, as well as the metallurgical problems associated with the fabrication and welding of the high-grade alloy steels now available.

Introduction

NOZZLES and blades for large steam turbines may be classified inclusively as elements incorporating a series of curved passages which control and direct the power-producing phases of the steam flow through the turbine. The general function of the steam passages is twofold: (1) The kinetic energy in the carry-over velocity from the preceding stage must be efficiently turned through a predetermined angle; (2) at the same time, there must be an efficiently carried out expansion through each element by means of which the kinetic energy of the working fluid is increased.

The foregoing general statement may be taken to cover moving or stationary elements or blading of the impulse or reaction type. Reaction-turbine designers often find it desirable to divide the thermal drops unequally between the moving and stationary blades of a stage. Impulse-turbine builders find that the highest efficiency can be achieved by the adoption of a certain amount of pressure drop in the moving blades. The original sharp distinction between reaction and impulse turbines has, therefore, largely disappeared, although there are still notable differences between the two types with respect to mechanical details. The present problem of the blading engineer is rather that of deciding what type of element makes possible the most reliable construction which also will meet the required efficiency level at the lowest manufacturing cost.

The research and engineering aspects of the thermodynamic and fluid-flow problems related to blading design are of the utmost importance. Extensive research has been carried out and is still under way in connection with the determination of the most efficient forms of steam passages. In recent years, attention has been given to the further development of steam-flow problems along lines adopted by aerodynamic engineers in studying the lift and drag of airfoil sections. It is not the purpose of this paper to present the steam-flow phases of the work, but rather to indicate some of the mechanical aspects of blading construction which have been developed in the last few years to meet the demands for high-capacity high-speed machines, designed for maximum pressures and temperatures. Some of the considerations given may seem elementary; others may be open to argument and discussion. In spite of the fact that the steam turbine is not a newcomer in the field of engineering, it must be admitted that recent developments have caused quite radical changes in design reasoning. It may further be said that the design development of machines for the highest pressures and temperatures is still in the process of revision and research.

In this paper, the author has been permitted to supply engineering data from the steam-turbine practice of the Allis-Chalmers Manufacturing Company. The subject matter concerns principally the recent mechanical developments in blading elements.

Blading Materials

Air-Hardening Versus Non-Air-Hardening Stainless Steel

Even the advanced metallurgical practice of the present day, has not produced a blading material in which the most desirable values of all the various physical and chemical properties can be provided in the same alloy. For example, in some materials in which there is high strength at high temperature, the hardness is so great that they cannot be machined. Other materials may have excellent properties, except that the corrosion resistance may not be sufficiently great. Among the materials available, there will be found certain classes of alloys which do not have the highest resistance to stress corrosion, but which do have other essential qualities, i.e., high physical properties at elevated temperatures and weldability without air-hardening. Consideration of all these properties indicates that such materials best meet the requirements for most blading service. In particular, these statements refer to certain of the alloy steels, in which the iron constituent is in the gamma phase, which come under the general classification of austenitic steels.

These materials must be properly processed to avoid undue carbide precipitation or growth of the crystalline grains at the steel mill or during the final-assembly heating operations. Under certain conditions of application, suitably low stresses may of necessity be adopted if impurities are present in the steam which might, in the presence of high stresses, cause stress corrosion. It is the conclusion that the strength at high temperature, the resistance to the various types of corrosion, and appropriate consideration of welding make alloys of this class the most generally useful in steam-turbine-blading practice.

Cyclops No. 17-A Alloy

The standard Allis-Chalmers blading steel is known as Cyclops No. 17-A alloy and is produced by the Universal Cyclops Steel Corporation, Titusville, Pa.

The composition is as follows:

	—Per cent—
Carbon	0.35 to 0.45
Nickel	19 to 20
Chromium	7 to 8
Silicon	0.95 to 1.25
Manganese	0.55 to 0.75

This material has an ultimate strength of 105,000 psi at room temperature in rolled bars $^3/_4 \times 1^1/_2$ in. The corresponding

[1] Engineer, Steam Turbine Department, Allis-Chalmers Manufacturing Company.

Contributed by the Power Division and presented at the Semi-Annual Meeting, Milwaukee, Wis., June 17–20, 1940, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

proof stress at 0.01 per cent plastic yield will be about 50,000 psi. The material has good physical properties at high temperatures.

Recent developments with this material have been in the direction of improved quality and closer control of process work. The austenitic structure of this alloy and its consequent capability of being welded without air-hardening facilitates the blade-assembly processes. During the last year, there has been an extensive study of the rolling-mill processes employed in the production of sections which are rolled to final size. In previous practice, the rolling-mill passes following the last rolling heat were carried out in such a manner that the percentage reduction at various parts of the blade section was not the same. The percentage reduction in the region of the outlet edge was much greater in the last roll passes than the corresponding reduction in the thick part of the blade section; hence, there was a substantial difference in grain shape and size between the material in the edges and the material in the thick parts of the sections. Harold Stein[2] has developed and made effective during the last year a change in the rolling-mill program, whereby the rate of reduction in the passes following the last rolling heat is made essentially the same throughout the widths of the blade sections. This procedure is effective in producing grains substantially equiaxed in form and practically equal in size over the full widths of the sections. The internal stresses set up between the thin and thick portions of the blade sections are reduced considerably by this procedure. It is the present conclusion that certain cases of stress corrosion will be prevented by this change in the method of rolling.

In the rolling of blade sections by the older method, the ends of the bars came out of the rolls tapered to a considerable degree, the bar being several inches longer on the outlet-edge side than on the thicker inlet-edge side. With the new process, the material in the inlet and outlet edges is of approximately the same length. In other words, the bars come out of the rolls nearly square at the ends.

Further improvements have been made at the steel mill with respect to finish-rolling. A cold-finishing pass has been adopted, which gives a higher degree of surface finish to the sections. After the final cold pass, the Cyclops material is stress-relieved at 1425 F.

13-Chrome Stainless Iron

The analysis of 13-chrome stainless iron is as follows:

	Per cent
Carbon	0.06 to 0.13
Chromium	11.5 to 13.0
Silicon	0.50 Max
Manganese	0.25 to 0.80
Nickel	0.50 Max

For the extreme low-pressure end where the operating temperature is low and where the maximum strength is necessary, the 13-chrome stainless iron is considered the best material available. It possesses reasonable corrosion resistance, combined with high strength and good endurance limit. Welding operations must be carefully planned and executed, otherwise the air-hardening characteristics of this material may introduce difficulties. The 13-chrome stainless iron is used by all of the large turbine builders in this country for the highest-stress low-pressure blades. In Allis-Chalmers practice, this material is used for low-pressure blades in which the annular-blade outlet area at 3600 rpm exceeds approximately 21 sq ft.

[2] Director of Research, Chemistry, and Metallurgy, Allis-Chalmers Manufacturing Company, Milwaukee, Wis.

19 Per Cent Chrome, 9 Per Cent Nickel Shroud Material

This is a standard alloy used for reaction-blade-shroud sections of the present standard type which are secured in place by welding. All new central-station machines will have reaction blading so shrouded.

The carbon content is about 0.1 per cent. The columbium content varies from 0.7 to 1 per cent to stabilize the material against carbide precipitation. This material is capable of being easily welded. Standard embrittlement tests show that the material is substantially immune to this type of attack.

25 Per Cent Chrome, 12 Per Cent Nickel Weld Rod

Coated weld rods of this material containing about 0.1 carbon with a stabilizing addition of columbium are made up in sizes as small as $^1/_{32}$ in. in diameter. They are used for welding 19-9 chrome-nickel shrouding on the Cyclops 17-A blading, or the welding together of the integral shrouding on the Cyclops impulse blades.

The welding of austenitic blading materials requires special welding units of the mercury-arc-rectifier type which permit welding with current flows down to about 2 amp. Such welds are formed with a minimum of local heating. Excessive grain growth is prevented by the rapid cooling of the weld by the chill effect of the adjacent material.

Everbrite Base Material

Intermediate blading for moderate pressures, temperatures, and blade speeds is prefabricated in segments in which the ends of the rolled blade sections are joined by casting them into a foundation of Everbrite alloy. Everbrite is a casting alloy of the following composition:

	Per cent
Copper	59.0 to 65.0
Nickel	29.5 to 31.5
Iron	5.0 to 8.0
Manganese	0.60 Max
Carbon	0.25 Max
Silicon	0.60 Max

The process work in connection with this development requires very accurate control of many factors, including extreme cleanliness of the blade ends, a carefully worked out process for the gating and pouring of the blade group castings, and an extremely close control of the temperature of each pot of metal that is poured. With proper control, an excellent bond between the rolled blade material and the cast foundation is obtained.

Summary of Application of Blading Types in Steam Path

1 Impulse blading is milled from bars of the Cyclops alloy with integral base and shroud sections. The shrouding is for the purpose of confining the steam flow to the blade path and also for reinforcing the structure mechanically. Circumferential-groove blading is used up to about 25,000 kw for top-turbine service and 75,000 kw for condensing machines at 3600 rpm. Axial-slot roots are used for higher capacities. An important recent development is the welding of the shrouding in groups of two blades for large machines.

2 High-pressure high-temperature reaction blading is milled from Cyclops bars with integral roots. After assembly in the spindle, the 19-9 chrome-nickel shrouding is welded in place. A characteristic of the high-temperature shrouding is the small number of blades per segment, usually not exceeding 4 to 6 for the highest temperatures.

3 The intermediate blading for moderate temperatures and stresses is prefabricated in segments by casting the rolled sections into foundations of Everbrite or cast iron. The 19-9 chrome-nickel shrouding is welded in place prior to casting.

4 Where stresses make necessary the use of milled low-pressure blading, the Cyclops alloy is used in conjunction with the welded 19-9 chrome-nickel shrouding up to annular areas of 21 sq ft at 3600 rpm.

5 Where the annular-blade outlet area exceeds about 21 sq ft at 3600 rpm, 13-chrome stainless-iron blading is used with roots of the axial-slot type. Shroud sections and lashing wires are of 19-9 chrome-nickel steel, welded in place.

PARTIAL-ADMISSION IMPULSE BLADING FOR HIGH-CAPACITY TOP TURBINES

Review of General Problem

Partial-admission impulse blading has been a standard element of design over a long period. However, the industry has experienced numerous troubles with such blading in the last few years. It may well be asked, what has happened so quickly to upset the design practice established by half a century of practical turbine experience with partial-admission wheels? The answer is believed to be that the magnitudes of the suddenly applied steam forces have been greatly increased beyond the limits of the older practice, largely because of the introduction of high-capacity top turbines at 3600 rpm and, at the same time, the operating temperatures have increased to such an extent that the physical properties of blading materials have been substantially reduced.

The older forms of analysis employed in the design of partial-admission impulse blading were based on static values of the tangential steam driving forces, usually without allowances for stress amplification due to the rapid rate of steam load application and removal, or the effect of the application of the steam driving load in successive revolutions under conditions of resonance. In the earlier partial-admission wheels, the tangential steam driving forces were of much lower magnitude, and the blade heights were also less; hence, the effect of the repeated application of the rapidly applied steam loads did not generally set up destructive stresses. In such machines, the errors introduced by neglect of the stress-amplification factor did not usually cause trouble because of the small magnitudes of the bending stresses. Where troubles developed in the older practice, due to exceeding the safe stress limits accidentally, they were usually corrected by the installation of stronger blades, sometimes without very complete knowledge of the exact cause of failure.

Blade developments for high-capacity top turbines have led to an extensive investigation of the performance of partial-admission impulse blading, with the result that it is now possible to predict with reasonable accuracy the maximum possible stresses in such blading.

Stress Amplification Due to Effect of Successive Impulses

In the following discussion, the successive steps in the development of the theory of dynamic loading will be reviewed. A cursory review of the elementary principles involved because of their importance will also be included.

Fig. 1 illustrates the elementary principle of suddenly applied loads. The spring in the diagram represents the elastic-spring scale of a given blade. The mass of the platform can be taken to represent the mass of the blade. The weight W represents the tangential steam driving force.

At the instant the load W is applied, the full magnitude of the force acts as an accelerating force. After an arbitrary deflection l is reached, the force W is still acting at the constant value established by its sudden application. There has been built up, however, at deflection l, an opposing spring force which is equal to the deflection l times the spring scale P. In other words, at the arbitrary deflection l, the net accelerating force is the difference between the steam force W and the opposing spring force Pl. The elementary theory shows that the triangular area having a horizontal base W and an altitude L_1 represents, to some scale, the energy that is imparted to the blade, which must appear in the mid-position as kinetic energy. Note that at the static deflection L_1 the force W exactly equals the opposing spring force, so that there is no acceleration at the mid-position.

If no damping is present and if the spring is assumed to have a straight-line characteristic, it is evident that the weight will overtravel a distance L_2, which is equal to L_1, in order that the kinetic energy shall be converted into strain energy in the spring. Therefore, the stress in the spring at the maximum extension is twice the stress at the equilibrium position.

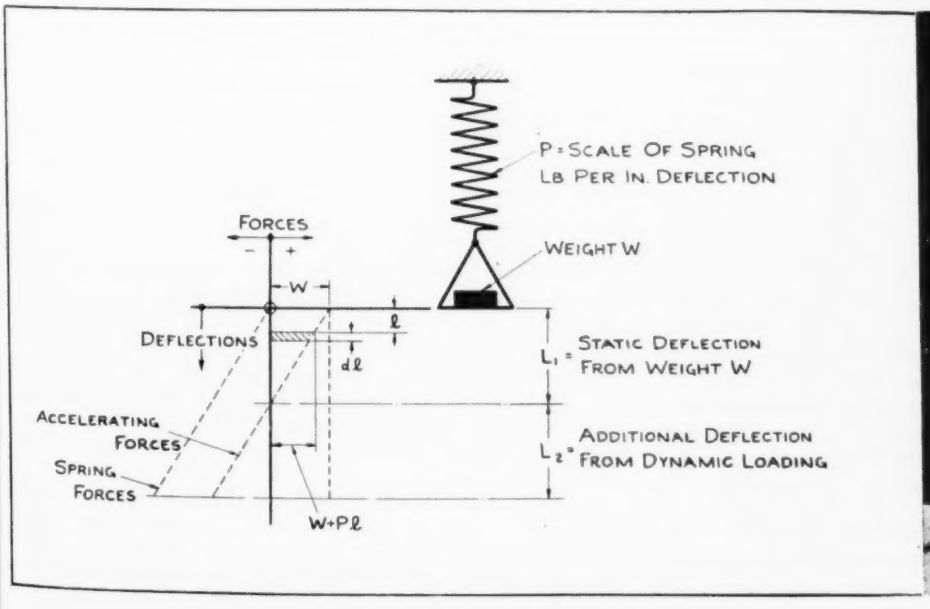

Fig. 1 Diagram Showing Principle of Suddenly Applied Loading

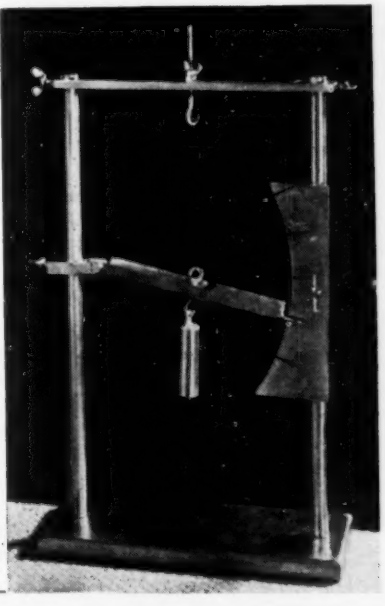

Fig. 2 Model Showing Principle of Suddenly Applied Loading

Fig. 2 shows a model which illustrates the same principle. Without the small weight, the pivoted spring-loaded beam will come to rest in the mid-position. This represents the position of a blade under the action of centrifugal force only. A slow application or removal of the steam driving force will cause the blade to fluctuate between the position of rest and the normal static deflection. This type of loading, the maximum value of which is indicated by the first index mark below the center, represents the operating conditions found in full-admission blades. If the weight representing the steam force is engaged with the hook but just out of contact with it, and is suddenly released, the model blade will deflect a greater amount than represented by the static deflection. In the limit case, as shown by the elementary theory, the maximum deflection will be twice the static value and will be represented by the lower index mark on the model.

Let it be assumed that there is no internal friction in the model and that the sudden application of the weight and the associated vibratory motion continues with no reduction in the amplitude. If the weight is suddenly removed while the blade is at the lower extreme of its motion, the model blade will then vibrate at double the former amplitude. The motion will continue from a positive position corresponding to a tension in the inlet edges of twice the static value to an equal stress in the negative direction. In other words, with a sudden single application of load under conditions of no damping, followed by a sudden removal of load, timed to produce the maximum amplitude, the stress range in the inlet edges will be 4 times that indicated by the static value.

These statements indicate only the beginning of the process. Let it be assumed, in the elementary case, that the load has been suddenly applied and suddenly removed and that the blade is now vibrating through the full amplitude indicated by theory. If, now, the blade enters the admission arc a second time with the motion in the right relation to the action of the steam force imposed by the nozzle, it is obvious that the amplitude will be further increased. The release of the steam force at the correct time will yet further increase the amplitude of vibration. The motion of the blade is thus increased in successive revolutions until, if there is no internal damping of the blade material or other friction effects, the blade would soon vibrate at a destructive amplitude. This condition of timed application and release of the steam forces is called primary resonance.

It is necessary to define primary and secondary resonance of partial-admission blading. Primary resonance is considered to be that state of motion in which the application and release of the steam driving force occurs at the phase relations to the blade motion which promote the maximum amplitude of vibration. This type of resonance is probably unavoidable in steam-turbine practice. It is, therefore, necessary to proportion the design of partial-admission blading so that primary resonance can occur and that the maximum amplitude set up by this condition will not be such as to produce harmful stresses. If, under a given operating condition, the application and release of the steam driving forces are timed to cancel part of the energy input and thus produce small amplitudes of vibration, which is quite possible, this cannot be expected to be the case for all operating temperatures or speeds. Hence, it is necessary to design the blading to run under a condition of primary resonance.

Secondary resonance is the condition which exists when the natural frequency of vibration of the blades is equal to the frequency of the impressed force from the nozzles. This condition is one which can be avoided by design, by proportioning the blades to secure the required mass-stiffness ratio. The periodic variation of the steam driving force, as the blades pass through the admission arc, may set up excessive motion if secondary resonance is not avoided.

In the practical case, in which internal damping is present, a maximum amplitude of the vibratory motion is reached in which the energy dissipated by damping equals the energy input from the intermittent steam forces. This criterion of the conditions regulating the stress-producing forces is capable of theoretical analysis and permits the determination of blade proportions which will survive such service.

It is of interest to note, in passing, that the kinetic energy imparted to an initially nonvibrating blade at the end of the admission arc is 4 times the amount imparted to the blade at the inlet end of the arc. This statement is correct only for one application of the load to a nonvibrating blade and one properly timed release of the tangential driving force in which the application and release each take place in zero time. The system in this example is assumed to have no damping.

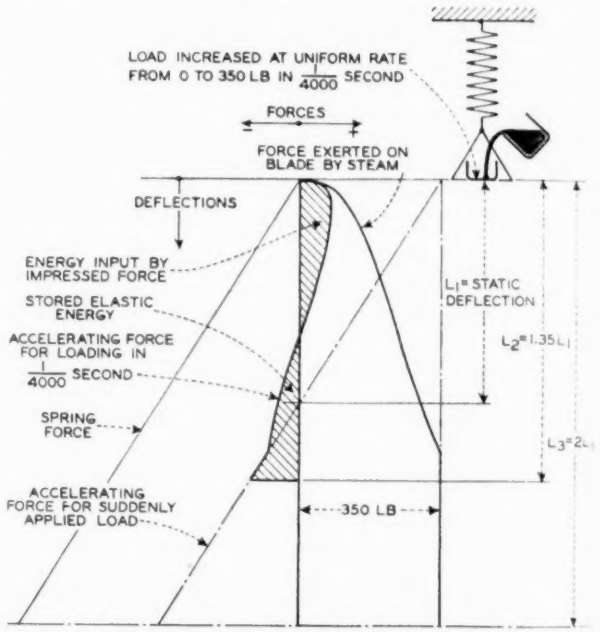

FIG. 3 DIAGRAM SHOWING EFFECT OF ACTUAL TIME OF LOADING ON BLADE MOTION

The foregoing discussion is based on suddenly applied loads. In an impulse wheel for a 50,000-kw top turbine, a standard design employs 66 blades. Each impulse blade will, therefore, receive its loading in approximately $1/66$ of $1/60$ sec, or in approximately $1/4000$ sec. Fig. 3 shows the substantial modification made in the elementary theory by the actual application of the steam load in $1/4000$ sec instead of in zero time.

As the blade enters the admission arc, the steam driving load starts at zero instead of at the maximum value which is established in the case of the suddenly applied load. The tangential driving force on the blade builds up as shown by the curve of steam force on the chart, Fig. 3. At the left of the zero-force line, the straight-line relation of spring force to deflection is shown. The accelerating force at any deflection is the difference between the force exerted by the steam and the opposing elastic force exerted by the blade.

The actual kinetic energy imparted to the blade is proportional to the shaded area at the right of the zero-force line. The energy in this case is about $1/8$ of that imparted to the blade by a suddenly applied load. On this basis, the stress-amplification factor for a single application of the driving force at a uniform rate in $1/4000$ sec would be 1.35 instead of the factor 2, which is found in the case of the suddenly applied load. This analysis

shows the substantial influence on the energy input to a blade under conditions of rapid loading in the short time interval of $^1/_{4000}$ sec, during which the full tangential driving load is built up. As indicated, the loading of such a blade in $^1/_{4000}$ sec results in 80 per cent less energy being imparted to the blade to start it vibrating than in the case of a suddenly applied load.

In the consideration of partial-admission impulse-blade stresses, the first step taken in the development of a rational design procedure was the principle of suddenly applied loads described in the preceding paragraphs. The second step was a process which included consideration of the actual time in which the blade received its load, the maximum amplitude of vibration which could be built up by successive impulses received and removed under conditions of primary resonance, and the principle that the energy input to the blade from the nozzle must be absorbed by the total damping of the system.

The third advance in the analytical reasoning on partial-admission impulse-blade design is divided into three parts. The theoretical work involved is the development of H. D. Emmert.[3] The three divisions are as follows:

a Theoretical solution of the effect of suddenly applied and suddenly removed steam forces on a vibrating blade, including damping.

b Theoretical development which includes correct consideration of the effect of the actual rate at which the steam load is applied and removed on a vibrating blade.

c Development of the complete solution of the practical problem in which the actual rate and time of steam loading of a vibrating blade is taken into account; allowance is made for the variation of steam driving force on the blade as it passes through the arc of admission; and the correct provision is made for the effect of the actual rate and time at which the steam load is removed.

The motion of elastically supported masses such as blades under the action of intermittent forces is a type of problem which

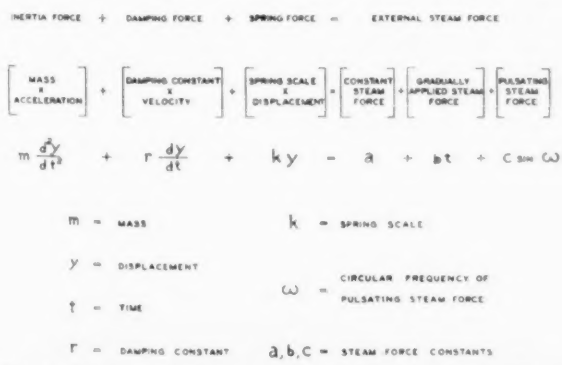

FIG. 4 FUNDAMENTAL EQUATION OF MOTION OF ELASTIC BODIES

has been fundamentally developed on a theoretical basis. The solution of the problem starts with the equation of motion, which, in simple language, is an equation the terms of which represent the various forces acting on the body.

The equation of motion as applied to this problem, referring to Fig. 4, may be expressed as

$$m\frac{d^2y}{dt^2} + r\frac{dy}{dt} + ky = a + bt + c\sin\omega t$$

where

m = mass of vibrating body
y = displacement of body
t = time
ω = circular frequency of impressed force
k = spring constant
r = damping constant

a, b, and c = steam-force constants

In the first term, m represents the equivalent mass of the vibrating body. The remaining part of the term is the second derivative of the displacement with respect to time. This quantity represents the acceleration of the body at any point in its path. In other words, the first term represents the inertia force, which is equal to the mass times the acceleration at the point considered.

The second term represents the damping force. The damping constant r is multiplied by the first derivative of the displacement with respect to time, this quantity representing the velocity. In other words, the damping force equals the product of the damping constant and the velocity.

This assumption represents the conventional procedure and is based upon the damping forces varying directly as the velocity of displacement. The actual damping forces of materials of construction may vary from this relationship. Such variation may be taken into account by experimental determination of the damping curve, and by using the value of the damping constant which is applicable for the actual working condition.

The third term represents the spring force. The term k is the spring scale and y the displacement.

The right-hand member of the equation represents the action of the steam forces on the blade.

The motion of a blade in the inactive part of the circumference is such that there are no steam forces acting, hence each of the constants a, b, and c of the three terms is equal to zero during this part of the motion.

If there is a condition of suddenly applied loading in which the steam load is assumed to reach its full value in zero time, the constant a will have a finite value, while the constants b and c will each be equal to zero.

In the case where the steam load is assumed to be applied as a linear function of time, the constants a and c become zero, and the right-hand member of the equation becomes bt.

If the steam force in the admission arc is assumed to have a harmonic variation which is found to be substantially correct in practice, the constant b of the right-hand member becomes zero, and the complete right-hand member for this case becomes $a + c \sin \omega t$.

The solutions of this type of differential equation of motion are capable of being evaluated by established methods.

IMPORTANCE OF INTERNAL DAMPING IN BLADE MATERIAL

A factor of importance in the practical application of the equations cited is the damping constant. A convenient assumption in damping problems in hard metals is that the damping forces vary as the first power of the velocity. This assumption is relatively accurate over short ranges of operating conditions. On this basis, it can be shown that the amplitudes of consecutive vibrations have a constant ratio. If this law were strictly true, the ratio of the amplitude of vibration at a predetermined time to the next consecutive amplitude would be the same as the ratio of any two consecutive amplitudes. The natural logarithm of the ratio of any one amplitude to the corresponding amplitude of the next cycle, taken as the vibration decays, is called the logarithmic decrement.

The damping constant given in the equation of motion bears the following relation to the logarithmic decrement

$$r = 2mf\delta$$

where

r = damping constant

[3] Steam Turbine Department Allis-Chalmers Manufacturing Company.

m = mass
f = frequency of vibration
δ = logarithmic decrement

Fig. 5 shows a series of damping curves, made by Prof. John T. Norton of The Massachusetts Institute of Technology, on various materials and reported by him in a paper.[4] These curves are determined by means of a torsion-pendulum apparatus, in which the specimen is subjected to alternating torsional stress. The curves are exhibited to show the great differences in the forms of the damping curves of the different materials. Considerable research is now under way in connection with the damping capacity of blading steels.

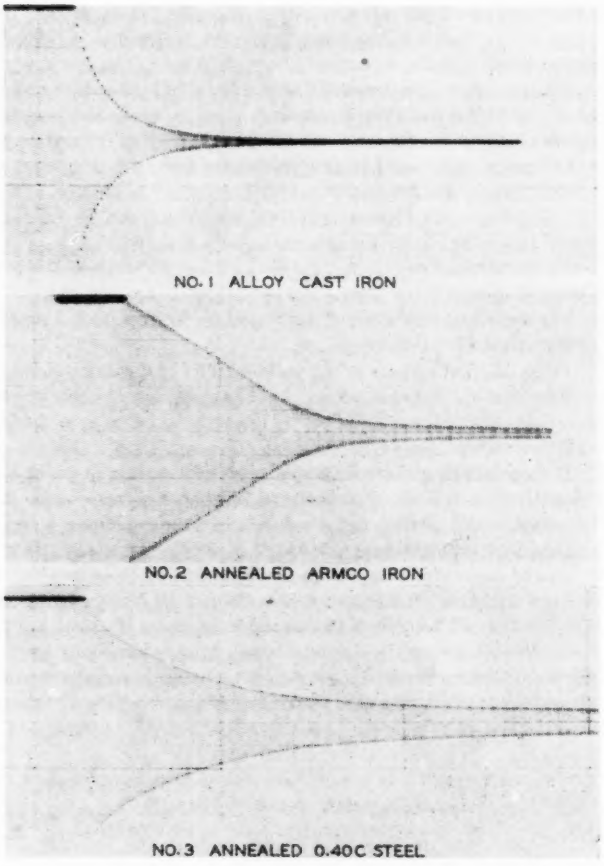

FIG. 5 DAMPING CURVES OF VARIOUS MATERIALS

At present for design purposes, with the Cyclops alloy, a logarithmic decrement of about 0.002 is assumed for blading operating with a maximum skin stress up to 20,000 psi and a temperature of 900 F.

Föppl and others have shown that the damping constant varies with stress. Other investigators have shown that the damping varies with frequency and with temperature. The research now under way will determine more completely the damping capacity of the various blading materials under operating conditions.

Proposals have been made and studied for the introduction of damping devices in the blades themselves, such as a quantity of liquid or powdered material in a cavity in the blade in which is embedded a small weight. While the idea is ingenious, it does not appear necessary to go to this refinement and, furthermore, there are design and manufacturing difficulties associated with this principle.

The first application of the third step in design reasoning is shown in Fig. 6. The length of the abscissa in each case represents the time required for the wheel to make 1 revolution. In the upper curve, the loading is increased from zero to the driving value in zero time and at the end of the arc again reduced to zero in zero time. The lower curve shows the motion of a blade after there has been a sufficient number of revolutions to set up a condition of energy stability. The blade enters the admission arc from the left with an amplitude of vibration which is reduced from the value existing at the end of the previous passage through the admission arc by the damping. The sudden loading increases the amplitude and the corresponding stress as shown. In calculating this case, it is important to note the assumption that the load was applied when the blade under consideration was at the extreme point of the backswing. This, on the chart, refers to the lowest point of the harmonic curve. This is considered a condition of primary resonance. In like manner, it is assumed that the load is released at the time the blade is at the extreme point of the forward swing, which corresponds to the upper point on the harmonic curve at the end of the admission arc. The curve shows the effect of damping in the admission arc and in the idle arc. The reduction of stress amplitude due to damping has been greatly exaggerated for illustrative purposes. By assuming acute primary resonance, as described, the motion builds up in successive revolutions, until, in the steady state of energy stability, the energy imparted to the vibrating blade is equal to that absorbed by damping.

In the case of the 50,000-kw top-turbine impulse blade, for the Northwest Station, which will be described later, application of

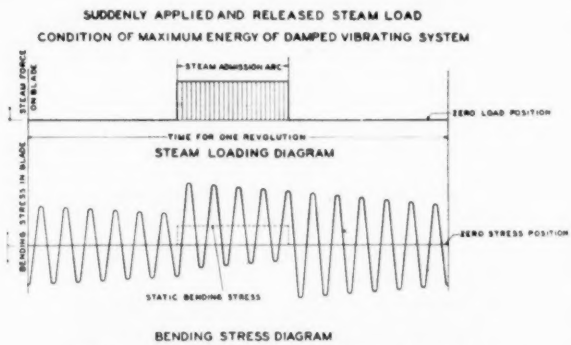

FIG. 6 DIAGRAM SHOWING DAMPED MOTION OF PARTIAL-ADMISSION BLADE WITH SUDDENLY APPLIED AND RELEASED STEAM LOAD

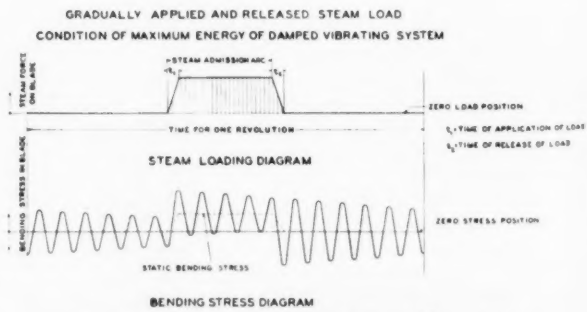

FIG. 7 DIAGRAM SHOWING DAMPED MOTION OF PARTIAL-ADMISSION BLADE WITH ACTUAL RATE OF APPLICATION AND RELEASE OF STEAM LOAD TAKEN INTO ACCOUNT

[4] "Torsion-Pendulum Instrument for Measuring Internal Friction," by J. T. Norton, *Review of Scientific Instruments*, vol. 10, March, 1939, pp. 77–81.

the process just reviewed shows that the maximum bending stress at the end of the first cycle in the admission arc will be about 10 times the static value.

The second application of the equation of motion is shown in Fig. 7. In this diagram, the tangential driving force is assumed to be built up at a uniform rate, which is also assumed for a certain condition of resonance, namely, the beginning of the application of load is at the time when the blade is at the extreme point in the backswing which on the curve is at the lowest point in the motion. For illustrative purposes it is assumed that the load application is completed in $^1/_2$ cycle of blade motion; in other words, at the time the blade reaches the extreme forward point in the swing. This case, which has been adopted for simplicity of illustrative purposes, is not quite that corresponding to exact resonance. In the latter case, the load is applied when the blade is in the position of zero deflection and starting on the backswing. This particular solution involves the assumption that the steam load is constant throughout the admission arc.

The solution further assumes that the release of the steam load starts at the time the blade is in the extreme forward point in the swing, which is at the top of the harmonic curve in Fig. 7. The condition of exact resonance at the release of the load would be that corresponding to the similar state at the point of loading.

The third application of the analysis is illustrated by Fig. 8. In this illustration, the motion of the blade in the idle portion of the arc is treated as a damped free vibration as in the other cases.

The application and release of the steam driving load is assumed to vary with time, this making necessary the treatment of the admission and release phases of the motion as separate calculations. As in the preceding case, the chart shows the load application beginning at the time the blade is in the extreme position of the backswing and ending at the extreme forward limit of motion. The release is taken in the reverse manner.

The steam force imposed on the blade in the admission arc is assumed to vary in the harmonic relation indicated on the chart.

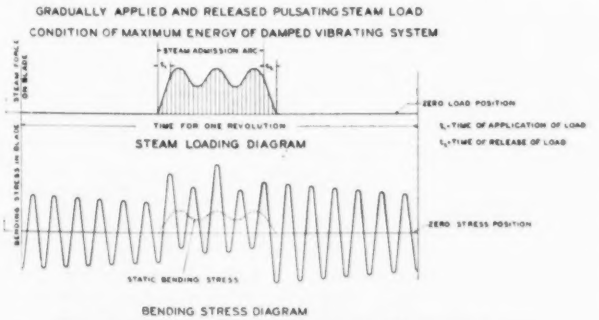

FIG. 8 DIAGRAM SHOWING DAMPED MOTION OF PARTIAL-ADMISSION BLADE WITH ACTUAL RATE OF APPLICATION AND RELEASE OF STEAM LOAD TAKEN INTO ACCOUNT

(The effect of the variation in the intensity of the steam force on the blade at the various points relative to the nozzle is included.)

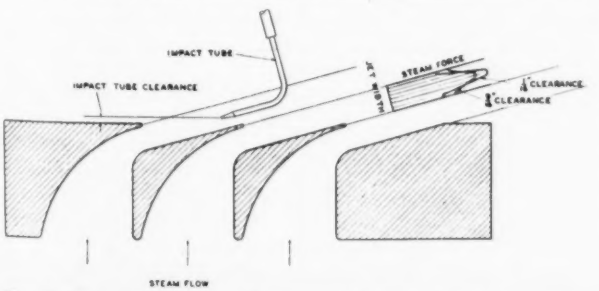

FIG. 9 DIAGRAM SHOWING RESULTS OF IMPACT TESTS OF NOZZLES AT VARIOUS DISTANCES FROM NOZZLE FACE

When this process is applied to the 50,000-kw Northwest turbine blade, the solutions of the equations of motion show that the bending-stress-amplification factor, due to the considerations mentioned, is approximately 3.

Impact-tube tests have been made with standard nozzles in which compressed air is used instead of steam. Fig. 9 shows a summary of the relative results of one set of such tests with the impact-tube-pressure measurements taken at various circumferential positions on the mean diameter of the nozzle.

It is interesting to note that the variation of the pressures per unit area is much greater for the set of readings taken at an axial

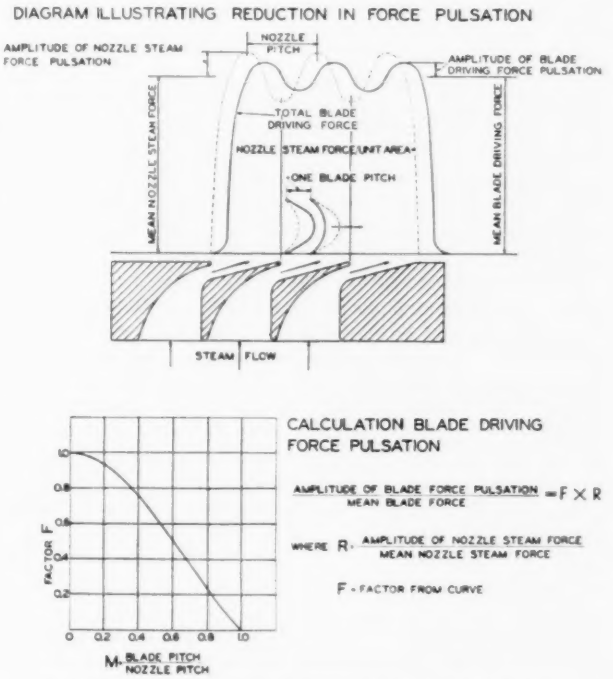

FIG. 10 DIAGRAM SHOWING EFFECT OF NOZZLE PITCH ON VARIATION OF STEAM FORCES ON BLADES AT DIFFERENT POSITIONS ALONG NOZZLE FACE

clearance of $^1/_{16}$ in. from the outlet of the nozzle than in the case of the readings taken at a clearance of $^9/_{16}$ in. This curve indicates the substantial reduction in the variation of the forces per unit area which occurs when a greater axial distance is allowed between the outlet edges of the nozzle vanes and the inlet edges of the blades.

An important factor in the design is the relation of the pitch of the nozzles to the pitch of the moving impulse blades. The upper dotted curve Fig. 10, shows typical steam forces per unit area for various positions along the mean diameter. If the integrated effect of this pressure can be assumed as transmitted directly to the blades with equal efficiency for all positions of the blades, then, theoretically, if the nozzles have the same circumferential pitch as the blades, the tangential driving force imposed on the impulse blades will be constant throughout the admission arc. If, however, the transfer of steam driving load to the blades does not occur with the same blade efficiency for all relative positions of the blades and nozzles, then there will be some periodic variation in driving force which is believed to be the case in practice.

If the other extreme is considered, in which the blades are considered as extremely narrow radial passages, then the driving force on the blades will vary in substantially the same manner as the steam force from the nozzle.

In order to design blades of relatively high frequency, a large circumferential pitch must be used. In the case of the 50,000-kw Northwest turbine blades, this pitch is 1.6 in. on the mean diameter. The Northwest impulse blades are calculated to have a running frequency of 7100 vibrations per sec. The nozzles have been spaced on a pitch of 3.484 in., which gives a frequency of the impressed force of 1837 per sec. The curve, Fig. 10, shows that the theoretical variation of force on the blade is about 0.69 of the variation of the equivalent nozzle steam force. There is, however, a considerable margin between the 7100 per sec frequency of the blade and the 1837 per sec frequency of the impressed force. The magnification of motion from secondary resonance is relatively small under these conditions.

In concluding this section on the stresses in partial-admission blading, it can be stated that the investigations briefly reviewed have shown that it is possible to calculate the effects of rapidly applied loads on partial-admission blades. The only safe ground for progress in matters of this kind is the establishment of a correct background of fundamentals. It is believed that this has been done and that the material constants are sufficiently well known to permit the prediction of safe proportions for this type of blading.

The importance of having the natural frequency of the blade remote from the frequency of the variable impressed force from the nozzle should be further stressed. Theoretically, if the action of the steam on the moving blades occurs at the same efficiency for all relative positions of blades and nozzles, then blades and nozzles of the same circumferential pitch can be used to avoid a periodic pulsation in the steam driving force. Actually, some variation in the efficiency must be expected, as each blade moves in and out of the flows of the various nozzles; hence, there will be some periodic variation in the steam driving force on the blades. If unsuitable design proportions are selected so that the frequency of the impressed force on the blades is equal to their natural frequency, then serious and destructive resonance may take place.

The best procedure is to design the blades so that the natural frequency is substantially higher than the frequency of the impressed force. The higher the frequency of the blades, the greater the amount of energy absorbed by damping in each revolution. The total damping will depend, to some extent, on the variation of the damping constant with stress.

The general procedure for determining the stresses in partial-admission blades can be outlined as follows:

a Determination of natural frequency of blade system including correction for rotation and stiffening effect of shrouding.

b Determination of the frequency of the impressed force exerted by the steam flow from the nozzle. An equivalent-steam-force curve is assumed of simple harmonic form, the amplitude of which must be based on research data.

c Design of blade to place natural frequency of assembled structure substantially above the frequency of the impressed force from the nozzles. Secondary resonance is thus avoided.

d The motion of the blade is calculated and plotted in curve form for the condition of energy stability, in which the energy imparted to a blade during one passage through the nozzle group is dissipated by the total damping of the system in the course of one revolution.

e Care must be taken to determine the most unfavorable phase relations between the free motion of the blade and the time of application and release of the impressed force. The phase relations that will give the maximum amplitude of vibration must be determined. In other words, the blades are designed to withstand primary resonance.

f The correct procedure must be adopted properly to take into account the actual rate of application of the steam load and the corresponding rate of unloading.

g There must be reliable data available on the damping characteristics of the blade material for the operating conditions under consideration.

h The ratio of the maximum amplitude for the condition of energy stability to the static deflection of the blade under the action of the steam driving force taken as a steady value gives the amplification factor to be applied to the bending stress calculated on the static basis.

i The centrifugal stress must be added to the amplified bending stress to determine the maximum resultant stress to which the blade is subjected. All stress concentration factors must be included.

Centrifugal Stability

There is good reason to believe that the initial tightness of high-temperature blading in the spindle grooves is not maintained for a long period of time at normal speed and full operating temperature. This comes about partly due to initial creep in which

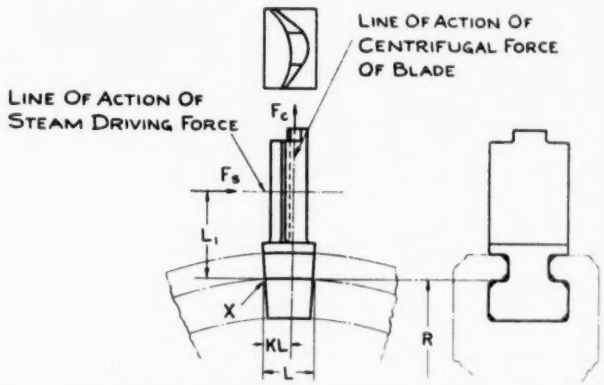

Fig. 11 Diagram Showing Principle of Centrifugal Stability

the minute irregularities of the machined surfaces are crushed until a good bearing surface is secured and partly due to elastic deformation and to the reduction in elastic modulus at high temperature. It is believed that all manufacturers produce excellent initial fits of the blade roots in the spindle grooves. At full speed and temperature, however, the close fit is believed to be lost for the reasons cited. If it be assumed that the blade root is only slightly loose at full speed and full operating temperature, conditions may arise, in which, in partial-admission wheels, the overturning moment set up by the suddenly applied steam load may exceed the stabilizing moment of the centrifugal force on the blade. If this is true, a single blade, or even a group of two or three blades which are joined together by a single shroud, may jump in the groove every time the admission arc is passed. If the blades jump or chatter in their grooves every time the steam forces are imposed on them, local stresses of sufficient magnitude to cause failure may be set up in the blade roots. It is, therefore, necessary to establish a safe ratio between the stabilizing moment created by the centrifugal force and the overturning moment set up by the suddenly applied steam load. Experience indicates that the ratio of the centrifugal moment to the steam driving moment about the base of the blade should, in most cases, be greater than 3 for a single blade, or greater than 6 for a pair of blades tightly shrouded together. In general, it is believed necessary that the stability factor shall be defined as the quotient of the centrifugal stabilizing moment divided by the amplified steam bending moment and that this ratio shall exceed 1.5.

Fig. 11 illustrates the principle of centrifugal stability. The centrifugal moment is the product of the centrifugal force *Fc* and the moment arm *KL*. The steam moment is the product of the

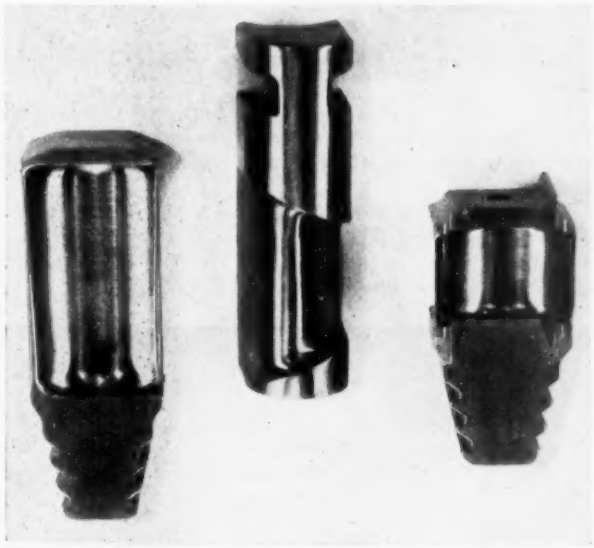

FIG. 13 INDIVIDUAL IMPULSE BLADES; DES MOINES

driving force F_s and the moment arm L_1. The stability factor without amplification is, therefore, expressed as F_cKL/F_sL_1.

LIMITING CAPACITY OF CIRCUMFERENTIAL-GROOVE BLADING

Fig. 12 shows the high-pressure impulse wheel for the 35,000-kw 3600-rpm condensing turbine at Des Moines, Iowa. The first-row blades are $1^1/_2$ in. wide, and the steam-port height is 1 in. The steam load is 238 lb per blade at the $^1/_2$ load point on the turbine. This condition exists when the first two nozzle blocks, to which steam is admitted simultaneously, are operated at full inlet pressure. These blades are of Cyclops 17-A alloy, with the integral shrouding welded together in groups of two blades. The second-row impulse blades are shown welded in groups of three. These second-row blades have since been modified by welding the shrouding in groups of two blades.

Fig. 13 shows a group of standard impulse blades for a two-row wheel of the type used for the high-pressure element of 3600-rpm condensing turbines up to about 75,000 kw or for 3600-rpm top-turbine service up to about 25,000 kw. One of the important features is the adoption of radial planes on the fronts and backs of the root and shroud sections of the moving blades. In the short first-row blades, the center portion of the root and shroud on each side is in a plane passing through the axis of the spindle. The overhanging edges have corresponding projections on the root and shroud to reinforce them. The cooperating fit between pairs of blades is on the central radial-plane surfaces. Note that between the unwelded shroud sections, a clearance of approximately 0.005 in. is allowed during the cold assembly.

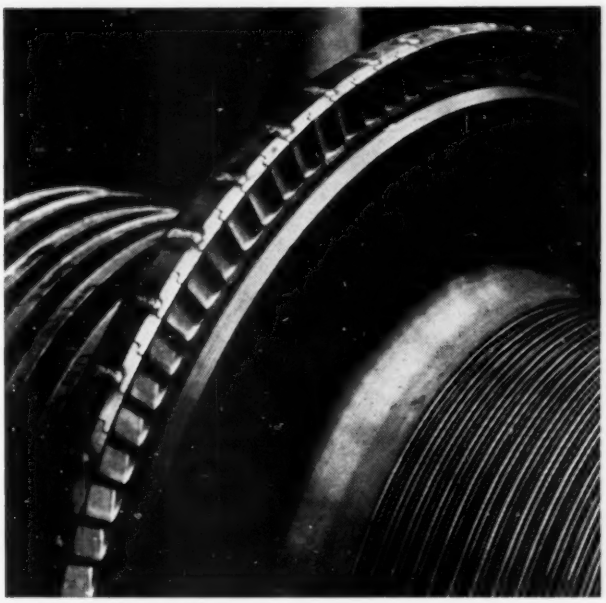

FIG. 14 ASSEMBLED SINGLE-ROW IMPULSE WHEEL

The limiting of the number of blades per group to two for high-temperature service is believed important, as severe bending stresses may be set up if a greater number of blades are joined together. These stresses may be caused by the more rapid heating and cooling of the blades with respect to the massive spindle.

Fig. 14 shows a single-row impulse wheel with the circumferential-groove-type blading. This impulse wheel represents the standard high-pressure element of large Allis-Chalmers high-pressure condensing turbines.

AXIAL-SLOT BLADING FOR HIGHEST-CAPACITY PARTIAL-ADMISSION IMPULSE WHEELS

For maximum-capacity top-turbine service, the design analysis briefly described calls for extremely wide blades. Such blades have a large circumferential pitch, which makes it undesirable to leave out a blade for assembly purposes. The centrifugal force of one of these large blades is such that a practical locking device, whereby the last blade can be secured in a circumferential groove of the conventional design does not appear available. An extensive survey has indicated the necessity for roots of the axial-slot type. Fig. 15 shows the impulse-wheel assembly for the 50,000-kw Northwest top turbine. The blades are inserted in axial slots which are milled and broached in the spindle body. In this way, the full complement of blades is inserted in the wheel without the need of a special entry slot or locking blade.

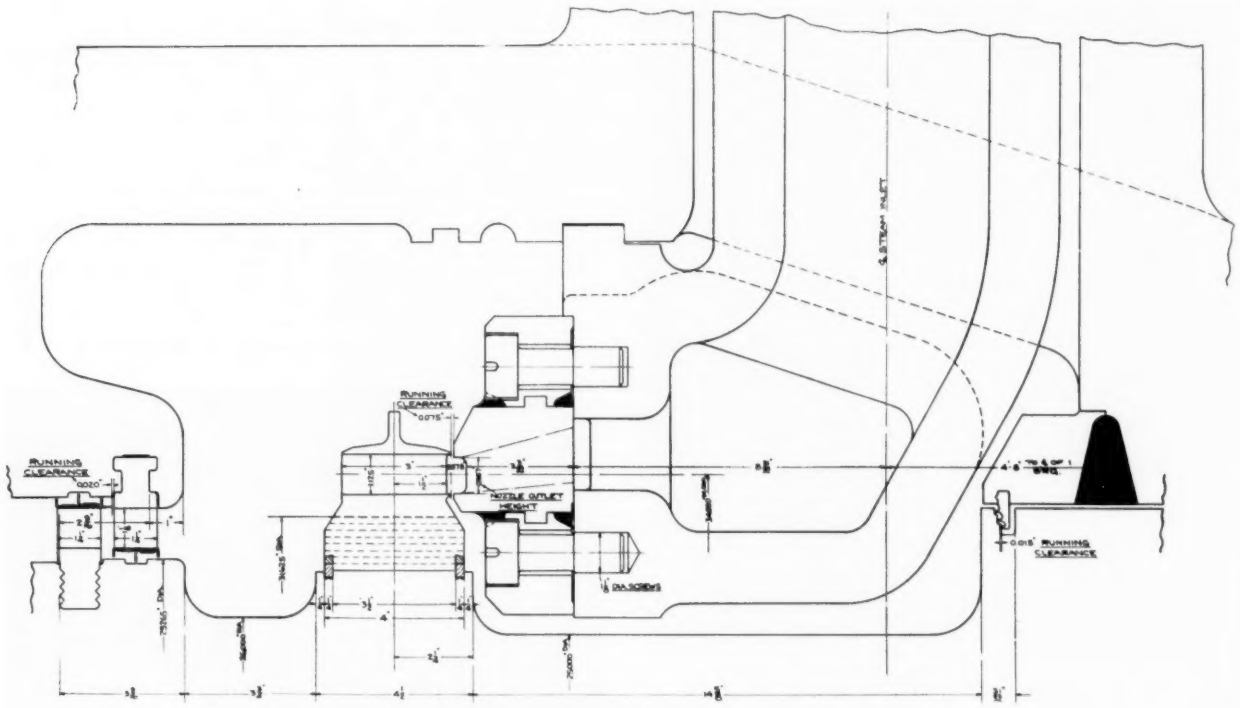

FIG. 15 SINGLE-ROW IMPULSE WHEEL 50,000-KW TOP TURBINE

In this scheme, the blades are arranged to be assembled in the axial slots by entering the complete ring of 66 blades in the spindle at the same time and pressing them home in a single operation. This is necessary because the form of the blade section requires that the edge portions overlap which, therefore, prevents individual assembly. For this purpose, each blade is first tried in its groove independently; each blade is then tried in its groove with the adjacent blade on one side and a third time with the adjacent blade on the other side, and so on around the circumference. By this means, it can be determined that there is no mechanical interference which will prevent complete assembly in one movement.

Figs. 16 and 17 show a model of the Northwest impulse blade. These illustrations show the design of the serrated root and the interlocking shrouding which requires the mass assembly of the complete row of blades.

Note that the axial width of this blade is 3 in. through the port section. The height of the steam port is $1^1/_8$ in. The mean diameter is 34 in., as shown by Fig. 15. The shroud sections are welded in pairs after assembly. The deep radial rib on the

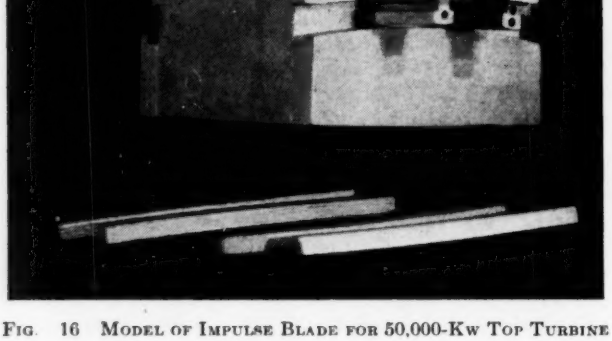

FIG. 16 MODEL OF IMPULSE BLADE FOR 50,000-KW TOP TURBINE

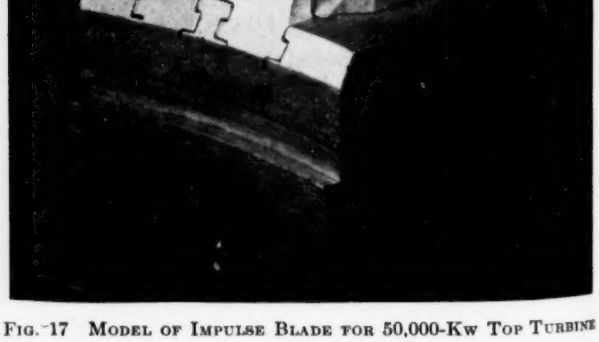

FIG. 17 MODEL OF IMPULSE BLADE FOR 50,000-KW TOP TURBINE

integral shroud is for the purpose of increasing the strength of the welded bonds between pairs of blades. The blades are milled from Cyclops steel bars. The maximum steam load is 350 lb per blade.

Effect of By-Passing the Impulse Wheel on Blade Loading

Some cases of trouble have been reported with top-turbine impulse blades in machines in which all of the steam was supplied through nozzles which acted on the first wheel. In such machines, the first group of nozzles, with which the highest blade loading occurs, occupied a relatively small arc of the circumference. This in turn required relatively high blades with a correspondingly greater length of moment arm on which the steam driving force acted. The small admission arc for the first nozzle group resulted in a correspondingly high driving force per blade. The combination of these factors resulted in extremely high stresses in some instances.

The latest top-turbine practice is to use the impulse wheel up to about $^3/_4$ load, by-passing this element for full load, and further by-passing some of the full-admission stages for maximum load. By this means and by using only two nozzle groups for the impulse wheel for the high-capacity machines, the first group occupying approximately one half the circumference of the wheel, the force per blade is substantially reduced, and, at the same time, the moment arm on which the steam force acts is also reduced greatly below the values found in former practice.

Effect of Avoiding Steam Underexpansion at the Outlet of the First Nozzle Group

In maximum-capacity top-turbine design, it is an accepted practice to design all of the first-stage nozzles of the nonexpanding type; in other words, the steam passages are designed to expand the steam down to the sound velocity. In certain early machines where all of the steam flow passed through the impulse-wheel nozzles, the quarter-load-nozzle group was allowed to expand the steam from 1200 psi down to something considerably less than the critical pressure. This procedure resulted in a large pressure drop through the blading and, in the case of some two-row impulse wheels, a substantial upsetting of the load distribution between the first and second moving rows of blades. With maximum-capacity wheels, the present practice is to arrange the first nozzle group to be fully open at the time that the pressure in the first stage is reached which corresponds to the sound velocity at the nozzle outlet. This practice aids in the reduction of stresses.

Effect of Edge Thickness on Flow Pattern Between Nozzle and Impulse-Blade Edges

It is well known that the maximum efficiency in high-velocity impulse blading requires thin blade and nozzle-vane edges. One concomitant of 1200 psi initial pressure and 925 F initial temperature is thick nozzle-vane-outlet edges and thick impulse-blade edges; at least the edges are relatively thicker than found in turbines of a few years ago. The increased edge thicknesses necessary in high-pressure high-temperature machines have had a small but detrimental effect on the efficiency. The steam-flow pattern opposite each nozzle outlet is also adversely affected to the extent that the alternating forces imposed on the blades as they pass from the stream issuing from one nozzle outlet to the next is believed to be the means whereby the amplitude of vibration of the impulse blades is increased over what it would be with nozzles and blades having thin edges.

Effect of Increasing Axial Distance Between Outlet Edges of Nozzle Vanes and Inlet of Impulse Blades

In the interest of reducing as much as possible the variation in loading on the impulse blades as they pass through the successive flow patterns of individual nozzles, the axial distance between the outlet edges of the nozzle vanes and the inlet edges of the impulse blades is increased to about $^9/_{16}$ in. in the case of the 50,000-kw Northwest top turbine. Taken parallel to the absolute direction of steam flow, the actual distance between the nozzle-vane edges and the blade edges is about 2 in. This is expected to result in some equalizing of the steam-flow pattern at the inlets to the moving blades. It is believed that by this means less total energy will be imparted to each blade in the form of vibratory motion as it passes through the successive flow patterns of the individual nozzles.

DETERMINATION OF STRESSES IN FULL-ADMISSION BLADING

Centrifugal Stresses

Centrifugal stresses in full-admission blading present no particular problem as the determination of forces and areas may be simply calculated from the drawing dimensions.

Bending Stresses

Bending stresses are calculated from the independent steam forces exerted on each blade, and a knowledge of the section properties of the blade section considered as a beam. The tangential driving forces and the axial forces resulting from pressure differences over the blade rows are independently considered.

Ripple Effect

Full-admission blades, especially in high-capacity high-temperature machines, in which relatively thick blade edges must be used, are expected to undergo some periodic variation in the driving forces. This ripple effect probably does not exceed 10 or 15 per cent of the steady driving force. In high-temperature machines, the ripple effect is taken as about 25 per cent of the steady tangential driving force.

Shrouding Correction

The effect of shrouding varies considerably over the blade path. In high-pressure blading, the effect of the shrouding on stress is considerable, although the normal bending-stress reduction may be between 25 and 60 per cent. The effect of the shrouding on bending stress is complex, the calculations on stress reduction being checked by experimental procedure.

Stress Amplification Due to Vibration

The high-pressure and intermediate-pressure blading, in which the natural frequencies of the blades are well over 5 times the rotational frequency, are assumed to be sufficiently remote from a resonant condition arising from periodic steam forces or inertia forces caused by the rotation of the spindle that the stresses are not intensified thereby. In low-pressure blading, in which the frequency of the assembled blades at full speed and at the operating temperature is less than 4 times the rotational frequency, tuning is resorted to in order to avoid resonance under operating conditions. This tuning involves a calculation of each specific blade group, which is followed by a check of the standing frequency when the row is assembled. Correction for temperature and speed is made by calculation. Changes of blade sections, of the rate of taper, or of lashing or shrouding members are sometimes necessary in order to avoid resonance.

Stress Intensification Due to Fillet at Base of Port Section

Milled blading with integral roots is designed with generous radii at the junctions of the port sections and the roots, so that

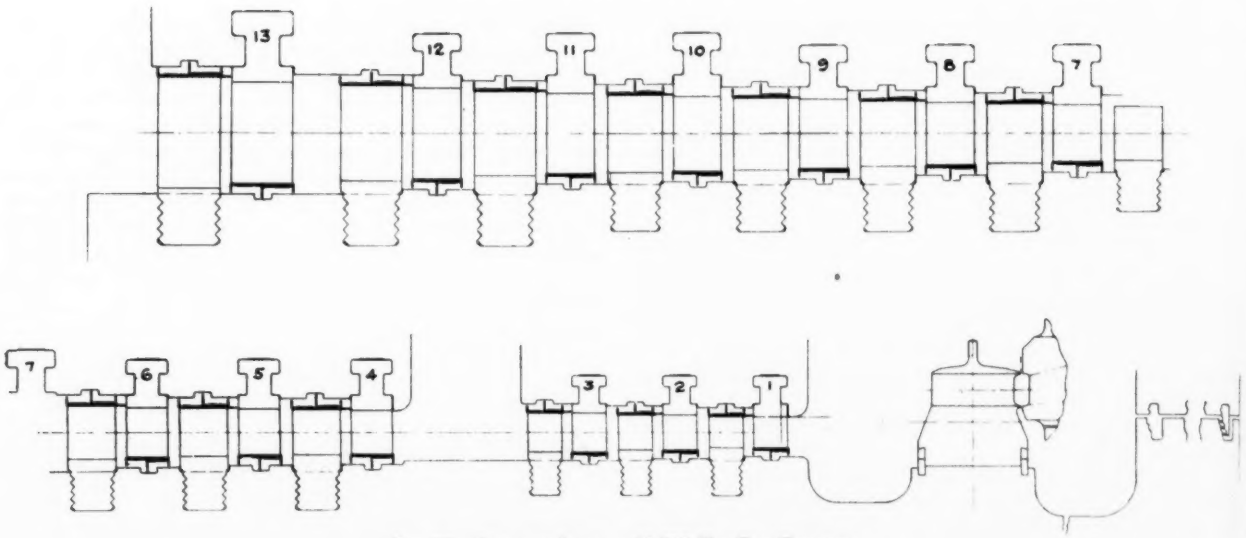

FIG. 18 BLADING LAYOUT 50,000-KW TOP TURBINE

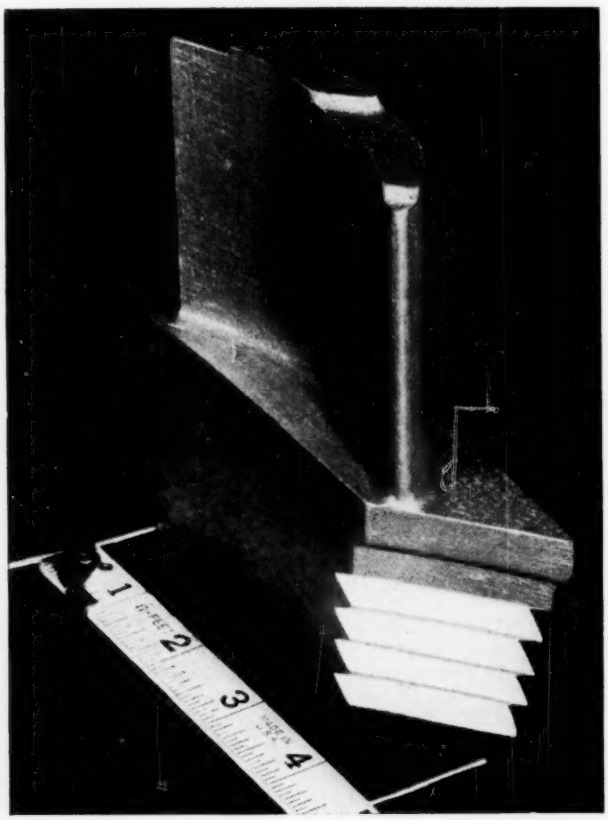

FIG. 19 MODEL BLADE, LAST ROW 50,000-KW TOP TURBINE

the stress-intensification factor can usually be taken at 1.5.

For the intermediate blading with cast foundations, the bending-stress-intensification factor, due to the form of the junction between the rolled blade and the cast base, is taken at 2.

HIGH-PRESSURE REACTION BLADING

BLADES WITH INTEGRAL ROOTS MILLED FROM BAR STOCK

Fig. 18 shows the blading layout for a 50,000-kw top turbine. In this example, all of the blading is of the individual milled type with integral roots. Fig. 19 shows the large size of high-capacity blades of this type. The nominal axial width of the last row of blades, one of which is illustrated in the view of the model, Fig. 19, is $2^1/_2$ in. This blading is milled from bars of Cyclops 17-A alloy. Fig. 20 shows some reaction blades of the milled type for top-turbine service.

DESIGN OF SHROUDING

Referring again to Fig. 18, it will be seen that the shrouding on the stationary blades is made up of two independent shroud sections secured in place by welding. There are three radial-seal strips for each blade row.

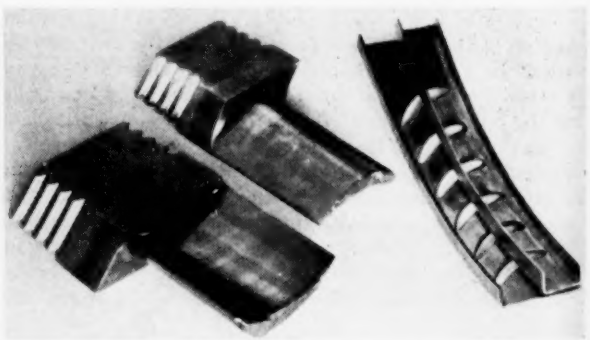

FIG. 20 MILLED REACTION BLADES FOR TOP TURBINE

There is a groove in the spindle to contain the center-seal strip and thereby provide interruption to the leakage flow. The inner axial-seal strip formerly employed is absent in this construction. This is done to avoid the disturbance set up by the high-velocity leakage flow cutting at right angles to the main flow through the blade path.

The shrouding on the spindle blading includes four separate seal elements; the first is of the normal end-tightened type; the remaining three are of the radial type as shown. The shrouding is of welded 19-9 chrome-nickel steel.

Note that the stationary blades of such high-capacity turbines are also of the individual milled type.

WELDING OF SHROUDING

The welding of shrouding has been adopted after considerable research as being the best means for the attachment of such

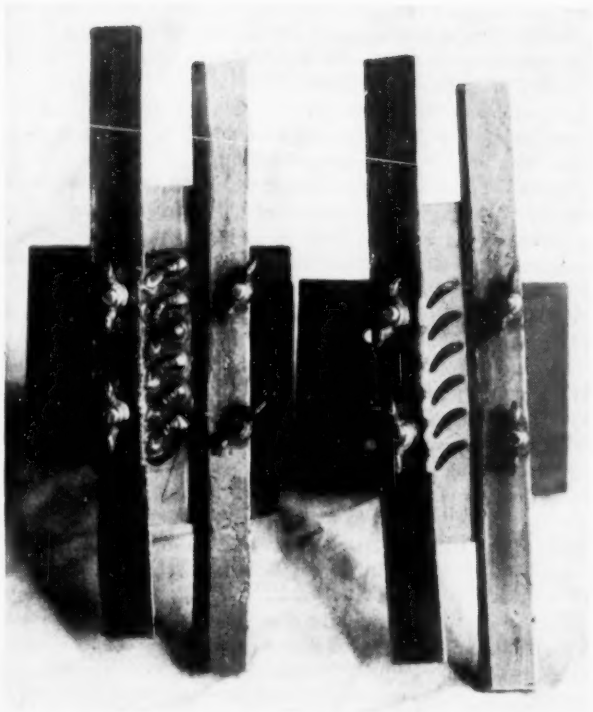

FIG. 21 WELDING OF SHROUDING ON SEGMENTAL BLADING

FIG. 22 WELDED REACTION-BLADE SHROUDING IN FISK TURBINE

members. The stresses set up by riveting are avoided. By the use of austenitic materials, air-hardening does not occur. Fig. 21 shows a group of blades with a section of shrouding ready for welding. A welded shroud section is also shown.

Fig. 22 shows the welded shrouding in the 30,000-kw top turbine at Fisk Station in Chicago.

BLADES WELDED IN SMALL GROUPS

It is important that the shrouding on high-pressure reaction blading include a relatively small number of blades per segment. The bending stresses introduced by rapid expansion and contraction of the blading under conditions of varying temperature may result in excessive stresses and lead to ultimate blade failures unless short segments are used. Fig. 22 shows that the reaction

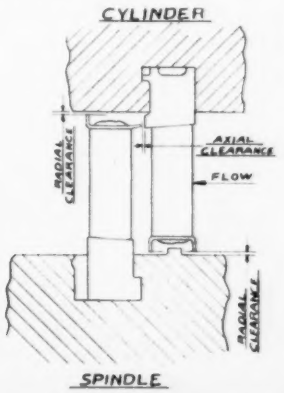

FIG. 23 ASSEMBLY DRAWING OF SEGMENTAL INTERMEDIATE BLADING WITH WELDED SHROUDING

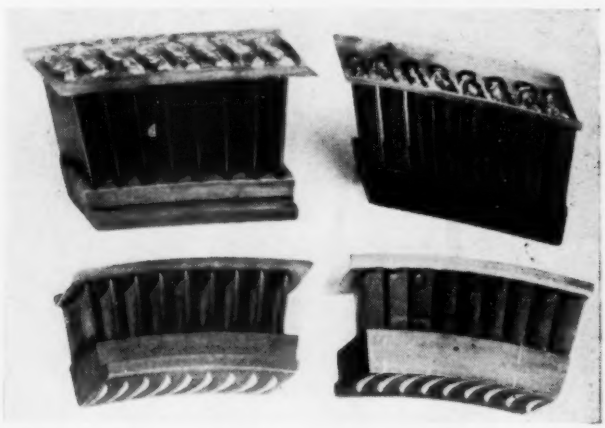

FIG. 24 INTERMEDIATE-BLADING SEGMENTS WITH WELDED SHROUDING

blades in the Fisk turbine have shrouding which contains from four to six blades per segment. It has already been pointed out that the impulse-blade practice is to secure two blades together for the highest-temperature service.

INTERMEDIATE BLADING

BLADES ROLLED TO FINAL SECTIONS

For the intermediate-pressure blading, sections are used which are finished to the final shapes by rolling. These blade sections are of Cyclops 17-A alloy. The material is given a final stress-relieving heat at 1425 F after the rolling operation. Before using the sections, the inlet and outlet edges are carefully polished to remove minute cracks which might have been introduced during the rolling. Fig. 23 shows in section the standard arrangement of intermediate blading. The welded shrouding and the design of the seal strips are shown. Fig. 24 shows a group of intermediate blades of the cast-in type with welded shrouding.

The study of the rolling of the blade sections and the improvements made at the steel mill have been previously described.

Shrouding Design

Blade sections, after being cut to length and after the inlet and outlet edges are polished, are assembled in a special fixture, after which the 19-9 shrouding is welded in place.

Cast Foundation of Everbrite or Cast Iron

After the shrouding is welded in place, the segmental-blade assembly is then placed in a core box, after which the blades and shrouding are encased in core sand, with the exception of the ends of the blades that are to be cast in the foundation. The blades in their assembled core are placed in a suitable mold and the foundation of Everbrite or cast iron poured. Great care is necessary to maintain clean blade roots. It is also necessary to keep the pouring temperature of the base material within close limits in order to secure a good bond with the blade bases without washing the blade-section material away. Optical-pyrometer observations are made on the metal poured in each mold.

Stress-Relieving of Assembled Cast Foundation-Ring Sections

After the foundations are poured, they are then finished on all surfaces, except at the bottom of the steam port, by machining.

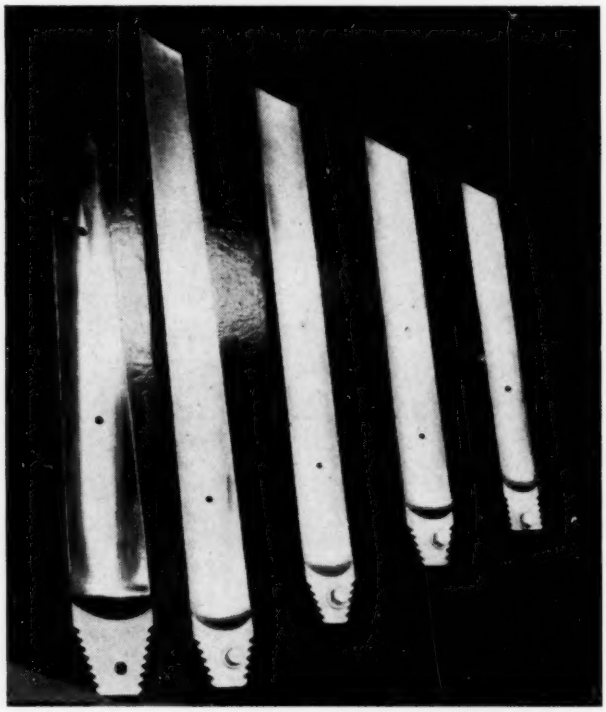

Fig. 25 Milled Low-Pressure Blading

After machining the foundations, the segments are placed in a gas-charged muffle, where they are annealed at 1425 F to remove stresses introduced by the cooling of the foundation metal. By this process, completely finished segmental blading is manufactured for the intermediate portion of the blade path. The blading is practically free from fabrication stresses and in an excellent condition to resist corrosion.

Milled Low-Pressure Reaction Blading

When the blade annulus referred to 3600 rpm exceeds approximately 9.2 sq ft, the blades are milled from bar stock of Cyclops alloy with integral roots, as shown in Fig. 25. Care is exercised in the mill operations to secure a grain size not exceeding 20 per sq in. at 100 diam magnification. The bar stock is stress-relieved at 1425 F after the final rolling.

The milled Cyclops low-pressure blading is reinforced by shrouding of 19-9 chrome-nickel steel which is welded in place as described for the high-pressure blading.

The use of lashing wires is avoided except in the case of low-pressure blades where they are useful for tuning purposes. Lashing wires are not used in blades where the natural frequency of the assembled blade groups under operating conditions is more than 4 times the rotational frequency.

When lashing wires are used in Cyclops blades, the blade is drilled and the edges of the holes suitably rounded. A short section of 19-9 chrome-nickel wire is welded in place in each blade. After welding, the blade is stress-relieved at 1125 F. When the blades are in place in the spindle, the ends of the individual lashing wires are joined in groups by welding. In this way the heating effect of the final-assembly welding does not reach the body of the blade.

LOW-PRESSURE BLADING FOR MAXIMUM TIP SPEEDS

Limiting Capacity of Condensing Machines

At the present time, the limiting exhaust-blade practice is a 20-in. blade with a tip speed somewhat over the sound velocity in steam at 29 in. vacuum. In Allis-Chalmers 3600-rpm practice, 20-in. blades are mounted with a tip diameter of 80.5 in. with a corresponding tip speed of 1264 fps. Regarding the capacities for which these blades can be used, this selection involves a commercial consideration of the actual load requirements and operating charges for a given system, which will in turn indicate the amount of leaving loss which can be allowed. If operating conditions of 1200 psi gage 925 F and 29 in. vacuum be assumed with four stages of feed heating, the leaving loss of a double-flow low-pressure end with 20-in. blades at 3600 rpm will be as given in Table 1 (on the following page) at the respective capacities. These blades are assumed to be mounted with a tip diameter of 80.5 in. and with an opening coefficient of 0.6.

The present outlook does not indicate a radical tendency toward an increase of tip speeds. The length of the Allis-Chalmers blades described is just under $^1/_3$ of the mean diameter. The form of the passage at the tip section must be a compromise with some sacrifice in efficiency in the interest of practical construction. An appreciable increase in blade length with respect to the mean diameter does not seem probable at this time.

The effect of water erosion is sufficiently serious

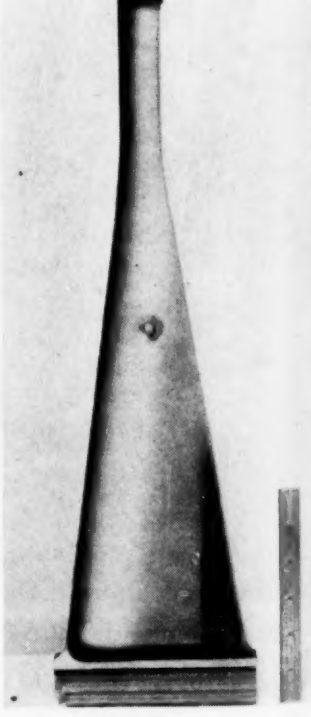

Fig. 26 Axial-Slot Type 18-In. 3600-Rpm Low-Pressure Blade

TABLE 1

Rated load	Leaving loss expressed as a per cent of total adiabatic drop including corrections for feed heating and underexpansion
40000 kw	1.9
50000 kw	2.9
60000 kw	4.0

at the present tip speeds to preclude any strong tendency for increased tip speeds. The present trend of 3600-rpm construction is, therefore, in the direction of multiple-cylinder low-pressure elements where maximum-capacity units are considered.

The present limiting annular area for 3600-rpm low-pressure blades is about 26.4 sq ft. This is the area corresponding to the 20-in. blades mounted with a tip diameter of 80.5 in. previously referred to.

Fig. 26 shows an 18-in. blade of this type with a tip diameter of 76.5 in., with a corresponding annular area of 23 sq ft. Fig. 27 shows an assembled row of these blades in place in the spindle, and Fig. 28 shows the axial-entry spindle slots in which the blades are installed. The design of these blades is based on a cross-sectional-area ratio of 6, i.e., the sectional area of the base of the blade is 6 times the area at the tip. The ratio of mean diameter to length is approximately 3, which means that there is a substantial change in the contour of the steam passage from the base to the tip.

For annular blade-outlet areas between 21 and 26.4 sq ft at 3600 rpm, the 13-chrome stainless iron is used because of its greater strength at low temperature. This material is forged to within about $^1/_{16}$ in. of the finished surfaces and then completely machined to the final sizes.

Shrouding and lashing members are necessary in the last row of blades to reduce bending stresses and to bring up the natural frequency of vibration to the required value. A section of shrouding, one blade pitch in length, is welded to the tip of each low-pressure blade. The shrouding is of the 19-9 chrome-nickel steel. A short stub end of 19-9 chrome-nickel lashing wire is welded to each side of each blade, thereby eliminating the lash-

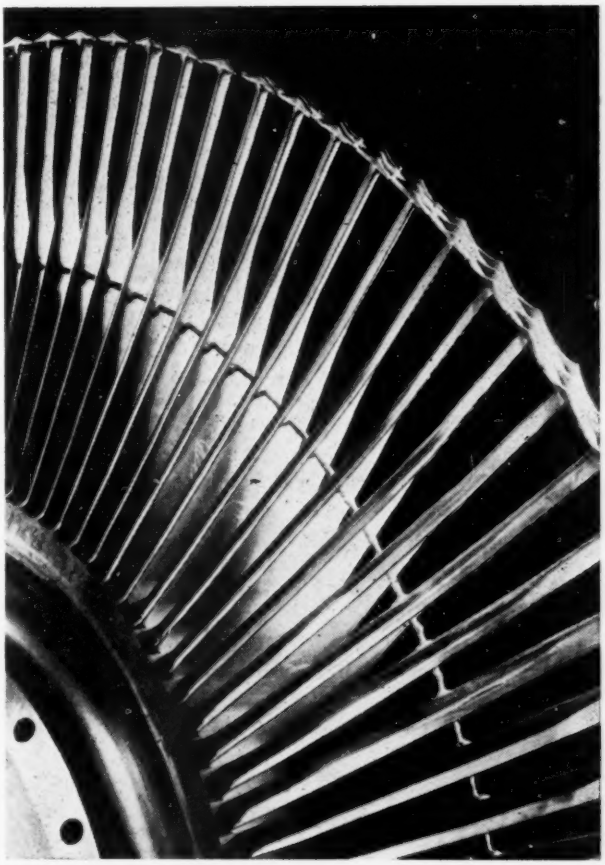

FIG. 27 ASSEMBLY 18-IN. 3600-RPM LOW-PRESSURE BLADES

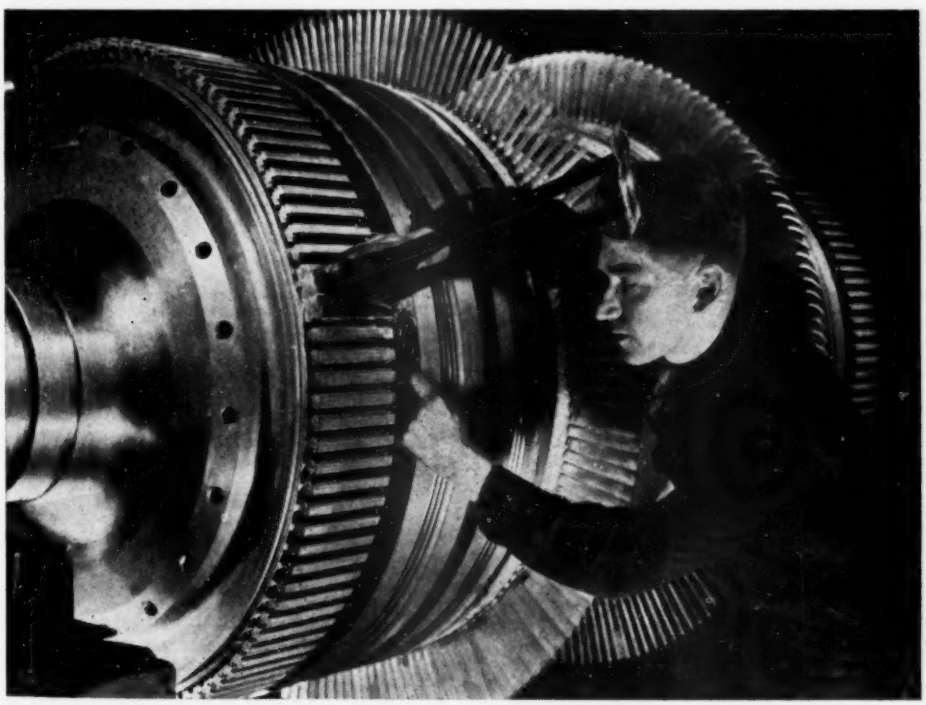

FIG. 28 SPINDLE FOR AXIAL-SLOT BLADES

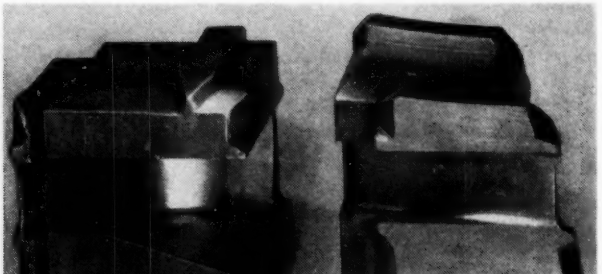

FIG. 29 NOZZLE ELEMENTS

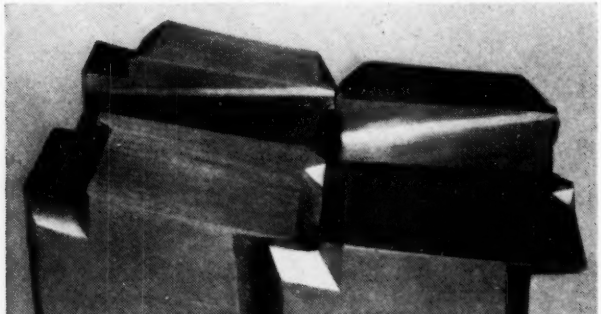

FIG. 30 NOZZLE ELEMENTS

ing-wire hole. A generous coating of stellite is welded on the inlet edge of each blade for about $^2/_3$ of the length from the tip to resist water erosion. The stellite is fused to the blade with an acetylene torch. The blade is preheated to about 900 F for these welding operations.

After the welding is completed, the blade is heat-treated by quenching in oil from 1750 F and drawing at 1125 F. In this way the harmful effect of the air-hardening is greatly reduced.

After the blades are assembled in the spindle, the corresponding shroud and lashing members are joined by welding. The welding after assembly is entirely between non-air-hardening materials. The local heating of the final welding operations does not extend to the body of the blade.

The sectional shrouding is of cantilever form, each section being secured to the blade by a generous welding bead. The extreme overhanging ends of each cantilever are joined by light welds after assembly. The overhanging cantilevers are designed to be stable in the event of accidental breakage of the assembly welds so that failure from centrifugal stress will not occur.

The two machines, equipped with 18-in. low-pressure blades which operate at a tip speed of 1200 fps, are in their second year of service and have thus far disclosed no troubles of any kind in the low-pressure blading. Two rows of these blades are installed in the low-pressure turbine of the 35,000-kw 3600-rpm turbine at Des Moines and one row in the single-flow machine at Springfield, Ill. From this experience, there is good reason to expect that the 20-in. blades, which will be designed on the same engineering principles and stress limits, will also operate satisfactorily.

NOZZLE DESIGN

Figs. 29 and 30 show the type of nozzle elements used in high-pressure high-temperature machines. The nozzle ports are machined in individual stainless-steel elements which, when assembled, form the accurately machined steam ports. The assembly drawing of a similar nozzle is shown in Fig. 31. Each individual steel block in the group of central elements is defined by radial end planes which are carefully fitted together. After

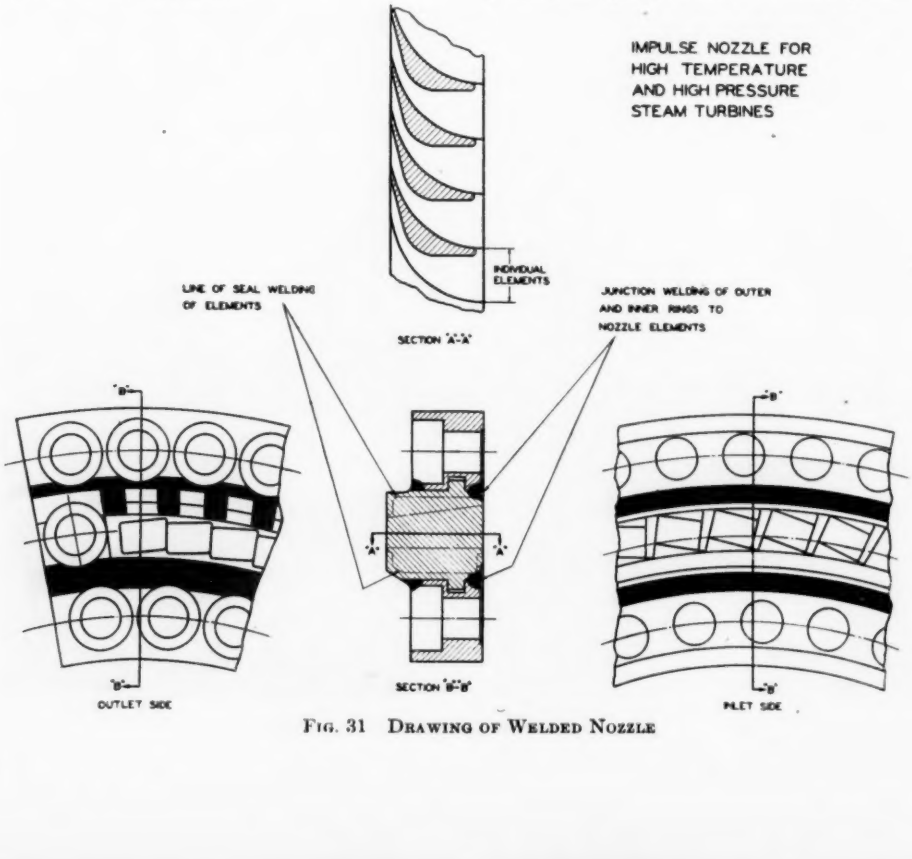

FIG. 31 DRAWING OF WELDED NOZZLE

the central group of elements is assembled, the inner and outer ring segments are fitted over tenons and welded in place.

Acknowledgments

The author wishes to thank the Allis-Chalmers Manufacturing Company for permission to publish the blading-design data included in this paper; Professor J. J. Ryan, of the University of Minnesota, and Dr. J. T. Rettaliata, of the Allis-Chalmers steam-turbine department, for their suggestions during the early development of the partial-admission impulse-blade reasoning; Professor John T. Norton, of the Massachusetts Institute of Technology, for suggestions in connection with damping phenomena and for permission to use Fig. 5; Mr. H. D. Emmert,[5] of the steam-turbine department of Allis-Chalmers, for his assistance in preparing the mathematical solutions of the various phases of the motion of vibrating blades; and to numerous other members of the Allis-Chalmers organization for their help in the preparation of this paper.

Discussion

R. P. Kroon.[6] Air-hardening 13 per cent Cr steel and non-air-hardening nickel-chrome austenitic steels have been described as applied to turbine-blade service. Many years ago the Westinghouse Company adopted 13 per cent Cr blade steel because it was one of the few corrosion-resistant alloys adapted to forging. More recently, the forging process has been abandoned for manufacturing reasons on all except low-pressure blades. We are, therefore, in a position to use any of several high-temperature alloy steels suitable for machining.

A large number of such materials were made into blades for experimental purposes and some have been used in turbines in the field. Among these materials, the 13 per cent Cr steel has distinguished itself because of its superior yield strength and its metallurgical simplicity and uniformity.

We recognize the problem of air-hardening in 13 per cent Cr steel as a result of shroud welding, but have used this process for a number of years under proper control and with but slight difficulty. It has been found recently that the 13 per cent Cr is unique in that it possesses many times the damping capacity of any other high-temperature material known to the art. We continue to regard the 13 per cent Cr stock as that having the most desirable combination of qualities for turbine blading.

We cannot very well agree with the statement that blades having a natural frequency well over 5 times the running frequency are sufficiently remote from resonance so that the stresses are not intensified thereby. It is our experience that, even with full admission, the resonance effect is important at frequencies up to say 12 times the running speed. We are using statistical data to insure a safe design for these medium-size blades.

By this time it should be well recognized that the impulse-blade problem is industry-wide. It behooves us that this fact should be admitted; the problem is there whether we do so or not.

The writer has been particularly interested to find that the assumptions, on which the author has based his calculations, are almost identical with our own original suppositions. However, we have felt very strongly that quite a few of these assumptions are based on such loose grounds as to make necessary the experimental determination of the exact nature of the forces and motions involved in actual operation.

We started a research program using optical equipment to measure actually the blade deflections, first on a small pilot turbine which was placed in operation 9 months ago, then on a full-size Curtis turbine, operating at 1250 lb 900 F. This work was recently described.[7] We are more and more convinced that this investigation is of vital necessity to give those data which cannot be derived theoretically.

There is, for example, the assumption that a blade receives its load gradually as it travels one blade pitch. In the absence of experimental data this assumption is probably as good as any other. But one must not forget that actually the forces on the blade are caused by the reactions of a very complex nonsteady steam flow on either side of the blade. Actually, we find that it may take a distance of several blade pitches before the blade force steadies out.

Instead of a gradually increasing steam load which the author has assumed, we often find that the first shock on the blade entering the steam jet is in a direction opposite to the torque force. This can be explained physically by the fact that, as the steam first enters the blade passage, it tends to push the blades apart. This pressure wave causes a negative rather than a positive torque force on the trailing blade.

Our findings have also indicated that, in general, it is not sufficient to limit consideration to vibration in the circumferential direction only. We formerly believed that the lateral vibrations of the blade were not important, but we now know that, on an impulse-blade group, there are at least three natural modes of vibration which should be considered. The first is a vibration in the plane of rotation, the second is one in which the blades vibrate perpendicularly to the plane of rotation, and the third is a torsional motion of the group as a whole. Under certain conditions, it is necessary to take into account all three modes.

In our opinion, expanding the steam down to more than sound velocity in nozzles of the nonexpanding type is quite feasible, provided that this superacoustic range is explored experimentally to establish safe limits. This we are doing in our developmental turbine. We believe that, with this background, the additional efficiency at low turbine loads can be made available without a risk.

The statement is made in the paper that, with a gradually increasing load, the maximum displacement of the blade will be produced when the initial displacement is zero, as the load is applied. That this is not so can be appreciated when one considers the limiting case of suddenly applied load, for which we know that maximum displacement is produced when the initial velocity, and not the displacement, is zero at the instant the load is applied.

The writer believes the author will be able to check his conclusions that the phase angle for optimum displacement depends upon a relation between loading time and natural period and trusts he will see fit to revise his calculations to take this into account.

G. B. Warren.[8] The author has presented an interesting analysis of the forces on the first-stage partial-arc-admission impulse-blade element, which should have common application in varying degrees to all types of turbines incorporating this construction. Such analyses should be of great value.

The group of engineers with which the writer is associated has followed a somewhat different method in its endeavors to attain the same result, namely, a stable and reliable construction

[5] These solutions in detailed form have been presented by H. D. Emmert in a "Mathematical Section" of this paper, as originally published by the Allis-Chalmers Manufacturing Company, prior to the 1940 Semi-Annual Meeting of the Society. Copies are available on request to that Company.

for the heavily loaded buckets of first-stage impulse elements.

Fortunately, we had as background nearly 35 years of experience in building first-stage partial-admission impulse buckets, which included several hundred rows, a few of which had given trouble in service. We became convinced during the course of this experience that the difficulties were due to vibrations produced by the operating conditions. However, it has always been felt that these vibrations and their consequent stresses were so complex and of such varied form as to make any simple rational analysis inexpedient. A statistical study of the conditions under which such troubles occurred, and those under which they were not present, indicated a rather definite function of the ratio between the severity of the conditions and the strength of the bucket and its attachment. Formulating this knowledge into design practice was undertaken about 12 years ago with the result that, except for a few isolated and special cases, difficulties with these elements have practically disappeared. Recent tests appear to indicate that no sacrifice in efficiency seems to result from the use of the wider and, hence, stronger buckets.

The indications from the paper are that the author's analysis is leading him to conclusions of about the same type and magnitude as our own.

As to the details shown, we differ in materials used, in attachments of buckets to rotors, in method or shrouding the buckets, and innumerable details of design and construction. The fact that two or three turbine manufacturers differ in such things is probably the greatest safeguard to the power industry. It insures a minimum average of trouble, and the maximum possible progress.

The design and construction technique shown for the last rows of blading on limiting-capacity turbines is most interesting. From the illustrations, it seems evident that the shroud band and lashing members finally are reduced to one continuous piece. Some additional discussion of this construction would be of interest.

A. L. KIMBALL.[9] This paper brings to focus two things, i.e., the importance of avoiding a condition of resonance, wherein a periodic exciting force is in step with one of the natural frequencies of the elastic bucket system; it brings out the importance of safeguarding possible dangerous resonant-vibration amplitudes by having as much internal damping in the buckets as possible.

The dangerous effect of resonance is well shown from the authors' Equation [19],[10] by setting the exciting frequency equal to the natural frequency so that $\omega = \omega_n$. In this case Ω is seen to be equal to zero and R reduces to the logarithmic decrement δ divided by π or $R = \delta/\pi$. The last two terms of Equation [19] then become

$$y_{max} = \frac{a}{k} + \frac{c}{k}\frac{\pi}{\delta} = \frac{a}{k} + 1570\frac{c}{k} \quad \ldots\ldots [1]$$

$$y_{max} = 158\frac{a}{k} = 0.0055 \text{ in.} \quad \ldots\ldots [2]$$

This is seen to be over 50 times as great as for the case chosen by the authors which gave $y_{max} = 0.000106$ in. Furthermore, the first term of Equation [19] was omitted, which makes the value of Equation [2] of this discussion conservative.

Note also that Equation [1] herewith may be directly derived from the case of a simple linear oscillator,[11] which alone gives us the important part of the picture.

Note that, since the deflection given by the authors equals 0.000035 in. for a steady force of 350 lb at the tip of the bucket, an equivalent force of amplitude 55,000 would be necessary to produce the deflection at resonance given by Equation [1] of this discussion, where the term amplitude in this case, equals the + or — amplitude of the periodic force, the total range of which from + to — is therefore 110,000 lb. This can be seen to produce a maximum stress far beyond the fatigue limit when it is noted that the total volume of this bucket is about 0.6 cu in. of material. Thus, if it is assumed to be of rectangular shape, 1 in. high, 1 in. wide, and 0.6 in. thick, the maximum vibration stress at its base is over 500,000 psi.

The analysis in this paper gives an excellent idea of the importance of impulse excitation of bucket vibration, and shows that its intensity is always far below that arising from resonance produced by even a moderate periodic force, which was taken as 0.1 the average bucket load in the author's case. Furthermore, the analysis also shows that the damping in the buckets is not an important factor in controlling impulse excitation.

The real reason for damping is to control the amplitudes which might arise on resonance as given by Equation [2] of this discussion.

The writer personally dislikes the use of the terms "primary resonance" and "secondary resonance." The former represents a condition of impulse excitation and is not a resonance at all in the sense that the second type is, which is by itself the true resonance.

A complicated elastic system like that of the bucket zone of a turbine wheel may have several modes of high-frequency vibration to each of which a resonant vibration will build up if in step with some periodic exciting force, and some of which may be dangerous. Furthermore, such modes of vibration are not readily predicted by available methods of analysis, so the only sure way is to find what they are from actual test.

Prevention of such failures therefore requires:

1 The definite location of the type and frequency of possible modes of vibration from actual tests, which may be in the range of known high-frequency exciting forces which arise during turbine operation.

2 A thorough study of the damping of bucket materials under operating conditions, the latter being an insurance against danger from the former.

3 Adequate area of cross section for safe performance.

These methods of attack are now being applied by turbine manufacturers who appreciate the danger only too well, and steady progress is being made.

T. C. RATHBONE.[12] The authors[10] are to be commended for the presentation of this valuable and instructive paper and the research behind it on blade-failure problems which have caused some anxiety.

The writer is particularly interested in the reasoning leading to the conclusion that, as some resonance in impulse blading is unavoidable, the blades must be designed to withstand the most unfavorable combination of conditions.

The frequency calculations are based on the assumption that the blades remain tight in the root, that is, the node point is fixed. It was pointed out that looseness in the root with partial admission permits a rocking impact or chatter which may well

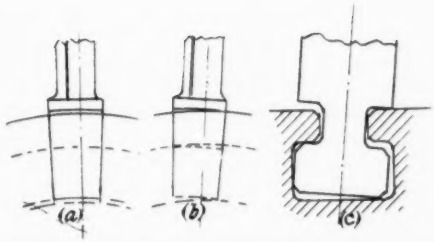

FIG. 32 EFFECT OF LOOSENESS IN BLADE ROOT

(*a*, Blade with loose root fastening, at rest; *b*, position at one extremity of movement; *c*, section through blade root.)

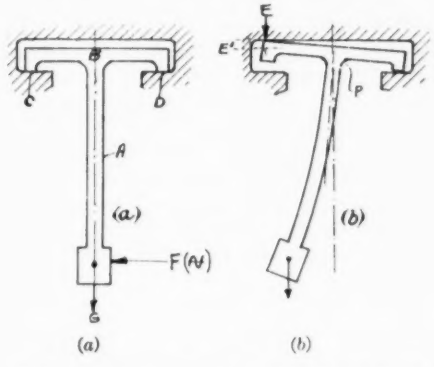

FIG. 33 SCHEMATIC REPRESENTATION OF BLADE-ROOT SYSTEM

have set up excessive repetitive stresses, explaining past failures. By designing for a centrifugal-stability factor over the overturning steam-force moment, the authors insure the nodal fixity at the root necessary for the assumptions in the frequency calculations which follow.

It will be interesting to point out here that, with any appreciable looseness in the root, the natural frequency of the blade becomes a function of the amplitude of vibration as well as of its mass and elastic properties, and thus may undergo wide variations. Fig. 32 (*a*) represents a blade with loose root fastening in repose, and Fig. 32 (*b*) the position at one extremity of movement, having rocked on one bearing shoulder until stopped by the limiting clearance in the groove.

The system can be illustrated schematically by Fig. 33 (*a*), where the blade is represented by a pendulum *A* rigidly attached to a bracket *B*, serving as the root, and supported at the two points *C* and *D* (root shoulders). Gravity (centrifugal force) is pulling downward, attempting to hold the system in repose while the pulsating steam force *F* is tending to rock the system about the bearing point *D*.

If the pendulum is displaced slightly to one side and released, it will oscillate or rock back and forth under the action of gravity alone, at a frequency which increases rapidly as amplitude decreases, precisely like a rubber ball dropped on the floor, until the system comes to rest. So far, neither mass nor elasticity enters the picture; only centrifugal force (gravity).

Assume now that the displacement is great enough for the corner of the bracket or root to strike at *E*. First there will occur an elastic deformation at *E* due to the impact, and also a flexural bending of the pendulum in attempting to carry on in the leftward movement. In addition to the steam and centrifugal forces there, we have both bending and impactive forces at the fillet *P*, with the stress-magnification factor due to impact depending upon the "softness" at the contact points.

The restoring forces to complete the other half of the cycle now depend on:

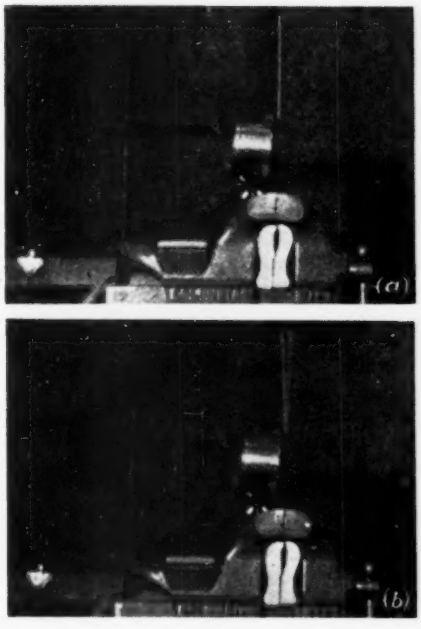

FIG. 34 MODEL ILLUSTRATING TURBINE VIBRATION CAUSED BY IMPACTIVE INTERFERENCE NEAR BLADE ROOT

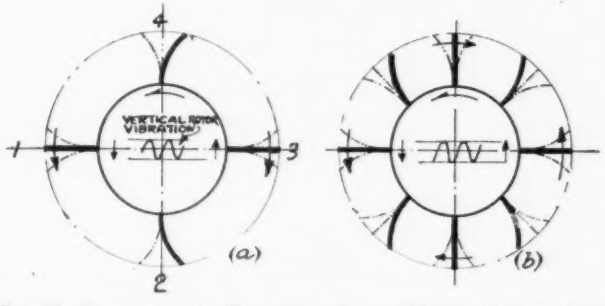

FIG. 35 INSTANTANEOUS POSITION OF BLADE MAKING (*a*) 1 AND (*b*) 2 COMPLETE VIBRATIONS DURING TIME REQUIRED FOR 1 REVOLUTION

1 The elastic "rebound" at the impact areas.

2 The elastic and inertia properties of the pendulum system.

3 The gravity force acting through the clearance space *E* to *E'*.

An intermediate impact also occurs in this simple system as the rocking points *C* and *D* strike their seats.

The frequency of such a system depends not only upon the mass and elastic characteristics of the blade itself, but also on the impactive resilience, and finally on the extent of free movement or amplitude limited by the clearances. The frequency is practically indeterminate. The vibration of such a system can no longer be expressed by linear differential equations, and hence is called "nonlinear" vibration. Professor Timoshenko[13] points out that such systems may often nullify the effect of resonance because, as resonant amplitudes build up, the change in amplitude itself becomes a sort of inhibitor by altering the natural frequency away from resonance.

There have been examples, however, where impactive interference with free vibration caused a great increase in amplitude and hence stresses. These cases seem to involve a critical condition in which the elastic rebounds from impact somehow augment

[13] "Vibration Problems in Engineering," by S. Timoshenko, D. Van Nostrand Company, New York, N. Y., 1937, pp. 117 and 145.

or aggravate critical vibration. Increased turbine vibration due to impactive movement from excess clearance in turbine bearing keys is a familiar example. This is further illustrated by the model Fig. 34. In Fig. 34 (*a*) the cantilever or blade is shown vibrating steadily in response to magnetic impulses; at (*b*), with no change in the magnetic impulses, the vibration has been greatly increased or "drawn out" by impactive interference near the root.

It is pointed out in the paper that, when the natural frequency of the last-row low-pressure blades is less than 4 times the running speed, tuning is resorted to, to avoid resonance. Presumably, the periodic forces from which this blading is to be protected arise from torsional oscillations of the rotor or linear vibration of the rotor due to unbalance, at the frequency of rotation, rather than periodic steam forces.

Primary resonance occurs when the natural frequency of the blade coincides with a torsional oscillation once per revolution, but resonance with linear vibration from unbalance does not occur until the natural frequency of the blade is twice the rotational frequency. Therefore, a blade frequency of 4 times the speed of rotation actually represents a multiple of only 2, as regards fundamental resonance. Likewise, no resonant amplitude should be built up when the blade frequency is just equal to linear vibration at the frequency of rotation.

In Fig. 35 (*a*) are represented the instantaneous positions of a blade making one complete vibration during the time required for one revolution. It is assumed that the blade vibration is caused by the linear vibratory movement of the rotor due to unbalance, acting on the blade through the root fastening. The blade is shown in the neutral position at 1, and at the extreme limit of its vibration in the leading direction at 2, after 90 deg rotation. The blade passes through the neutral position again at 3, and reaches the opposite extreme at 4, in the trailing direction.

But the inertia forces on the blade from the rotor vibration, which caused it to be displaced forward at 1 as shown in the first part of the cycle, would again cause the blade to travel forward at 3 during the second half of the rotor vibration cycle, instead of the backward motion attempted by the free vibration of the blade. In other words, the "return-stroke" exciting force opposes the completion of the blade-vibration cycle, and should discourage building up resonant amplitudes.

In Fig. 35 (*b*) is shown the situation where the natural frequency of the blades is twice the running frequency. Here the natural blade movements are in proper phase with the rotor vibration to produce fundamental primary resonance.

Fortunately, as the author points out, there has been little difficulty with fatigue failures of the last-row blades due to resonance. Curiously, we had all been far more concerned over the possibility of fatigue failures in these large blades than in the rugged shorter blades which actually have given more trouble.

Author's Closure

With reference to Mr. Kroon's discussion concerning the 13 per cent chrome blading steel, the author believes that all turbine builders are in the same position as that assumed by Westinghouse, namely, each is ready to use the material which he considers the best for steam-turbine blading. That the 13 per cent chrome steel has justified its adoption for this service is well demonstrated by the number of turbine builders who make successful use of this material. The author states in his description that this alloy is the best material for low-pressure blading. Many years of development and metallurgical research were required before the 13 per cent chrome steel was produced as a useful blading alloy. It was the author's privilege to be associated with Francis Hodgkinson and Norman Mochel during the early development of this material by the Westinghouse Company.

Paralleling the work of the Westinghouse and General Electric Companies on the 13 per cent chrome steel, the Allis-Chalmers Company has developed the austenitic Cyclops alloy described in the paper. They, too, are in the position of being able to use the blading steel that they consider the best for blading. The conclusion that the Cyclops alloy offers advantages for all but the longest rows of low-pressure blades is again a matter of many years' development and research which was only briefly indicated in the paper. The author recognizes that each material has advantages and disadvantages, so that a careful survey of the merits of the two materials is necessary. The excellent service record of the Cyclops alloy speaks well for its reliable qualities for blading service.

With reference to the difference in damping capacity, this property is still under investigation. It is necessary to point out that, as stated by the author during the discussion of the paper when presented, partial-admission impulse blading, such as illustrated for the Northwest top turbine, is designed so that the structure is safe with a logarithmic damping decrement as low as 0.0002, including a stress-concentration factor of 2.0 due to the fillet at the base of the blade. It is believed that the construction described, in which due allowance is made for amplification of the bending stress from primary and secondary resonance, is based on logical reasoning and that safety is insured if the proportions permit the operation with safe stresses with the low damping decrement mentioned in this paragraph.

Mr. Kroon indicates that he is not in agreement with the statement that full-admission blades having a natural frequency over five times the running frequency are sufficiently remote from resonance so that the stresses are not intensified thereby. He also indicates that he has found the resonance effect to be important at blade frequencies up to about 12 times the running speed. The author's experience is not in agreement with this, although quite a number of cases have arisen in which this was first thought to be the cause. Careful analysis of other effects, such as pressure differences in the blade path or defects in the mechanical construction, were in each instance sufficient to cause the high resonance ratio to be abandoned as a reason for trouble.

Mr. Kroon points out that his company is using statistical data to insure a safe design for blade structures. This practice is today and, so far as the author is aware, always has been the underlying principle employed by all blading designers. Blading stresses and calculation processes have always been checked and compared and the constants evaluated by comparison with practical results taken from field experience or laboratory research.

With respect to Mr. Kroon's comments on the general character of the impulse-blade development, the author agrees that the assumption that a blade receives its load gradually as it travels one blade pitch is much on the safe side as very elementary considerations will serve to show. The author agrees that it may take a distance of several blade pitches before the normal driving force is established on the blade. The statement that, in the experimental turbine built by Westinghouse, the first movement of the blade entering the steam jet is opposite to the torque force is very interesting. All of these effects appear to the author of a nature that does not modify the general validity and safety of the primary assumption of the paper with respect to the time of loading.

The author is in agreement with Mr. Kroon, in that it is necessary to consider the vibration of blade structures axially and torsionally, as well as circumferentially. The study of impulse-blade structures in the paper is limited to the circumferential motion, because, in wide-root blades of the type described, this mode is the only one that need be considered. In long blades

that may be shrouded and lashed together in groups, consideration must be given to the other modes of vibration.

With respect to expansion ratios that correspond to more than sound velocity, the author's statement in this connection applied specifically to high-capacity top-turbine design. In such machines, it is the present practice to arrange the first group of nozzles to be fully opened at the time the pressure in the first stage is reached which corresponds to the sound velocity at the nozzle outlet. In normal condensing turbines, in which the steam flow is less than in top-turbine practice or in top turbines of moderate size, the design is arranged so that the sound velocity is exceeded under light load conditions.

With reference to Mr. Kroon's comments concerning the phase relation of the blade motion with respect to the time of application of the steam load, the mathematical supplement shows that for maximum amplification the steam load is applied at a point where the blade is at zero displacement and starting on the backswing, under conditions where the blade is loaded in an odd number of half cycles. At this time of application the velocity is a maximum in the backward direction. This is not the same as the case of a suddenly applied load. With a high natural frequency of the impulse-blade system, the time required to establish the mean driving load on a blade should always be greater than a half cycle of blade motion. In such cases, the maximum amplification will take place when the mean driving load is established in an odd number of half cycles with the phase relation here mentioned. If, however, the mean driving load is established in less than a half cycle, then the phase angle changes, depending on the exact time relation, until in the limit case, in which the load is applied in zero time, the maximum displacement of the blade will be produced when the initial velocity is zero at the instant the load is applied, as stated by Mr. Kroon. This limit case cannot be realized in practice.

It is desirable to review the conditions that define primary resonance. This summary was given in the abstract of the paper as presented in Milwaukee and also in the mathematical supplement by Mr. Emmert.

(*a*) The start of the application of the steam load takes place at a point where the blade is at zero displacement and starting on the backswing at which time the vibrational velocity is a maximum backward.

(*b*) The full steam driving load is assumed to be reached in an odd number of half cycles of blade motion. If the frequency of the blade is such that there is not an odd number of half cycles in the actual time of load application, the time is adjusted slightly for purposes of calculation.

(*c*) The full steam driving load is assumed to be applied for an even number of cycles of blade motion. The time adopted for calculation purposes is adjusted slightly if necessary.

(*d*) The time at which the release of the load starts is assumed to be at a point where the blade is at zero displacement with respect to the static deflection and when the blade is starting on the forward swing. In other words, the blade is moving at its maximum velocity forward.

(*e*) The removal of load is assumed to be completed in an odd number of half cycles.

(*f*) The idle portion of the arc is assumed to include an even number of cycles.

With reference to Mr. Warren's discussion, he stresses the statistical study of impulse-blade performance from which his company's design practice has been evolved. As indicated in the author's comments on Mr. Kroon's discussion, this same type of statistical analysis has been a necessary standard practice for many years with turbine-blade designers.

Referring to Mr. Warren's comments on the continuous joining of low-pressure blade-shroud bands, this has been the practice of the Allis-Chalmers Company for many years. What the author considers an exceptional record of reliable operation of low-pressure blading justifies this construction. The very few cases where last-row-blade trouble has occurred have been explained by well-recognized causes. In Allis-Chalmers practice, the low-pressure blades are first shrouded in groups leaving, say, ten or more gaps open between sections. The spindle disk, or in 3600-rpm machines the entire spindle, is heated in a suitable oven to about 350 F. The body of the spindle is then protected with insulating material and the blading allowed to cool for a predetermined period, after which the open junctions in the shrouding are joined by welding. When the temperatures in the spindle and the blading are equalized, the shrouding is then in compression. Experience has shown that there is little trouble in the breaking of these joints. Where broken joints between shroud sections have occurred, these have been traced to some recognizable cause, such as the close proximity of ribs in the exhaust chamber, or the unequal draft of steam through a bleeder connection in which the extraction belt was not well proportioned.

Mr. Kimball points out the dangerous effect of resonance of the type classed by the author as secondary resonance. As indicated by Mr. Kimball, resonance between the natural frequency of the blade structure and the periodic force set up by the nozzle flow can produce amplification factors of a high order. In fact, if all terms of Equation [19] are considered for the case reviewed, the amplification factor for true resonance is of the order of 1000.

Mr. Kimball further points out that the intensity of what he terms "impulse excitation of bucket vibration" is responsible for an intensity far below that arising from resonance produced by even a moderate periodic force. This is extremely important, and fortunately a condition that is capable of control by proper design. The author is in full agreement both with Mr. Kimball and Mr. Kroon regarding the desirability of experimental investigation of the vibration of blading, although, in the author's opinion, the real value of such experimentation is not realized unless guided by a sound background of fundamentals.

The author wishes to point out that the steam load of 350 lb is applied at the mean diameter, not at the tip of the blade as assumed by Mr. Kimball.

The cubical contents of the port section of the Northwest blade are over three times the 0.6 cu in. used in Mr. Kimball's discussion.

With reference to Mr. Rathbone's remarks, impulse blading must be designed to withstand primary resonance. Secondary resonance can be avoided by design.

The author is in agreement concerning the important effect of looseness of the blade roots on frequency and the difficulty of predicting the frequency of a blading system in which looseness of the blade roots enters the problem. In past practice, some cases of partial-admission impulse-blade failures have been attributed to undue looseness of the roots.

Where looseness of the roots of partial-admission blades is a cause of failure, it is the author's belief that the blades are not correctly proportioned.

The difficulties associated with securing tightness of the roots in their grooves under conditions of full speed and full operating temperature are stressed in the paper, and the necessity of adopting proportions for the blades and roots that will maintain stability by the effect of centrifugal force is emphasized. If, for example, the stress-amplification factor on the bending moment is found to be 10, the centrifugal stability factor, expressed as the ratio of centrifugal stabilizing moment to the static value of the steam overturning moment, should be at least 15, if stability is to be maintained.

Mr. Rathbone's discussion gives this opportunity to stress

further the importance of maintaining design proportions so that the rocking or chattering of the blades in their grooves due to looseness can never occur.

With reference to the resonant conditions described by Mr. Rathbone in connection with the last-row blades, the author is in agreement with the general principles indicated in Fig. 35. The periodic forces against which the blading must be protected are probably not as much due to the variation in the steam driving force from blade to blade, as to the effects produced when a given blade passes through different pressure zones. The cylinder design is planned to reduce to a minimum such pressure differences. The effect produced when the low-pressure blades move in and out of zones of different pressures is similar to that which would be induced by torsional oscillation of the spindle.

The limiting frequency ratio above which trouble from blade resonance is thought not to occur is in fair agreement with field experience, which indicates that resonant vibration does not cause trouble if there is close agreement with higher multiples of the rotational frequency than 4 or 5.

In closing, the author wishes to express his appreciation to the A.S.M.E. for the privilege of presenting this paper and to the discussers for their valuable contributions.

Discussion of Attack on Steel in High-Capacity Boilers as a Result of Overheating Due to Steam Blanketing

By E. P. PARTRIDGE and R. E. HALL

This paper was presented at the Spring Meeting in New Orleans, La., February 23–25, 1939. Due to the fact that preprints were not available, discussion at the time of presentation was limited. Subsequent to publication in the October, 1939, issue of the Transactions it was decided to continue discussion at the Spring Meeting in Worcester, Mass., May 1–3, 1940. This discussion, together with the authors' closure, appears herewith.

P. B. Place.[1] Although the authors group the given examples of tube failure under a general classification of steam blanketing, there is sufficient difference in the nature of the failures so that they may be arranged in at least two groups, i.e., failures caused or accompanied by cracking, and failures by corrosion without cracking.

The first type of failure is characterized by cracking of the metal in areas that are alternately wet and dry. This type of failure is a form of stress corrosion in which attack is greatly accelerated by alternate heating and cooling and occurs along the bottom of the tube where the water laps the overheated metal. A typical case occurred in a circulator tube between an upper side-wall header and the steam drum. Cracking developed into failure at the bottom of a tube bend which was above the normal water level and normally out of the gas stream. Leakage of gases through a superheater seal near the point of failure caused local overheating, and a surging type of circulation, typical in this part of a boiler, periodically quenched the overheated section.

The second type of failure is characterized by corrosion and loss of metal. Such corroded surfaces have been found along the tops of sloping tubes in the form of a narrow groove and also as deep pits in the bottom of sloping tubes under sediment deposits. Often the corroded surface is covered with soft smutty oxide mixed in some cases with colored chemical deposits. This type of failure appears to be due chiefly to direct chemical attack by steam or water, or by salts which concentrate or deposit locally.

In the analysis of these failures we can perhaps start from the following accepted facts:

1 The failures are not accompanied by a deformation of the tube, except as such deformation may have resulted from excessive heating caused by the insulating effect of deposited corrosion products.

2 The corrosion product is iron oxide which requires a source of oxygen.

3 The protective oxide coating, which normally covers a tube surface, must first be broken down to expose fresh metal before corrosion can develop.

The absence of deformation in a tube, the wall of which is corroded to one half its original thickness over a long period of time, definitely indicates that excessively high temperatures are not a prerequisite of the corrosion. Temperatures in excess of 1200 F are reported, which are believed either to be incidental or a result of accumulation of corrosion products rather than a cause.

There has been built up in the last few years a popular belief that very high metal temperatures are involved in these types of failure. Dissociation of steam has been given in many cases as a direct cause of corrosion and a source of oxygen. It is the writer's belief that dissociation has erroneously been construed to mean a decomposition of water vapor by heat into oxygen and hydrogen with resulting attack on the metal by the liberated oxygen. At temperatures that will not cause deformation of a tube, the amount of dissociation of steam by heat is very small. The oxygen needed for corrosion is not oxygen freed by heat dissociation of water vapor but is extracted from steam, water or oxygen-containing salts by a reduction process. The metal is available for that reduction only after its normal protective oxide coating has been broken down.

The concept of temperature difference in steam-blanketed tubes as given in Fig. 1 of the paper makes no allowance for heat conductance around the tube wall. Any appreciable increase in the temperature difference between the top and bottom of a steam-blanketed tube must result in an increasing proportion of the absorbed heat being conducted through the tube wall around the steam space.

Thermocouple measurements of tube temperatures and metallurgical analyses are given as evidence of high-temperature conditions in conjunction with these failures. Chromel-alumel couples peened into boiler tubes in gas temperatures above 1500 F are quite dependent upon the method of installation for their reliability. The failure of such couples is not due to overheating where they are attached to the tube but due to oxidation and deterioration of the lead wires exposed to the gases. During one investigation of tube failures, we installed platinum thermocouples adjacent to chromel couples on all of the boiler tubes in question. At no time did any of the platinum couples register excessive temperatures although many of the chromel couples did and we found that the maximum period of reliability for chromel couples in gas at 1700 F was 2 days. Though many apparently lasted for weeks, any variations in temperature registered after 2 or 3 days were open to suspicion. Relative to metallurgical analyses, it is common for reports to state that, because of changes in grain structure, it is concluded that the metal has been at temperatures in excess of 1000 to 1200 F for so many hours. In many cases, because of corrosion, this may be quite true. However, in one case reported in this manner, the sample had been taken adjacent to a header located outside of the furnace where such temperatures could not have existed.

The breaking down of the protective coating is slow and difficult in an atmosphere of steam alone. The experience with superheaters, experimental corrosion tests, and the commercial production of hydrogen, all indicate that the action of steam on hot metal is to form the protective coating and that the oxidation slows up as the time of contact increases. Water quenching, chemical attack of salt deposits, or mechanical effect of rapid temperature changes are necessary to break down the coating and allow corrosion to proceed.

[1] Test and Research Department, Combustion Engineering Company, Inc., New York, N. Y. Mem. A.S.M.E.

In dry areas, formed by steam blanketing along the top of sloping tubes, there is little quenching except by water splashed against the top of the tube. However, the evaporation residues from the splashing remain on the tube forming a concentrated salt mat on the dry area. It is believed that the corrosion along the top of screen tubes is chiefly by chemical attack. This attack can be accelerated if the steam pocket periodically vents itself and quenching stresses are added.

A similar concentration of chemical may develop under deposits of loose sludge on steam-generating surfaces with resulting chemical attack and corrosion under the deposit. Boiler water may diffuse into such deposits at a rate sufficient to keep the metal from burning and blistering but not at a rate sufficient to wash away the evaporation residues. Once corrosion is started by the chemical attack, the accumulation of products of corrosion accelerates the action and, unless the tube is cleaned out, the deposit may eventually insulate the metal sufficiently to cause severe overheating and blistering. A failure of this type developed in the bottom row of a sectional-header, high-pressure boiler which was initiated by an excessive phosphate-sludge condition in the boiler.

Periodic quenching of overheated areas prevents the accumulation of chemical deposits and the likelihood of corrosion failure. The quenching, however, sets up very severe local stresses because of the initial rapid absorption of latent heat and the protective coating is continuously cracked, exposing fresh metal to attack. Tube failures under such conditions are crack failures.

The expansion and contraction stresses in a thick-walled high-pressure tube, set up by overheating only 200 to 250 deg and repeatedly cooling by the rapid evaporation of quenching water, are very destructive to the protective oxide film. The metal exposed by cracking of the film reduces the steam by chemical action with liberation of hydrogen.

In conclusion it is believed that the presence of water and/or its associated salts is necessary to the tube failures of the type under discussion and that such failures can be initiated at tube temperatures lower than 800 F. Improvement in boiler design, and water conditioning; elimination of circulating sludge; better distribution of heat absorption; and standardization of conservative heat rates are the indicated trends toward the control and elimination of failures of this type.

H. KREISINGER.[2] The title of the paper implies that the type of corrosion discussed in the paper came into prominence with the use of high steam pressure. Many of the tube failures were accompanied or caused by cracking of the internal surface of the tubes at a point where the internal surface was alternately dry and wet. The stresses produced by repeated quick-cooling result in cracking. The cracks in the stressed metal provide a large and clean surface for the action of boiler water, and the surface corrodes rapidly. The question arises whether the very thick walls of the tubes are not a major contributing factor in the failures? The tubes are selected for a given pressure, with a factor of safety of about 10, whereas the steam drums are designed with a factor of safety of 4.5. Why is the factor of safety for the tubes so high compared with the factor of safety of the drums? Surely, if the drum failed, more damage would be done than by failure of a tube.

Mathematical analysis of the temperature stresses under normal conditions of operation indicate that the thick-walled tube is subjected to severe temperature stresses which would make failure by cracking almost inevitable, if the stresses were not moderated by the flow of metal.[3] Steam drums are shielded from heat because the shell is too thick and might be damaged by heating. At the same time, thick-walled tubes are located where they are subjected to severe heating. When inquiry is made concerning the reasons for the very thick walls of tubes with a factor of safety of about 10, the reason given is that the thickness is somewhat irregular and that the thinnest part of the tube wall after a certain amount of corrosion has taken place must still be strong enough to withstand the pressure. Some of the tubes have been corroded to less than one half their original thickness without any apparent distortion of the corroded area due to pressure. It appears that tubes with much thinner walls would hold the pressure and be less subject to the type of corrosion which is caused or accompanied by cracking of the inner surface of the tube.

The engineer might benefit by the use of thinner-walled boiler tubes. They would cost less and they might reduce appreciably the failures from corrosion. He might also select tubes of smaller diameter and thinner walls.

It is true that there have been some tube failures in low-pressure boilers with thin-walled tubes, but it is probable that the failures would have occurred in much shorter time had thick-walled tubes been used. The failure is due to temperature stresses and the stresses are greater in the thick-walled tube than in a thin-walled tube. Lower stresses must be repeated over a much longer period of time than high stresses before they result in failure. A thin-walled tube may last years, whereas one with a thick wall may fail in a few weeks.

R. T. HANLON.[4] Further tube failures were experienced in the top tubes of the 4-tube-high headers. Thermocouple temperatures at the top of these tubes showed a normal temperature of from 600 to 620 F when the saturation temperature corresponding to pressure was approximately 580 F.

When the boiler was operated under conditions of full rating and pressure, the tube temperatures would suddenly increase to approximately 1040 F at the top of the tube. This was probably considerably lower than that at the bottom of the tube where the damage occurred.

Reduction of drum pressure from 1300 to 1050 psi reduced tube temperatures in all cases to normal values.

It was also observed that elevated tube temperatures increased in frequency, elevation, and duration as the concentration of total dissolved solids in the boiler water was increased.

Various arrangements of the drum baffles and steam washer have been tried. The most effective baffle arrangement found to date takes advantage of the velocity of the water in the drum flowing from the uptake to the downtake tubes. The baffle is so located, as shown in Fig. 1 of this discussion, that it directs the flow of water to the sectional-header downtakes.

The effect of these baffle installations in combination with the installation of restrictor plates upon the upper half of the lower ends of the sectional-header tubes has been to permit the maintenance of approximately 500 ppm total soluble solids in the boiler water. It has been possible to maintain this concentration at full boiler pressure and rating without experiencing elevated tube temperatures or serious carry-over. It had not been possible to maintain concentrations in excess of 100 to 150 ppm under normal operating conditions previous to these installations.

During all of this period the feedwater to these boilers consisted of turbine condensate, the make-up being evaporated in low-pressure boilers. No further failures were experienced in the upper sectional-header tubes.

During October, 1939, after two months of operation with externally treated city-water make-up, drifts of loose sludge were observed near the downtake end of the bottom tubes of the sectional-header bank. Subsequently, several tubes failed in operation in this location, as is indicated in Fig. 2, herewith.

FIG. 3 SECTION OF TYPICAL FAILURE NEAR LOW END OF SECTIONAL-HEADER TUBES, BOILER NO. 52, WATERSIDE NO. 2 STATION

In every case of tube failure, large quantities of magnetic iron oxide were observed at or near the point of failure. The appearance and composition of a typical case are given in Fig. 3. Little if any indication of blistering or swelling of the outside of the tubes was observed. The apparent cause of failure was accelerated corrosion on the inside of the tubes at points where deposition had occurred. This deposition apparently caused localized tube overheating due to insufficient heat transfer.

Previous to the time when these failures occurred, continuous blowdown from the drum was employed for control of total solids. Under ordinary conditions of operation, blowdown from the drum is clear, indicating that, while soluble materials are removed from the boiler, insoluble compounds are not. In order to remove sludge from the boiler a procedure was, therefore, instituted by which each boiler was taken out of service every 4 days and blown from the lower waterwall headers and the mud drum.

The average alkalinity of the boiler water was also increased from 15–25 to 20–30 ppm NaOH. This appears to have prevented the further formation of a tough, adherent silica scale upon the tube surfaces.

The amount of calcium-and-magnesium deposit was apparently decreased by shortening the cycle of the external-treatment units. In this manner the total quantity of scale-forming salts introduced into the boilers was decreased and resulted in cleaner tube surfaces.

The over-all effect of the increased boiler blowdown, higher boiler-water alkalinity and the shortening of the cycle of the primary treatment has been to arrest corrosion of the sectional-header tubes due to deposition of sludge and scale. These procedures, however, have resulted in somewhat higher heat losses and carry-over to the turbine, necessitating washing of the blading.

W. L. WEBB.[5] Inasmuch as the authors' description of the Logan ash-screen-corrosion experience was carried only to the end of 1938, experience since that time may be of interest. As the authors indicated, the ash-screen tubes on the west half of the boiler were replaced during the November, 1938, shutdown with 3-in-outside-diam 12.5-deg-slope tubes of the same design as those installed on the east half of the boiler in May, 1938.

Visual examinations of representative screen tubes in February, 1939, showed the usual brownish black areas along the tops of the tubes, some being continuous narrow bands and others discontinuous bands of varying width. Those in the tubes on the west half of the boiler were more clear-cut than those in the east, due possibly to thinner deposits of sludge. Day loads on the boiler during the 3 months prior to this shutdown ranged between 800,000 and 1,000,000 lb of steam per hr.

Although no indication of active corrosion was found in the screen tubes, these markings showed that corrosion might not have been completely stopped. In order to produce more intimate contact of the water with the top surfaces of the tubes, twisted sheet-steel spirals were placed in all screen tubes during the March, 1939, shutdown. These were constructed of pieces of No. 18-gage steel, 5.5 ft long, having a width slightly less than the inside diameter of the tubes and bent to give a complete 360-deg twist in 1.5 ft of spiral. In addition to installing the spirals, the lower burners were tipped upward 2.5 deg, giving a total angle of 4 deg from the horizontal, in order to reduce further the flame impingement on the screen tubes.

No major inspections of ash screen tubes were again made until February, 1940. At that time, spirals were removed from seven representative tubes. All previously affected areas were

[5] American Gas and Electric Service Corporation, New York, N. Y.

evenly covered with a thin reddish colored sludge, no black oxide whatever being evident. The calipering of these tubes indicated no measurable metal loss. Except for a light coating of red oxide, the spirals were clean and smooth and showed no indication of corrosion.

As reported in the paper, hydrogen-evolution measurements in saturated steam were started in March, 1938. The gases were separated from the condensed sample by means of a separator of the boiling-chamber type, similar to that used by Potter, Solberg, and Hawkins in connection with their study of superheater-tube metal and were analyzed with an Orsat. Hydrogen was determined by the heated copper-oxide method. Usually two 2-hr samples were obtained each day. Hydrogen values obtained with this equipment appeared to have no direct relation to corrosion rate. Tests of the gas-removal efficiency of this separator, measured in terms of oxygen removal, showed it to have too poor efficiency to be suitable for measuring accurately the concentrations of hydrogen expected.

An automatically controlled separator for continuous operation, patterned after a tray-type deaerator, was therefore designed and constructed. After completion of preliminary tests, this unit was placed in operation in April, 1939, and has been in almost continuous service since then. Two gas samples are collected per day over 8- and 16-hr periods, respectively. Unfortunately, this new separator was developed too late to be used during the period of severe screen-tube corrosion.

Since hydrogen-evolution measurements are being more extensively made on steam samples from high-pressure boilers, actual values in the Logan saturated steam may be of interest. During the last year the evolution values have had a direct relationship to load and are approximately 18 and 22 l per 1,000,000 lb of steam at half load and full load, respectively. This relationship has been substantially the same when feeding ferrous hydroxide or sodium sulphite in proportion to dissolved oxygen in the feedwater as a scavenger, or when no scavenger was fed. No tests have been made to determine the effect of excess ferrous hydroxide on hydrogen evolution.

Equipment is being provided at both Windsor and Twin Branch for hydrogen-evolution measurements, the latter being equipped with a two-point recorder. Values of hydrogen in the feedwater, sampled at the economizer discharge (in one case equal to one half to three quarters that in saturated steam), indicate the necessity of sampling at both of these points, preferably simultaneously, to show the quantity of hydrogen actually evolved at the steam-generating surfaces.

The Logan boiler water pH is still being maintained between 9.6 and 9.8, since, under present load conditions, it is not considered advisable to conduct experiments at higher pH values and because evaporator carry-over and condenser leakage are at a minimum. It is hoped that the pH ultimately can be carried at about 10.8.

As was indicated by the authors, during the Logan screen-tube corrosion experience, soluble boiler-water chemicals "hid out" during high loads and were redissolved at low loads or when the boiler was taken off the line. At one time when the phosphate as PO_4 in the boiler water was being maintained at 30 to 50 ppm, a total of 350 ppm of PO_4 "hid out." Since the tube corrosion has been stopped, hiding out has ceased.

Experience with the Logan boiler as well as others can lead to no other conclusion than that hiding out is an unfavorable sign, indicating tube starvation or steam blanketing which may be a forerunner of tube corrosion resulting from the reaction between steam or water and the hot metal.

Uncompleted experiments with a 250-lb gage controlled-circulation test boiler, having a single horizontal tube in a gas-fired furnace, indicate that, with heat-absorption rates up to 125,000 Btu per sq ft of circumferential tube area, and with boiler-water pH values of 9.6 to 12, the hydrogen evolution and top-tube temperatures remain normal as long as the steam-water velocity exceeds a critical value. However, as the velocity is decreased below this critical value, the tube-wall temperature rises rapidly. With increasing tube-wall temperatures, hydrogen evolution increases, a higher hydrogen evolution occurring at a boiler water pH of 11 than at a pH of 9.6.

The writer wishes to commend the authors for presenting the case histories and particularly for the accuracy and completeness of the Logan experience. It is evident that too few 1300-lb boilers have escaped the type of tube corrosion which is known not to have been caused by dissolved oxygen in the feedwater and which is apparently beyond correction by chemical control of boiler water. A better understanding of this type of corrosion, both by the boiler manufacturer and the purchaser, should lead to a definite solution of this problem.

L. E. HANKISON.[6] The discussion of any paper presented over a year ago should offer a very excellent opportunity to substantiate or disprove the various observations, theories, and conclusions presented in the paper; and in so far as our experience goes, the findings and theories advanced by the authors have been borne out to an extraordinary degree. Therefore, the writer believes the paper under discussion should be considered as authoritative on the various ideas brought forth.

With regard to the case history reported for Springdale, the observations and causes of the troubles outlined in the paper have been confirmed, and the loss of steam-generating tubes stopped, we believe, by the removal of the cores that were placed in the tubes to promote circulation, and the installation of distributing apparatus in the headers to prevent steam binding. The manufacturer of the steam-generating equipment furnished to Springdale is to be highly commended on the handling of the various problems, the analysis of troubles as they developed, and the application of the proper corrective measures for producing the desired results. As the coal conditions and boiler-water concentrations with which we are now operating are considered much more severe than existed at the time of our troubles, we feel justified in the belief that our present satisfactory conditions will continue.

We have always held to the theory that the steam generator should be so designed as to allow the use of properly treated feedwater, and that undertreating of feedwater in an effort to remedy the shortcomings of boiler design should not be tolerated. The paper suggests that, by the use of inadequate treatment of the boiler water, the detrimental effects of steam binding and the wasting away of boiler metal may be retarded in the dry areas, but that lower alkalinity may possibly cause deterioration throughout the boiler. It seems that metal cracking is likely to take place under these conditions, and that, instead of correcting the trouble, the time is only prolonged until general deterioration takes place. On the theory that proper boiler-water conditions should be maintained, we carried sufficient alkalinity and conditioning chemicals properly to treat the high-pressure boilers at Springdale, even while undergoing tube troubles. Our experience shows that correction of the circulation and steam-binding conditions is all that is required to permit satisfactory operation with properly treated boiler water.

We have had further opportunity at Springdale to confirm the conclusions outlined in the authors' paper. Because of unexpected characteristics of the coal, it was considered advisable to make the walls of the secondary furnace entirely water-cooled by adding extra tubes to the back and side walls. It was thought as

FIG. 4 RUPTURED PART OF WATERWALL TUBE AFTER 17 DAYS OF SERVICE

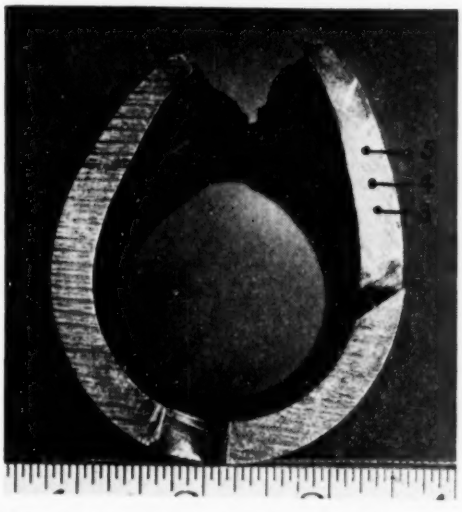

FIG. 5 CROSS SECTION OF TUBE AT RUPTURE MARKED TO SHOW LOCATION OF MICROGRAPHS

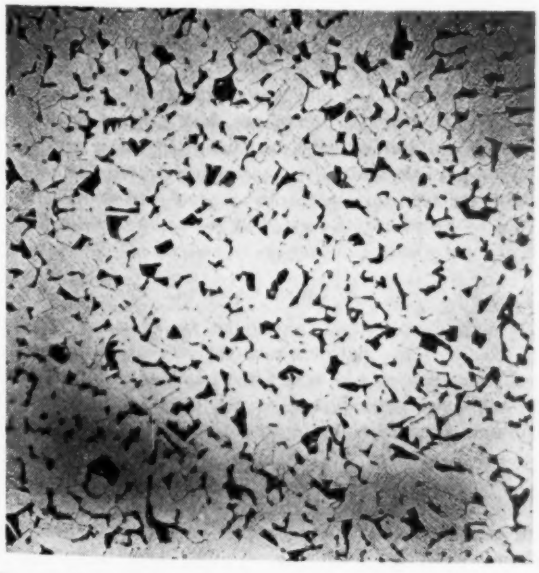

FIG. 6 MICROGRAPH AT POINT 3 (FIG. 5), SHOWING PEARLITIC STRUCTURE OF ORIGINAL TUBE METAL; ×100

the time that the water-supply and steam-relieving conductors already installed were adequate to take care of this extra water-wall surface. After 17 days of operation of the full waterwalls, tube failures were experienced at each end of the back wall, the tubes being the fourth from their respective ends. The ruptured sections were replaced and, after 18 days, one of the replaced tubes failed. Also, one of the side-wall tubes failed at the same time, this tube also being the fourth tube from the cooler end of its header. At a later period, the same tube in the opposite side wall failed, all of which seems to bear out the hypothesis that these failures were caused either by inadequate water supply to the waterwalls or by insufficient steam-relieving tubes from their upper headers.

In an effort to overcome these troubles, the water-supply and

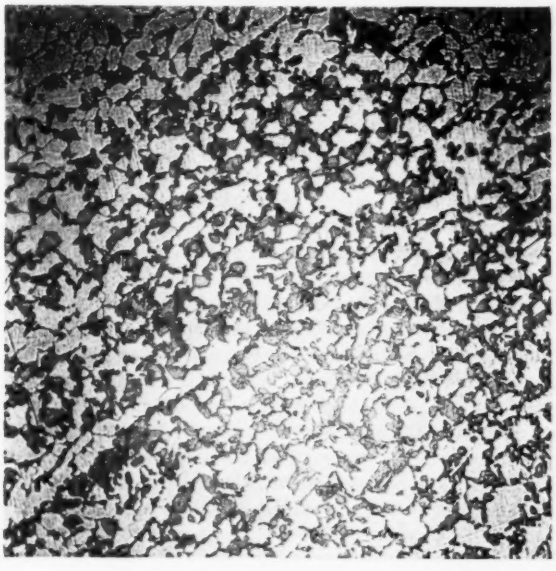

FIG. 7 MICROGRAPH AT POINT 4 (FIG. 5), SHOWING LOCATION OF METAL STRUCTURE CHANGE
(This point is where oxidation and thinning begins to show on inside of tube; ×100.)

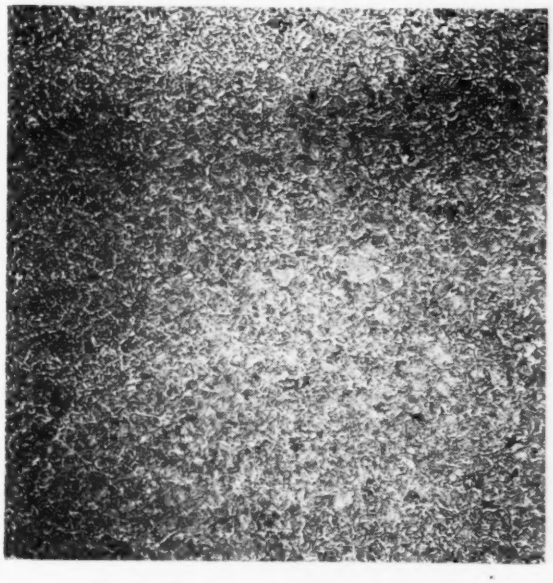

FIG. 8 MICROGRAPH AT POINT 5 (FIG. 5)
(This shows changed metal structure which is typical of metal from this point to rupture; ×100.)

steam-relieving tubes of the headers were increased by approximately 100 per cent. Since these additions, there has been but one failure and this was attributed to oxidation that occurred before the extra water-supply and steam-relieving tubes were installed. These failures were in the nature of metal cracking as described in the authors' paper. As all the tubes were in a vertical position, the conclusion is reached that vertical waterwalls, having inadequate supply and delivery connections, can have certain tubes, presumably the ones in the hottest zone, delivering an upward circulation; others, in the cooler portions of the wall, a downward circulation; while some tubes probably have little or no circulation.

At the time of these failures we were carrying concentrations in the boiler water of 1000 ppm total solids. The standard is now set at 2000 ppm and it is anticipated that this limit will be increased in the near future. The boiler water carries excess phosphate and hydroxide, and from 3 to 10 parts of sodium sulphite. Some of this highly concentrated boiler water is recirculated to the economizer inlet so that the economizer or first heat-absorbing surface of the unit is at all times protected against oxygen corrosion by the alkalinity and sulphite. Boiler feedwater having a pH of about 8 is raised to a pH of 9.5 or 10 by this recirculation. As a constant quantity of boiler water is recirculated, the pH of the water through the economizer naturally varies with the rating on the boiler and the concentration of the boiler water.

Regarding the decomposition of sodium sulphite, we have definite proof of its stability under normal 1300-lb service. During the time when steam binding was taking place, we were able to predict the failure of boiler tubes by the disappearance of sodium sulphite in the boiler under question. While the sulphite content of the other boilers in the plant would remain practically constant, the one suffering deterioration would change the sulphite to sulphate, and the chemical balance of the boiler-water constituents fully accounted for all the sulphite which had formerly been present.

It has been found at Springdale that, by maintaining an excess of sulphite, we are amply protected against the admission of oxygen which seems to appear when adding to or taking off equipment. Even though the Winkler test usually shows zero oxygen, there is a constant slow disappearance of the sulphite and this is particularly noticeable over the week end when severe load changes are experienced.

Further confirming the observations made by the authors in their paper, sections of the vertical waterwall tubes that failed show metal cracking, and micrographs of specimens from the overheated surface emphasize a definite zone where overheating caused the metal structure to change. These pictures are very interesting in showing that the metal structure undergoes a drastic change at the line where thinning by oxidation begins.

Fig. 4 shows the ruptured part of a waterwall tube after 17 days of service. In Fig. 5, the cross section of this tube at the rupture is marked to show the location of the micrographs in Figs. 6, 7, and 8. The micrograph in Fig. 6 exhibits the pearlitic structure of the original tube metal at point 3. At point 4, where oxidation and thinning begin to show on the inside of the tube, the structure shows a change, as indicated in Fig. 7. Fig. 8 illustrates the changed metal structure which is typical of the metal from point 5 to the rupture.

The authors refer to the "hiding out" of boiler-water chemicals and show graphical records of this more or less detrimental factor to boiler-water conditioning. While Springdale has not experienced this "hide-out" in so far as we are aware, we are experiencing it in other plants on the system. A search in one of our high-pressure boilers for this hide-out disclosed a residue of boiler-water solids in the intermediate uptake waterwall header 30 ft below the

FIG. 9 CHEMICAL DEPOSITS IN INTERMEDIATE UPTAKE WATERWALL HEADER, WHICH IS LOCATED 30 FT BELOW CENTER LINE OF BOILER DRUM

normal water level of the boiler. This deposit was found adhering to the surfaces of the header and tubes when the boiler was drained, more than 22 hr after it had stopped steaming. The beautiful frost-like patterns of chemical deposit are shown in Fig. 9.

A very important factor in the satisfactory operation of the Springdale high-pressure boilers is the steam-purifying equipment which was described in a paper by M. D. Baker at the same meeting at which the authors' paper was presented. This equipment is continuing to give first-class performance and shows no deterioration. The clean steam we are able to obtain with high boiler-water concentrations is, in the greatest measure, attributable to this purifying apparatus.

The highly concentrated boiler water, carrying its proportional amount of sulphite, phosphate, and alkalinity that is standard for Springdale, has produced the following beneficial results:

1 Complete economizer protection, as provided by recirculating boiler water through the economizer.

2 Clean metal surfaces as regards scale deposition and corrosion, and reduction of the amount of deposit to a point where this trouble is negligible.

3 A clean, crystalline type of sludge deposit.

4 Reduced blowdown, relieving the load on the evaporated make-up and heat-exchanging equipment.

These desirable conditions are all obtained at a decrease in cost of operation and maintenance, and a paper is being prepared for presentation in the near future in which will be given more detailed information on steam quality, economies gained by higher boiler-water concentration, proof of stability of sodium sulphite, and the benefits derived by recirculation of boiler-drum water through the economizer.

AUTHORS' CLOSURE

The discussion certainly continues the spirit in which the paper was written—that of a cooperative venture in which evidence from many sources was fitted together to produce as rational and consistent a picture as possible. In this same spirit, the authors venture a brief correlation of the preceding comments.

Fundamentally, what has been under discussion is the reaction between iron and water and the effect upon this reaction of dissolved substances and of temperature. As Mr. Place has pointed out, iron is a strong reducing agent. The chemical driving force for iron to take oxygen from water and liberate hydrogen is very great, even at room temperature, but the iron oxide, which is

one product of the reaction, quite literally gets in the way and slows down the reaction to such an extent that it is scarcely noticeable. Anyone can observe the progress of this reaction, however, by allowing a quantity of very finely divided metallic iron to stand in distilled water in a small bottle on his desk. On shaking this bottle once a day, small bubbles of gas will be observed to rise from the powder. This will continue day after day; a test after a sufficiently long time will demonstrate that the gas is hydrogen.

This same oxidation of steel by water, or reduction of water by steel, goes on continuously in every boiler, but it is only when the oxide resulting from it fails to retard the reaction that the boiler operator has a problem on his hands.

The protective oxide film can be at least partially destroyed or rendered more permeable by very high concentrations of sodium hydroxide. Because it is brittle and differs in thermal expansion from steel, it may also be cracked by repeated temperature changes. Anything which causes excessive local concentration of a boiler water containing some caustic soda or repeated overheating and quenching of a tube surface is thus potentially dangerous. To the authors, steam blanketing seems inevitably to tend to produce one or the other or both of these effects.

The factor of caustic attack has not been questioned in the discussion, but Mr. Place has gently indicated his disbelief in the validity of thermocouple measurements or of changes in the microstructure of steel as indications of excessive temperature in the top of a steam-blanketed tube. Base-metal thermocouples admittedly do fail all too rapidly when exposed to the conditions in a boiler furnace, yet recent studies at the Bureau of Standards show a maximum error of only 21 F, and this low rather than high, when chromel-alumel couples were heated for long periods of time in air. This maximum error was found after a couple had been exposed for 200 hr at 2200 F.[7] Failure occurred before 300 hr.

While the authors attach more significance than does Mr. Place to the temperature measurements mentioned in the paper, they feel that the microstructure of the steel is a still more certain criterion of overheating. This is demonstrated particularly well by the photomicrographs presented by Mr. Hankison correlating the change in structure in the tube wall with the zone of damage along the internal surface. Perhaps the sample which inspired Mr. Place's lack of faith in metallographic evidence actually had been overheated at some time in some unrecorded manner.

Mr. Place has argued that, if a tube were seriously overheated, it would deform to a greater extent than has been observed in many cases where grooving along the ceiling produced failure. In a tube of 3.5 in. outside diam with a wall thickness of 0.5 in. subjected to an internal pressure of 1400 psi, the nominal stress tending to rupture the tube is, however, only 3500 psi for metal in the longitudinal section of the wall. That creep of a low-carbon steel subjected to this stress at a temperature of 1000 F is slight has been shown by White, Clark, and Wilson.[8] They observed that SAE 1015 steel held at 1000 F for 16,000 hr under a load of 4000 psi showed an average rate of creep of only 0.043 per cent per 1000 hr.

It must be remembered also that a narrow band of steam along the ceiling of a tube would produce only a narrow band of overheated metal and a narrow groove, as in Fig. 15 of the paper. Deformation in such a case might be limited to a strip not more than 1 in. wide. Where the steam blankets more of the tube ceiling, as in the cross section shown by Mr. Hankison, there, usually is definite stretching of the tube wall prior to failure resulting in longitudinal cracks in the internal and external layers of oxide.

Overheating of a tube is, of course, not a new or unique occurrence. While we have thought for years in terms of the overheating due to deposits of solid on a heat-transfer surface, much less consideration has been given to the insulating effect of a blanket of steam, which was the starting point of the paper.

The experiences at Springdale and at Waterside described in the paper and the discussion by Mr. Hanlon bring us back to the fact that sludge settling out on the bottom of a tube can interfere with the transfer of heat from metal to water just as seriously as steam along its ceiling. The sludge which caused the failures at Waterside, reported by Mr. Hanlon, like that which led to the failures along the bottom of the cored tubes at Springdale was not, however, the relatively light calcium phosphate sludge which results from phosphate conditioning but, instead, a heavy sludge of magnetic iron oxide and metallic copper. Unless powdered metallic iron or ferrous hydroxide is being introduced intentionally into the boiler feed, such a sludge can result only from undesirable attack of water on steel in some region within the boiler, not necessarily the region where the sludge is found.

The initial settling out of the sludge on the bottom of the tubes described by Mr. Hanlon may have been favored by the presence of restrictors at the inlet ends of the lower tubes, as it was apparently by the cores in the tubes at Springdale. Overheating of the portion of the tube covered by the sludge could then have led to progressive oxidation of the tube wall.

Attempts to increase flow in one particular region of a boiler by specifically retarding it in another region seem, in a number of cases, to have transferred trouble rather than to have prevented it. Of the various expedients which have been tried to minimize steam blanketing in tubes through which there was positive circulation, the spirals introduced into the screen tubes at Logan, described by Mr. Webb, seem the most promising.

The suggestion of Mr. Kreisinger that tubes in high-pressure boilers are too thick-walled for their own good merits further study. Reduction in wall thickness will not, however, change the heat input to a tube or minimize the formation of a steam blanket within it. While cracking of tubes subjected to repeated overheating and quenching may be slower with thin than with thick walls, as suggested by Mr. Kreisinger, the paper records extensive damage to the thin-walled tubes of the low-pressure boilers in the Beacon Street Heating Plant in 8 years. The authors believe that grooving along the top of a tube might occur as rapidly in a thin-walled as in a thick-walled tube.

It was first demonstrated at Port Washington that grooving of the ceilings of inclined tubes could be minimized without mechanical changes by eliminating caustic alkalinity from the boiler water. This expedient was adopted at Logan, but the slope of the screen tubes affected was also increased, the spirals were inserted to throw water against the tops of the tubes, and the burners were tilted upward to reduce flame impingement. At Springdale, no change was made in water conditioning, but the difficulties first encountered were eliminated solely by mechanical changes. An appropriate conclusion to the question of the relative importance of the chemical and the mechanical factors has been written into the record by the announcement that, after operation for $2^1/_2$ years with no caustic alkalinity in the boiler water, extensive damage of the original type was recently discovered in the screen tubes at Port Washington.[9]

Determination of the Purity of Steam by Gravimetric and Spectrographic Methods

By M. C. SCHWARTZ,[1] W. B. GURNEY,[2] AND T. E. CROSSAN[3]

This is the first paper in a series of three covering investigations on the determination of purity of steam. In it the authors discuss the mechanism of steam contamination and methods of measuring steam purity classified according to impurities present. Principally, however, the subject matter is devoted to the apparatus and procedure followed in making gravimetric determinations of the residue from evaporated samples of condensed steam with the results obtained. As a check on these analyses, estimates are made for solids in steam from turbine-blade deposits. The results of spectrographic analyses are also given.

THE purity of steam produced from a boiler is a function of the composition of the boiler water and the boiler feedwater, as well as the mechanical design of the boiler in which it is produced. The production and consumption of huge amounts of steam at high pressures and temperatures have demanded the utmost in purity of the steam leaving the boiler, because of the economic importance of maintaining clean superheaters, turbines, and process equipment. Any changes made to increase the purity of steam are thus quite important and, particularly, since they may involve considerable expense, should be undertaken with due consideration of the methods used to determine the purity of the steam. Investigation of the methods of determining steam purity has been made at the Louisiana Station and has been applied in the control of steam production at this station.

Mechanism of Steam Contamination

Steam becomes contaminated with gases or moisture containing dissolved or suspended solids present in the boiler water or in the feedwater which may be used as a scrubbing medium for the steam. The contamination of steam results from the continuously occurring phenomenon of foaming or from the intermittent and irregular phenomenon of priming. An excellent summary of the factors contributing to foaming and priming has been presented by Powell (1).[4] Under boiler design this author covers such considerations as steam disengaging space, steam storage space, maximum water space, size of steam header, velocity of steam, various obstructions in the steam drum, and boiler pressure. Boiler operation covers such matters as rate of evaporation, load swings, and water level. Water treatment covers such items as composition and concentration of dissolved and suspended solids in the boiler water and in the feedwater, as well as the chemical condition at the metal surfaces exposed to the water.

Methods of Measuring Steam Purity

Methods of measuring steam purity may be classified according to the impurities present. For example, if an appreciable amount of moisture is being determined, the steam calorimeter can be used. If all the soluble electrolytes, arising from the solids or gases in the steam, are being determined in the condensate, then the electrolytic-conductivity method can be used. If specific chemical substances, such as ammonia, carbon dioxide, sodium chloride, and the like, are being determined, then specific chemical methods for these substances can be used. If the total solids present in the steam is being determined, then the residue after evaporation of the condensate can be weighed or, alternatively, it is apparently possible to deposit the solids on a surface and determine them in this manner. It is useful to consider the subject from the viewpoint of the impurity, because it is quite possible that some method, perhaps satisfactory in its own way, serves no really useful purpose in determining why the deposits in the equipment are forming and in what way they may be avoided.

Gravimetric Determination of the Residue From Evaporated Samples of Condensed Steam

The gravimetric determination of the total solids, including thus soluble and insoluble substances, in the steam by weighing the residue after evaporation of a sample of steam condensate can probably be considered the standard procedure. The minute weight of the residue offers no serious drawback since it may be determined readily with a sensitive balance. The problem of evaporating the sample of condensate free from subsequent contamination offers more difficulty. Sufficiently slow evaporation of the sample to avoid loss by spattering results in a serious loss of time and it is this factor which so far has prevented this method from becoming adaptable to routine use.

Although the preparation of pure water has been the subject of numerous researches in the laboratory, the investigators very seldom have determined the residue on evaporation. However, Acree and Fawcett (2) evaporated 30 l of pure water, contained in a quartz flask, in a platinum dish. The maximum residue was never more than 0.15 ppm and was as low as 0.03 to 0.06 ppm. Ulmer (3), using condensed-steam samples from a commercial boiler, determined the residue on evaporation to be 0.19 to 1.01 ppm, depending upon the boiler-water concentration.

A semimicro apparatus has been developed for evaporating 2-l samples of condensed steam. Ulmer (3), Powell (4), and Seyb (5) have considered the problem of evaporating condensed-steam samples. Fig. 1 shows the manner in which the evaporator works. The apparatus was built upon a triple-beam balance, of which Sargent No. 3455 is an example. The knife-edge mechanism, brass lever arm, and transite holder for the Pyrex micro bell jar were built in the University shops. The Pyrex jar is Corning No. 6880.

Contributed jointly by the Gulf States Utilities Company, Louisiana Station, Baton Rouge, La., and the Engineering Experiment Station, Louisiana State University, and accepted by the Joint Research Committee on Boiler Feedwater Studies and presented at the Spring Meeting, Boiler Feedwater Sessions, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, Worcester, Mass., May 1–3, 1940.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The rubber tubing is pure gum. A 2-l Pyrex Erlenmeyer flask, protected from carbon dioxide with a soda-lime-sodium-hydroxide guard tube, contained the sample of condensate. Pyrex tubing was used to convey the water under constant head from the flask to the platinum dish beneath the bell jar. Block-tin tubing was available for use in place of Pyrex tubing if it seemed necessary,

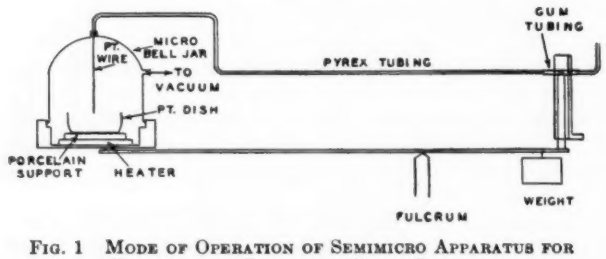

FIG. 1 MODE OF OPERATION OF SEMIMICRO APPARATUS FOR EVAPORATING CONDENSED-STEAM SAMPLES

but the results did not seem to warrant any change. A piece of platinum wire was sealed to the Pyrex tubing so that hot water would not come into contact with the Pyrex-glass tubing. A 200-w $2^1/_2$-in. Chromalox heating unit was used and the heat input was controlled by a rheostat. The platinum dish used, weighing 10 g, was the lightest obtainable commercially for its size. It was 2 in. in diam and 1 in. deep. This dish was supported upon a porcelain ring. The side arm of the Pyrex bell jar was connected to a Fisher air ejector. The trap in this line prevented the possibility of any water being sucked back.

In operation, the lead weight on the balance beam is initially adjusted to balance the weight of the platinum dish and water as well as the Pyrex jar and other accessories. For an actual run, control is made by using small weights on the brass lever arm. A change of about 10 g starts or stops the flow of water. After an initial adjustment of the rate of flow, the evaporation always continues with practically no attention for the time necessary, which is about 48 hr.

The total solids have been determined on condensed-steam samples from the station boilers. Test data are presented in Tables 1 to 3.

From the results of Tables 1, 2, and 3, it will be seen that for this station the totals of solids in the condensate from saturated-

and superheated-steam samples are practically identical. The copper degasifier, which will be described later and which removes carbon dioxide from the samples, gives results approximating those obtained on samples subjected to no treatment for degasification. In all cases, the samples were collected within several feet of the sampling points.

From previous experience with deposits forming on glass conductivity cells, as well as by the deposits formed in the platinum dish, it was obvious that either copper or iron or both were present in the condensed steam. Tests for copper with diphenylthiocarbazone or dithizone on the condensed steam, and on samples concentrated by evaporation, gave negative tests. However there seems to be no doubt that high steam velocities will cause erosion of copper tubing. Whether or not these minute particles of copper will dissolve seems to depend upon a number of factors, one of the most important of which is the rate of flow of condensed steam through the sampling system. Interesting but old data on the solubility of copper in distillled water are given by Carnelley (6).

Semimicro determination of the iron in the residues from samples Nos. 9 and 10, Table 2, showed 0.23 and 0.25 ppm Fe_2O_3, respectively, out of a total of 0.3 ppm solids. Since these samples were collected in a most satisfactory manner, as far as avoiding possible contamination of iron from the sampling line is concerned, the conclusion seems logical that minute particles of iron are in suspension in the steam and are so finely divided that they show no tendency to settle out in the condensed steam. These iron particles are not visible in the solution but are removed by ultrafiltration. There is no reason to assume that these iron particles will affect the electrolytic conductivity of the solution of condensed steam. Upon the basis of these results of gravimetric determination of the residue from evaporating condensed-steam samples, coupled with determination of iron and of copper in these residues, there is apparently no more than about 0.1 ppm soluble solids in the steam at the Louisiana Station.

ESTIMATION OF SOLIDS IN STEAM FROM TURBINE-BLADE DEPOSITS

The values obtained for the purity of steam by any given method should correspond to the actual practical data observed in the plant. For example, the amount and kind of deposits observed on the turbine blades should be in proportion to the indi-

cations obtained by any one of the usual methods of determining steam purity. Data of this kind, as useful as they are, do not furnish a continuously available record of steam purity as a guide to efficient operation.

The authors have attempted to determine the solids present in the superheated steam by washing a turbine with condensate, while the machine was rotating at slow speed under no load. Data are presented in Tables 4, 5, and 6 for three different turbines.

Although the solids were removed from the turbine by washing with condensate, all of the deposit so obtained was not soluble. Table 7 shows the relative amounts of insoluble and soluble material.

Spectrographic Analysis of Condensed Steam

The spectrographic analysis of condensed steam was made at the spectrographic laboratory of the Massachusetts Institute of Technology. The authors in order to avoid contamination of the sample by the container, selected what was believed to be the most inert substance besides platinum, which was prohibitive in cost. The sample was collected in a 500-ml silver Erlenmeyer flask with a silver stopper. A qualitative analysis of the sample showed the presence of the following elements in diminishing amounts: silver, copper, iron, magnesium, sodium, and silicon. In addition, minute traces of boron, lead, and calcium were found. Phosphorus was not detected even with extreme concentration of the sample; however, this element is one to which the spectrographic method is less sensitive. A quantitative analysis gave the results shown in Table 8.

TABLE 8 QUANTITATIVE ANALYSIS OF CONDENSED-STEAM SAMPLE

Substance	Ppm
Copper	2.4
Iron	0.06
Sodium	0.14
Magnesium	0.056
Silicon	0.015

The presence of such large amounts of silver and copper was entirely inconsistent with the gravimetric results, as well as with the known electrolytic conductivity of this sample. Apparently the silver flask was the source of this unusual contamination. Accordingly another sample was collected for spectrographic analysis, this time in a Pyrex glass-stoppered bottle. Table 9 shows the results obtained.

TABLE 9 QUANTITATIVE ANALYSIS OF ADDITIONAL CONDENSED-STEAM SAMPLE

Substance	Ppm
Copper	0.05
Silicon	0.10
Calcium	less than 0.01

The drop in copper concentration from 2.4 to 0.05 ppm with the change in the container shows contamination from the silver flask, evidently from the silver solder used in fabrication. Correspondingly, the silicon concentration changed from 0.015 to 0.1 ppm, evidently due to the effect of the glass container.

By combining the results of both analyses, we derive the probable composition of the solids present in condensed steam, as shown in Table 10.

On the basis of the results shown in Table 10, one would expect a value for the total solids of condensed steam to be higher than 0.33 ppm, the exact value depending upon the actual negative ions associated with the positive ions shown in the table. It seems somewhat surprising that the results shown by spectrographic analysis should be greater than those obtained by evaporation and subsequent weighing, particularly since it has been assumed that the evaporation might probably be affected by contamination during the long period required. For further investigation using the spectrographic method, it will be desirable to establish the kind and amounts of impurities which may be present in the electrodes which are used in the analysis. That this type of error may exist is quite probable because of the fact that both calcium and magnesium are absent from turbine-blade deposits. In addition, it is well known that the electrodes used in spectrographic analysis are freed from traces of impurities only with difficulty. Traces of boron, silicon, copper, calcium, magnesium, and sodium usually exist even in treated electrodes (7, 8). Hilger H.S. carbon rods of very high purity contain traces of boron, calcium, copper, magnesium, and iron (9).

TABLE 10 RESULTS OF COMBINING ANALYSES OF TABLES 8 AND 9

Substance	Ppm
Sodium	0.140
Calcium	0.010
Magnesium	0.060
Silicon	0.015
Iron	0.060
Copper	0.050

The sensitivity of the spectrographic method, as is evident from the foregoing analyses, makes it an extremely valuable tool with which to attack the problem of steam purity. From data presented by Owens (10) the authors have calculated the sensitivity of the spectrographic method to be as shown in Table 11.

TABLE 11 SENSITIVITY OF SPECTROGRAPHIC METHOD

Sensitivity (inorganic liquid)	Minimum concentration (using 0.1 ml), ppm
Al	0.25
Ca	0.20
Mg	0.15
Si	2.50
Cr	0.10
Cu	0.05
Fe	0.05
Mn	0.01
Na	0.38
Pb	0.10
Sr	0.05

Even with the sensitivity shown in Table 11, some concentration of the condensed-steam samples is required in order to obtain indication of some of the substances present in the sample. In conclusion it should be remembered that spectrographic analysis will give the sum of the soluble as well as insoluble solids present in the condensed steam.

Acknowledgment

The authors wish to thank H. C. Leonard, vice-president of the Gulf States Utilities Company, and Dean L. J. Lassalle, director of the Engineering Experiment Station, Louisiana State University, for permission to publish this material. Grateful acknowledgment is made to E. B. Powell, consulting engineer of Stone and Webster Engineering Corporation, and to S. T. Powell, consulting chemical engineer, for their advice, highly valued suggestions, and encouragement throughout the course of the work being reported. Members of the chemical staff of the Gulf States Utilities Company assisting in this research were L. Young and J. C. Hill.

Determination of Ammonia in Condensed Steam

By M. C. SCHWARTZ,[1] W. B. GURNEY,[2] and T. E. CROSSAN[3]

Of the impurities which may affect the electrolytic conductivity and pH of water, the gases carbon dioxide and ammonia are most resistant to removal. Carbon dioxide has previously been given consideration almost to the exclusion of the ammonia-removal problem. This second paper in a series of three on the subject of purity of steam by the authors deals with the preparation of ammonia-free water by various methods, of which phosphorus-pentoxide batch distillation apparently gives the most satisfactory results. The Nessler method of ammonia determination is also thoroughly discussed, as well as the volumetric determination of ammonia with sodium hypobromite and naphthyl red. The authors have used such determinations of ammonia in condensed steam to assist in evaluating a suitable correction factor to compensate for its presence.

THE electrolytic-conductivity method of determining steam purity is the one most frequently used in practice. Fitze (1),[4] Hecht and McKinney (2), Rummel (3), Powell (4, 5), Place (6) have investigated this method. It has the advantages of extreme sensitivity and is susceptible to being made continuously recording. It has the disadvantages of a need for a correlating factor between electrolytic conductivity and soluble solids, as well as correction factors for gases such as ammonia and carbon dioxide which dissolve in the condensed steam to form electrolytes. Rummel (7), Gurney (8), Powell and McChesney (9) have developed apparatus designed to remove carbon dioxide and ammonia from the sample without affecting the solids present but, thus far, ammonia has resisted attempts at complete removal, hence, a correction must be made for its presence. The authors have investigated the determination of ammonia in condensed steam to assist in evaluating the correction to be applied for its presence.

Preparation of Ammonia-Free Water

The preparation of pure water has been investigated frequently in the intervening years since 1894 when Kohlrausch and Heydweiller (10) purified water to the extent that its electrolytic conductivity was 0.04 micromho at 18 C and 0.054 micromho at 25 C.

The methods for the purification of water may be classified as physical and chemical or a combination of both. Hibben (11) classifies the physical methods of purification as falling into four categories, namely, those employing vacuum, those employing heat, those employing both vacuum and heat, and those employing freezing. In his own experimental work (11), Hibben uses the vacuum-sublimation process which includes all the processes mentioned, since it employs heat, vacuum, and freezing. The liquids to be freed from gas are vaporized and frozen in vacuo. By chemical methods we refer to those cases in which chemical substances, such as alkaline permanganate, bromine, phosphoric acid, and similar reagents, are added to cause certain impurities existing in the liquid to be retained in solution or to be made volatile on the application of heat.

The most convenient methods for determining the purity of water are the determination of the electrolytic conductivity and that of the pH. The most resistant impurities to be removed from water, which may affect the electrolytic conductivity and pH of the water, are the gases, carbon dioxide, and ammonia, which, in addition to physical solution in water, undergo chemical reaction to form electrolytes as the bicarbonate and carbonate and ammonium ion. Other gaseous impurities which may undergo similar reaction, as sulphur dioxide, have not been considered in reported work.

For some time carbon dioxide has been given consideration, to the general exclusion of ammonia, as the gaseous impurity in water to be removed. The probable reason for this has been due to the indefiniteness of the electrolytic-conductivity method as an indicator of purity, and to the lack of methods of determining pH without adding electrolytes, which change the pH themselves, as in colorimetric methods. The presence of carbon dioxide in solution tends to lower the pH of pure water. When the glass-electrode method for determining pH was applied to water considered to be free from carbon dioxide, the pH was found to be 7.9 to 8 (12). The increase in pH above that of 7, the value for pure water, was later ascribed to the presence of dissolved ammonia. When definite measures were taken to insure the absence of this impurity, the pH fell to 7 (13, 14).

Presumably the best procedure for preparing ammonia-free water is by distillation, adding acidic substances, as P_2O_5 to retain ammonium compounds in solution, and passing purified air through the distillate (13, 14).

Procedure for Preparing Ammonia-Free Water—Batch Distillation With P_2O_5

Phosphorus pentoxide was added to 1 l of laboratory-distilled water. The solution was distilled at a rate of about 8 ml per min in an all-Pyrex-glass still as shown in Fig. 1. The distillate was collected in the conductivity-cell holder *A* from which it could be collected for use or run to waste. Determinations of ammonia in the distillate, as well as electrolytic-conductivity measurements, indicated that about 200 ml of distillate should be discarded. From then on a receiver could be placed at point *B* and the next 600 ml could be collected. Two such portions were collected and 1 l of this water was then redistilled again, discarding the first 200 ml, and collecting for ammonia-free water the next 600 ml of distillate. The flask from which the solutions were distilled was equipped with a side tube and ground stopper which allowed

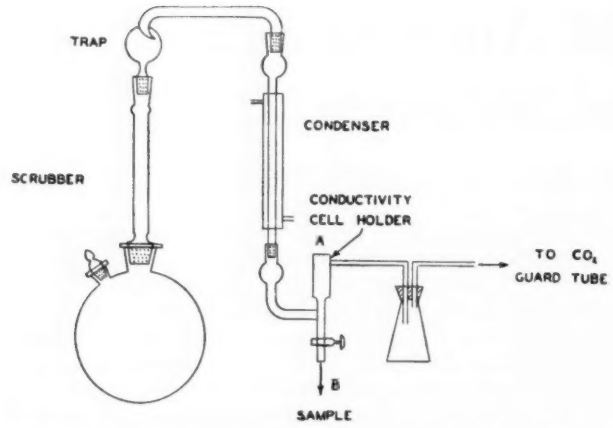

FIG. 1 DISTILLING APPARATUS FOR PREPARATION OF PURE WATER

the vessel to be filled and emptied without dismantling the apparatus. Passing purified air into the distillate was not done in this work. A Leeds and Northrup No. 4866 mho-ohm conductivity indicator with cell constant and temperature compensator was used. The electrodes were platinized platinum.

Tables 1 to 8 and Fig. 2 indicate the comparative effectiveness of various methods of preparing ammonia-free water and seem to confirm the work of Ellis and Kiehl (13) and Cranston and Brown (14) in establishing a phosphoric-acid distillation as the most satisfactory method available.

It is interesting to note, as indicated by the data in Tables 1 to 8 and in other experiments where distillation has been carried practically to completion, that as the distillation proceeds the electrolytic conductivity decreases continuously. On the other hand, in cases where chemicals have been added, the electrolytic conductivity commences to increase when sufficient concentration is reached to start carry-over.

The data of Table 8 indicate that simple distillation will not drive off the ammonia completely, even when some 700 to 800 ml of an original 1 l are distilled.

Considering the simplicity of the still used for preparing ammonia-free water, in comparison with some of those described in the literature, the electrolytic conductivity of the distillate

DETERMINATION OF AMMONIA—NESSLER METHOD

Although Nessler proposed a reagent for the direct determination of ammonia in 1856 (27), his method with various modifications apparently remains the most widely used. Naturally, in the intervening time a considerable volume of literature has accumulated, but there are few other methods proposed for the determination of small quantities of ammonia. Bjerrum (28) proposed an acid titration for determining both ammonia and carbon dioxide in distilled water. Makris (29) proposed a test using tannin solution and silver nitrate which he claimed was more sensitive than the Nessler test. Teorell (30) proposed a titrimetric determination for minute amounts of ammonia by using the reaction $2\ NH_3 + 3\ NaBrO = 3\ NaBr + 3\ H_2O + N_2$, the excess NaBrO being determined iodometrically or by means of naphthyl red, which is decolorized by NaBrO.

The most unfortunate feature of the Nessler method for determining ammonia is the variation in the preparation of Nessler's reagent and its resulting varying sensitivity. In addition, the reaction taking place is rather complex, and the Nessler reagent undergoes change with time.

Nichols and Willits (31) indicate the reaction to be

$$2\ (HgI_2.2\ NaI) + NH_3 = (NH_3.HgI_2) + 2\ NaI)$$
$$2\ (NH_3.HgI_2) = NH_2Hg_2I_3 + NH_4I$$
$$2\ (HgI_2.2\ NaI) + 2\ NH_3 = NH_2Hg_2I_3 + 4\ NaI + NH_4I$$

The compound $NH_2Hg_2I_3$ gives the color to Nesslerized ammonia solutions.

AMMONIA IN THE NESSLER REAGENT

In their study of the Nessler reaction, Nichols and Willits (31), working with a solution containing 2 ppm ammonia nitrogen, and adding 5 ml Nessler reagent to a 100-ml sample, found that the apparently clear yellow solution formed could be made clear and colorless by passing it through a microfilter, using 0.06-gage cellophane as the filtering medium, under a pressure of 290 lb of nitrogen. With the exception of one other statement to this effect quoted in Yoe (32), "J. H. Robertson and A. Hisey have recently made an extensive experimental study on the nature of the Nessler color and conclude that it is due to colloidally dispersed particles in suspension and not in true solution (private communication);" it is believed, in general, that an ammonia-free Nessler reagent has a slight yellow-green color definitely distinguishable from distilled water. In fact, the American Public Health Association liquid standards for ammonia nitrogen call for an addition of platinum salt (standard) to make the 0.00 standard. From the previously quoted statements, one would be led to believe that the color in a Nessler reagent is due to the presence of colloidal-like particles resulting from reaction with the ammonia present in the water used to make the reagent.

In the limited time that was available for experimental work on the filtration and ultrafiltration of a Nessler reagent, no success resulted in trying to get a colorless solution, and the filtered Nessler reagent gave results that were only 0.01 ppm lower than those obtained with unfiltered Nessler reagent. Filtrations were made through 12 sheets of quantitative filter paper and through very thick mats of asbestos. Experiments with cellophane in a

silver-plated steel ultrafilter, using nitrogen, resulted in accelerating the formation of a precipitate in the solution, instead of obtaining further clarification. Normally a precipitate forms in a Nessler reagent with the passage of time. Considering the complexities arising from attempting to filter a strongly alkaline liquid by ultrafiltration, it was decided not to attempt further experimentation along this line.

Sensitivity of the Nessler Reagent

Wirth and Robinson (33) point out that a zero blank does not necessarily mean there is no ammonia present but, as they determined experimentally using distilled water and the "standard methods" reagent, that 0.02 ppm or less of ammonia nitrogen is present. However, since they apparently prepared their ammonia-free water by simple distillation, it is quite possible that their minimum of 0.02 is actually somewhat higher.

Experimental Results

For the purpose of simplifying the determination of ammonia by the Nessler method, La Motte liquid standards and reagents were tried. Comparison of solutions was made in a La Motte-Nessler tube comparator. Ammonia-free water, an ammonium-chloride standard, and a Nessler reagent were prepared for comparison of results.

Using 1 ml of Nessler reagent per 50-ml sample and a 10-min reaction time as recommended by the American Public Health Association Standard Methods of Analysis (34), the results seemed definitely to limit the sensitivity of the determination. Using our ammonia-free water, it took 0.05 ppm of added ammonia nitrogen to give any indication of ammonia when compared with the La Motte standards. After considerable testing we decided to use 2 ml Nessler reagent per 50-ml sample and compare after 30 min. Tests were made in Nessler tubes, which were then closed with rubber stoppers. We used ordinary Nessler tubes after we had tried Nessler tubes as advocated by Powell (4) and found that we obtained the same results in both types of tubes. Where the sample to be collected was freely flowing, we caught the solution in an open Nessler tube by allowing it to flow under constant head into the bottom of the tube and then to overflow until the sample was ready to be tested. A flow of about 90-ml per min, for 30 min, was used. For accurate work, we checked and prepared anew, if necessary, the ammonia-nitrogen liquid standards used with a given Nessler reagent. It is quite simple to add ammonia nitrogen to ammonia-free water to make a series of standards and we prefer this procedure.

Electrolytic-Conductivity Correction for the Presence of Ammonia in Condensed Steam

The "ammonia correction" was determined by actual full-plant test. The data are presented in Table 10 and shown graphically in Fig. 3. Ammonia was introduced into the boiler-feedwater suction.

The slope of the line obtained in Fig. 3 gives 1 ppm ammonia nitrogen = 8 micromhos. Extrapolation to zero ammonia gives an extremely low electrolytic conductivity for gas-free condensed steam. From the pH value of the condensate and the known equilibrium existing between the bicarbonate and carbonate ions, it is probable that the ammonia exists in solution in combination with the bicarbonate and carbonate ion.

Determination of Ammonia Volumetrically With Sodium Hypobromite and Naphthyl Red

In order to check the results obtained by the Nessler method for the concentration of ammonia in condensed steam, we have considered other methods of analysis. As a result, we have investigated the oxidation of ammonia by sodium hypobromite, using naphthyl red as an indicator (30, 35). The method has demonstrated excellent possibilities but, as yet, has not been applied to routine testing. The reactions taking place are:

$$2\ NH_3 + 3\ NaBrO = 3\ NaBr + 3\ H_2O + N_2$$

$$NaBrO + \text{naphthyl red} = NaBr + \text{colorless product}$$

The reaction is very sensitive; 1 ml 0.0005 N naphthyl red being equivalent to approximately 1.9 gamma ammonia nitrogen (1 gamma = 0.001 mg).

The procedure as developed by the authors for use in determining ammonia in condensed steam is as follows:

Reagents (use ammonia-free water):

- 0.1 N NaOBr—2.5 g NaOH, 1.25 ml bromine, dilute to 500 ml
- 2 N Na_2CO_3—106 g per l
- 0.001 N NaOBr—dilute 0.1 N NaOBr using 5 ml 2 N Na_2CO_3 per 500 ml
- 4 per cent HBr—24 ml 48 per cent HBr, dilute to 200 ml
- $(NH_4)_2SO_4$—0.4716 g per l; dilute 1 ml to 100 ml; 1 ml = 1 gamma ammonia nitrogen
- 0.0005 N naphthyl red—30 ml glacial acetic acid, 3.75 ml 89 per cent H_3PO_4, 1.9 ml 25 per cent HBr, 10.5 ml freshly prepared 0.1 per cent solution of naphthyl red in water, water to 500 ml.

Procedure:

1. Take 10-ml sample for test in 25-ml Erlenmeyer flask
2. Add 2 ml 0.001 N NaOBr (exact); shake for ½ min
3. Add 0.2 ml 4 per cent HBr and shake
4. Add naphthyl-red solution from a microburette until just visible red color appears while sample is being shaken after addition of reagent; calculate ammonia-nitrogen

TABLE 10 EFFECT OF ADDING AMMONIA TO BOILER FEEDWATER ON THE ELECTROLYTIC CONDUCTIVITY OF CO_2-FREE CONDENSATE[a]

Electrolytic conductivity, micromhos	Ammonia nitrogen found, ppm	Remarks
1.29	0.17	Aug. 31, normal operation
6.60	0.83	Introduced NH_3
2.00	0.25	Discontinued NH_3
1.36	0.15	
4.21	0.50	Introduced NH_3

3.27	0.40	
1.17	0.16[b]	Sept. 1, reflux condenser in
1.20	0.13[b]	
0.86	0.08[c]	Reflux condenser out
0.90	0.10[c]	

[a] Readings taken on the half hour; 2 ml Nessler reagent used; readings taken after 30 min.
[b,c] Different dilutions.

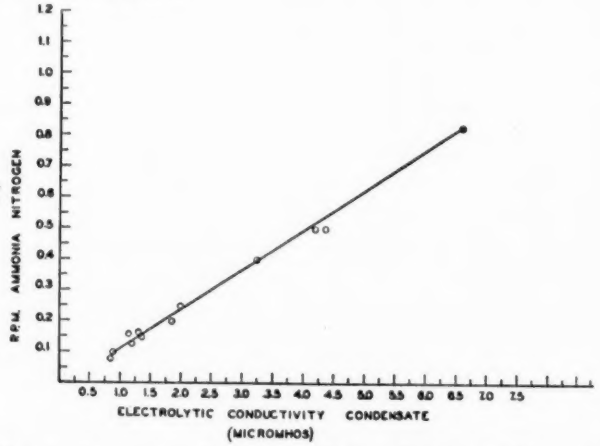

Fig. 3 Results of Full-Plant Test to Determine "Ammonia Correction"

concentration from naphthyl-red factor as obtained under standardization; 1 gamma per 10 ml = 0.1 ppm.

Standardization:

A Take 10-ml sample of ammonia-free water and follow procedure

B To 1 ml ammonia-nitrogen standard add 9 ml ammonia-free water and follow procedure.

Sample calculation:

a 10 ml ammonia-free water require 2.10 ml naphthyl-red solution

b 1 gamma ammonia nitrogen requires 1.60 ml naphthyl-red solution

0.5 ml naphthyl-red solution is equivalent to 1 gamma ammonia nitrogen

1 ml naphthyl-red solution = 2 gamma ammonia nitrogen.

The time required for a titration is only a matter of a few minutes. The standardization of the naphthyl-red-ammonia-nitrogen factor should be made at least every day because the solutions are not stable. Since the standardization is so easily made, our practice has been to make it twice daily if tests are made during an entire day. The constant check obtained by frequent standardization serves a useful purpose. Our results have shown that the method is good in the region 0.1 to 0.3 ppm ammonia nitrogen. In that range results are reproducible to within 0.02 ppm or less, as shown in Table 11. For solutions containing 0.5 gamma or 0.05 ppm ammonia nitrogen, the naphthyl-red factor deviates from the constancy shown at higher concentrations. Krogh (35) states that it is advisable to reduce the volume of hypobromite used when working regularly with amounts of ammonia nitrogen less than 1 gamma.

TABLE 11 TEST RESULTS

Ammonia nitrogen	Ppm	Naphthyl-red-solution factor in gamma ammonia nitrogen	
1 gamma	0.1	1.79, 1.88, 2.00, 1.85	1.88 avg
2 gamma	0.2	1.80, 1.96, 1.90	1.89 avg
3 gamma	0.3	1.96, 1.90, 1.91	1.92 avg

ACKNOWLEDGMENT

The authors wish to thank H. C. Leonard, vice-president of the Gulf States Utilities Company and Dean L. J. Lassalle, director of the Engineering Experiment Station, Louisiana State University for permission to publish this material. Grateful acknowledgment is made to E. B. Powell, consulting engineer of Stone and Webster Engineering Corporation, and to S. T. Powell, consulting chemical engineer, for their advice, highly valued suggestions, and encouragement throughout the course of the work being reported. Members of the chemical staff of the Gulf States Utilities Company assisting in this research were L. Young and J. C. Hill.

Determination of Purity of Steam by the Electrolytic-Conductivity Method

By W. B. GURNEY,[1] M. C. SCHWARTZ,[2] and T. E. CROSSAN[3]

In order to assure correct boiler operation and to evaluate the effect of changes in water treatment or boiler design on purity of steam being delivered, it is essential to be able to measure any contamination that may occur. This paper, which is the last of three papers by the authors on the subject of steam purity, gives the procedure for making a practically continuous determination of steam purity by the only satisfactory method thus far available. In this method the electrolytic conductivity of the condensed steam is measured and then converted to a solids basis. The distillation and the gravimetric methods are also discussed by the authors.

THERE are two important and practical reasons for measuring the purity of steam: (*a*) To determine the extent of carry-over or steam contamination during normal operation so that correctness of operation may be maintained at all times and any irregularity detected at once; (*b*) to evaluate the effect of any changes in water treatment or of any changes in the mechanical design of the boiler on the purity of steam being delivered. Therefore, any method of measuring steam purity must be capable of practically continuous determination in order to be of real value. Thus far, the only method that is able to meet this requirement is one in which the electrolytic conductivity of the condensed steam is measured and thereupon converted to a solids basis by means of the proper calculations and corrections.

If either operation, a change in water treatment or a change in the mechanical design of the boiler, is such as to result in priming or a condition approaching that state, the increase in electrolytic conductivity of the condensed steam is sufficiently great to be readily recognized as such. It is only when conditions are such that the steam contamination is quite low, less than 1 ppm, and remains at nearly that value after various changes, that the electrolytic-conductivity method and other methods encounter difficulties in evaluating the results of the changes. It is understandable why there will be difficulty in securing the necessary accuracy when it is observed that condensed steam, containing 0.5 ppm solids, is 99.9995 per cent pure.

Procedure for Determining Steam Purity by Electrolytic Method

The following procedure has been employed for determining steam purity by the electrolytic method:

1 Determine the cell constant of the conductivity cell with a solution of potassium chloride at constant temperature. All electrolytic-conductivity values are referred to 25 C or 77 F by use of the temperature compensator on the conductivity meter.

2 Remove carbon dioxide and some ammonia from the steam sample by passing it through the degasifier. If the pH of the condensed-steam sample rises from the acid to the alkaline side on degasification, removal of carbon dioxide is indicated.

3 Observe the temperature of the condensed-steam sample. Adjust the conductivity meter to correct for the measured cell constant and temperature. Measure the electrolytic conductivity of the condensed steam.

4 Determine the carbon dioxide and ammonia in samples of condensed steam collected at the same time.

5 Compute the conductivity correction due to the presence of ammonia and carbon dioxide, if any; subtract these from the measured conductivity.

6 Subtract the value 0.05 micromho, that of pure water, from the measured conductivity.

7 Compute the total solids in the steam by applying the proper factor to the corrected electrolytic conductivity of the condensed-steam sample.

For measuring the electrolytic conductivity of the condensed-steam samples, Leeds and Northrup Meter No. 4866 is satisfactory as a portable instrument. The instrument is equipped with cell-constant and temperature-compensator control dials. For continuous recording of conductivity measurements, we use a Leeds and Northrup meter with a range of 0 to 2 micromhos in steps of 0.02 micromho. The adjustment for cell constant and temperature, however, is manually controlled. It is possible to compensate for temperature changes automatically by using resistance thermometers, equipped with auxiliary slide-wire drums which can be connected in the bridge circuit of the recording conductivity meter and thus correct for any variation from 77 F. A glass dip-type conductivity cell, having a cell constant not greater than 0.1 is used. The electrodes are platinized platinum.

Potassium-chloride solutions are universally accepted as standard reference solutions for electrolytic measurements. Jones and Bradshaw (1)[4] have prepared potassium chloride as follows: "The purest material available by purchase was recrystallized several times with centrifugal drainage. Qualitative chemical tests for magnesium and sulphate (the most likely impurities) gave negative results. The salt was fused in a platinum crucible, poured into a platinum dish, and transferred to a closed bottle while still hot. The salt showed no tendency to gain in weight by absorption of moisture when allowed to stand on the balance." Jones and Bradshaw (1) have considered the preparation of potassium-chloride reference solutions and, as a result of painstaking work, have recommended the following value for an approximately 0.01 N solution, which is the most dilute solution they considered. The solution is precisely defined as follows: 0.745263 g of KCl per 1000 g of solution in vacuum. At 25 C the conductivity is 1408.77 micromhos. For preparing the standard solution, Jones and Bradshaw recommend using conduc-

tivity water prepared in contact with air. Such water will have a specific conductance of approximately 1 micromho at 25 C. The conductivity of the water used should be measured in advance and subtracted from the measured conductivity of the solution. It is desirable to have available a more dilute standard reference solution but, presumably, none has been prepared and measured with the exactness with which Jones and his associates have done for the more concentrated potassium-chloride solutions. Powell (2) states that a 0.0001 N potassium-chloride solution has a specific conductance of 15.27 micromhos at 25 C.

Removing Carbon Dioxide and Ammonia From Condensed Steam

The removal of carbon dioxide and ammonia from condensed steam is difficult. Available methods have been considered by the authors (3). An apparatus, represented in Fig. 1, has been developed for this purpose. So far as the authors have been

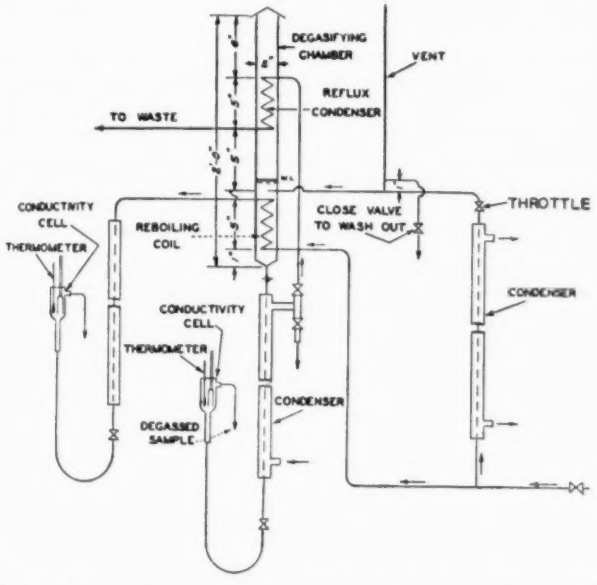

Fig. 1 Arrangement of Apparatus for Removing Carbon Dioxide and Ammonia From Condensed Steam

able to determine by the use of this system, carbon dioxide is removed to the extent that only undetectable amounts remain. Removal of ammonia, however, is incomplete. The pH of the condensed steam, measured with a glass electrode, is on the alkaline side. Steam is sampled with the standard A.S.M.E. sampling nozzle (4) installed in the main steam header close to the boiler. From a steel shutoff valve it is then conveyed in stainless-steel tubing to a tee where part of the steam passes directly to a copper reboiling coil in the copper degasifying chamber. From there the steam passes to a copper condenser. In addition to the dissolved or suspended solids present, this condensed-steam sample contains any soluble gases present in the steam and is referred to as the straight-through sample. It gives a prompt indication of changes in steam composition. The sample passes through a Pyrex-glass holder which contains a thermometer and a conductivity cell.

The remaining portion of steam from the tee passes through a stainless-steel condenser for partial cooling and from there into the copper degasifying chamber. Upon coming in contact with the steam-heated reboiling coil, the condensed steam again boils violently. Dissolved gases are flashed out and steam serves also as a scrubbing medium to assist in removing soluble gases. A copper reflux or vent condenser condenses any steam that might escape along with the dissolved gases and thus eliminates any increase in concentration in the degasifying chamber. A vent and overflow line assist in maintaining a constant water level in the degasifying chamber. The cover on the degasifying chamber fits loosely.

The degassed condensed steam issuing from the degasifying chamber is further cooled by passing it through another stainless-steel condenser from which it passes into a Pyrex-glass holder containing a thermometer and conductivity cell. This sample is referred to as the degassed sample.

The steam flow should be about 280 ml per min. The flow from the reboiling coil should be about 150 ml per min. The flow of degassed condensed steam should be about 80 ml per min. These flows are approximate for 720-F steam. Steam at other temperatures requires variation in flow through the reboiling coil.

The copper reboiling coil is made of $^1/_4$-in. tubing, $10^1/_2$ turns, and $1^1/_2$ in. diam. The copper reflux coil is made the same as the reboiling coil. With respect to the materials suitable for conveying steam and condensate with minimum contamination, it has been our experience that stainless steel is most suitable for high-pressure high-temperature steam, and copper is satisfactory for condensate if a suitable flow is maintained.

In testing for the presence of carbon dioxide in the condensed steam, it is customary to use N/44 or N/50 sodium hydroxide and a sample of at least 250 ml. One or two drops are usually sufficient to give a pink color with phenolphthalein. Under these conditions, the amount of carbon dioxide present is considered negligible. For determining ammonia in condensate, we have used both the colorimetric Nessler method and the volumetric sodium-hypobromite-naphthyl-red method, described in another paper (3). It is important to note that the relative-conductivity corrections to be applied for residual carbon dioxide and ammonia in the condensed steam are approximately in the ratio of 1 to 10 per ppm of each present. It is thus evident that, not only does ammonia affect the results more appreciably, but the residual ammonia must be determined with an accuracy of 0.01 ppm.

Our experience with the degasifier has indicated that no detectable amounts of carbon dioxide remain in the condensed steam, therefore no correction to the measured electrolytic conductivity has been applied in this respect. The value of 1 ppm ammonia nitrogen = 8 micromhos (25 C), which, as we have determined experimentally, agrees well with currently used values (2).

To convert electrolytic-conductivity measurements to ppm dissolved solids, the procedure has been as follows: Small increments of boiler water are added to degassed condensed steam. The total solids in the boiler water are determined gravimetrically. Providing the concentration increments are kept small, the linearity of the relationship between ppm solids and electrolytic conductivity is assured. A typical calibration is shown in Table 1.

TABLE 1 TYPICAL CALIBRATION OF ELECTROLYTIC-CONDUCTIVITY MEASUREMENTS

Boiler water added, ml	Solids added, ppm	Conductivity, micromhos
0.00	0.00	0.82
0.10	0.32	1.49
0.20	0.64	2.09
0.40	1.28	3.38

Boiler water 1601 ppm.

Fig. 2 represents the plotted results. The slope of the line gives the factor for converting micromhos to ppm; in this case it is 1 micromho = 0.5 ppm dissolved solids (25 C).

A typical calculation for degassed condensed steam follows:

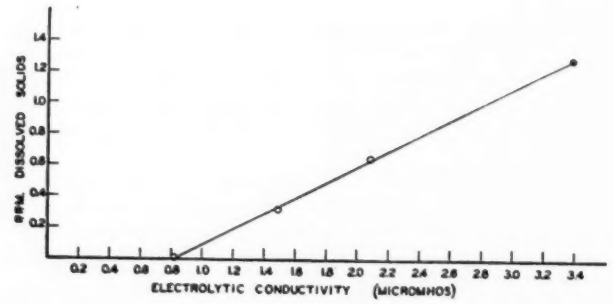

FIG. 2 RELATION BETWEEN PPM DISSOLVED SOLIDS AND ELECTROLYTIC CONDUCTIVITY

1.37 micromhos, measured conductivity; 0.14 ppm ammonia nitrogen; no carbon dioxide; dissolved solids in condensed steam = $(1.37 - 1.12 - 0.05) \times 0.5 = 0.10$ ppm.

DISTILLATION METHOD

Place (5) has recommended distilling a given volume of condensed steam in a glass still and measuring the electrolytic conductivity of the solution remaining in the distilling flask. The portion to be distilled is that sufficient to remove the volatile impurities. Then, providing no dissolved solids have been added from the glassware during the distillation, the remaining liquid will contain only the dissolved solids originally present in the sample. Place, however, considered carbon dioxide as the only gaseous impurity in the solution. As the authors' tests have shown, it is not possible completely to remove ammonia by simple distillation. Ammonia should therefore be determined in the solution remaining in the flask and the proper correction applied for its presence. A typical distillation on a sample of degassed condensate is given in Table 2 (it is not necessary to take a degassed sample for distillation).

TABLE 2 TYPICAL DISTILLATION OF DEGASSED CONDENSATE SAMPLE

Distilled, ml	Conductivity, micromhos	Ammonia nitrogen, ppm
0	0.71	0.07
73	1.15	0.10
71	0.99	0.07
67	0.955	0.07
71	0.875	0.06
67	0.72	0.03
73	0.60	0.01
64	0.50	0.01
65	0.42	0.01
65	0.37	0.01
59	0.35	0.01
Residual volume 83	Residual volume 2.56	Residual volume 0.03 (Total volume 758 ml)

Corrected conductivity of dissolved solids
$= [2.56 - (0.03 \times 8) - 0.05] \times (83 \div 758) = 0.25$

Dissolved solids $= 0.25 \times 0.5 = 0.125$ ppm

GRAVIMETRIC METHOD

In another paper (6), certain values for total solids in condensed steam, obtained by evaporation and weighing, are given. Examination of the residue disclosed appreciable amounts of iron which originally were presumably not in solution but in suspension and hence would not affect the conductance of the sample. More direct evidence was found by adding pure water to the residues in the platinum dish and obtaining the increase in conductivity. On the basis that 1 micromho = 0.5 ppm dissolved solids, the results given in Table 3 were obtained. These values are in line with those derived from more direct electrolytic-conductivity methods.

TABLE 3 VALUES FOR TOTAL SOLIDS IN CONDENSED STEAM BY EVAPORATION AND WEIGHING

From Bibliography (6)	Condensed	Dissolved solids, ppm
Table 2, No. 6(a)	Superheated steam	0.13
Table 2, No. 6(b)	Superheated steam	0.10
Table 2, No. 7	Saturated steam	0.05
Table 2, No. 8	Saturated steam	0.05

ACKNOWLEDGMENT

The authors wish to thank H. C. Leonard, vice-president of the Gulf States Utilities Company and Dean L. J. Lassalle, director of the engineering experiment station, Louisiana State University for permission to publish this material. Grateful acknowledgment is made to E. B. Powell, consulting engineer of Stone and Webster Engineering Corporation, and to S. T. Powell, consulting chemical engineer, for their advice, highly valued suggestions, and encouragement throughout the course of the work being reported. Members of the chemical staff of the Gulf States Utilities Company, assisting in this research, were L. Young and J. C. Hill.

Discussion[1]

D. S. MCKINNEY[2] AND MAX HECHT.[3] In papers Nos. 1 and 3 the authors have made valuable contributions to the analysis of water of high purity, and to the application of conductivity methods to such water. For the sake of completeness, and for a better understanding of the technique used, some details should be amplified. For example, the drying temperature, which determines the degree of hydration of the weighed residue, is not given. The method of protecting the residue from hydration or carbonation during weighing is not described.

Examination of Table 1, in first paper, indicates that the residue was weighed to 0.1 mg. In view of the small quantity of material, it would seem advisable to weigh the residue to 0.01 mg. McKinney, in a discussion[4] of Ulmer's paper describes a method for securing this sensitivity at relatively low cost with an analytical balance.

DISCUSSION OF THIRD PAPER

Although numerous investigators have measured contamination in steam, few have considered the problem of proper sam-

[1] This is a combined discussion of the series of three papers on the general subject "Determination of Purity of Steam," by M. C. Schwartz, W. B. Gurney, and T. E. Crossan. These papers will be referred to in the discussion as first, second, and third, corresponding to the order in which they are published.

[4] "Determination by the Evaporation Method of Small Amounts of Dissolved Solids in Water Such as Condensed Steam From Boilers," by R. C. Ulmer, discussion by D. S. McKinney, Proc. A.S.T.M., vol. 39, 1939, p. 1228.

pling. It should be emphasized that the sample is secured from a heterogeneous system, i.e., steam containing suspended solid or liquid particles. In order to secure a representative sample from such a system, it is essential that the velocity of the steam entering the openings of the sampling nozzle be identical with that of the main body of the steam approaching the openings. If the sample is withdrawn too rapidly, too great a proportion of steam is obtained, if too slowly the proportion of suspended liquid or solid will be too high. It is pertinent to ask if the authors have met this requirement.

The writers wish again to call to the attention of those interested in conductivity measurements, that the relation of total solids to specific conductance is likely to be much more variable than the relation of dissolved salts to specific conductance. The authors apparently do not distinguish between the terms total solids and dissolved salts as indicated by their method of calibration. In Table 2 of the third paper, the authors determine gravimetrically the total solids in one sample of boiler water to obtain the relation between solids in the steam and conductivity. It should be noted that an unknown fraction of the boiler solids are nonconducting (Fe_2O_3, SiO_2, etc). Furthermore, the fractions of nonconducting material may vary considerably during the normal run of a boiler. Yet in Table 3, the same factor is used to calculate the soluble portion of the evaporated residue from steam samples, which was found to be only about one third of the weight of evaporated residue.

It is suggested that the dissolved salts in the boiler water should have been made the basis of the calibration. This point was discussed extensively in an earlier paper[4] by the writers and re-emphasized in the discussion by Hecht of Ulmer's paper.[6]

Various factors for calculating dissolved substances in water from conductivity measurements have been reported in the literature. Reference to Table 9 of the writers' paper[7] shows that, with the exception of H and OH, all common ions in water have specific conductances per ppm between 1.14 micromhos for NO_3 and 2.99 micromhos for Ca^{++}. For OH^- the value is 11.3 and for H^+ 347 micromhos per ppm; all values being referred to 25 C. It is obvious that variations in H and OH concentrations will materially affect the relation of dissolved salts to conductances. It should therefore be emphasized that the factor reported for specific plants applies only to those plants. In general the appropriate factor will depend upon the water supply and its treatment.

E. B. Powell.[8] The authors have demonstrated the practical feasibility of power-plant measurement of solids carry-over in proportions as low as 0.1 ppm, and have described procedures by which a highly creditable approach to precision can be maintained in such measurements continuously. The electrolytic-conductivity method obviously does not give a direct measure of total solids to be encountered in condensed steam. Extensive work on corrections and calibrations, given special impetus by that of Hecht and McKinney,[5] now regarded as a classic in the power-plant field, has been carried on more or less continuously over the last 10 years. Statistical data are not yet available to cover correction factors for all water conditions. However, by securing appropriate calibrations for different water conditions to be met, following the general procedures described by the present authors, it is entirely practicable to set up data from which the individual plant can interpret the conductivity values in terms of actual solids carry-over to the degree of precision mentioned. The ability to measure is indeed an important factor in the ability to control, and the solids in steam are no exception. The authors' contribution will be decidedly welcome to the industry.

S. T. Powell[9] and H. E. Bacon.[10] The steam-quality data presented in this series of papers indicate the unusually low soluble-solids concentration of about 0.1 ppm, yet they are confirmed by conductivity, gravimetric, and spectrographic measurements. The authors have certainly shown to the satisfaction of the most critical reviewers that the total solids in solution in the samples tested were less than 0.2 ppm. This demonstrates that, if currently accepted specifications for steam quality are changed in the direction of higher purity, it is entirely feasible to apply tests which will give meaning to the specifications.

There can be no doubt that the more critical operation of high-pressure boilers requires a specific knowledge of steam quality, which, to be of value, should cover the full range of possible operating conditions. Each of the variables, such as boiler-water concentrations, water levels, and steam flow should be changed one at a time to develop a basis for predicting performance under all conditions. This requires evaluation of the carry-over at frequent intervals, or preferably continuously, which precludes the use of gravimetric determination and leaves no other recourse except estimating solids by conductivity methods. Qualitative measurement, where carry-over is appreciable, presents no problem. The major difficulties, and magnification of all inaccuracies, become increasingly great with improved quality of steam.

Methods for measuring the purity of steam have primary significance in performance tests covering a limited period, but their utility for routine control of operations may be quite valuable. Permanent and continuously recording steam-conductivity apparatus has enabled the operators of one large plant to increase boiler-water concentrations from a tentative limit of 2500 ppm to 3500 ppm as the standard for controlling the plant. The availability of instantaneous indications of carry-over may thus permit the exploration of numerous changes in operation which promise greater economy and efficiency. In such cases, the refinements described by the authors and corrections for dissolved gases are not practicable except for brief periods when highly accurate tests are desired. However, the operators soon learn to discount even large errors from such recognized sources and to correlate the meter charts with actual operating conditions. At the plant mentioned, the conductivity of the boiler blowdown is also recorded to provide a check on boiler-water concentrations.

The experience of the writers has been almost entirely with the vacuum type of steam-sample degasifier. The residual ammonia left by this equipment is of the same order of magnitude as that cited by the authors for the reboiling type of degasifier. The vacuum apparatus, for which the practical application has been described previously,[11] operates for long periods with very little attention. It would be of interest to have the authors suggest the important details in using their apparatus for continuous operation in routine plant control.

In testing condensed steam for ammonia in the atmosphere of most steam-generating stations, it is almost impossible to make and preserve large quantities of ammonia-free water. We have found the use of Folin's ammonia permutit to be satisfactory for preparing water to be used in making up ammonium-chloride

standards. These are only used, however, in the adjustment of permanent standards for each new batch of Nessler reagents.

We hold no brief for conductivity measurements as providing absolute accuracy, realizing the deficiencies that exist. From our experience, however, we are convinced that steam-station operators now have available a means for closely estimating the performance of the boiler with respect to steam quality. Further improvement in apparatus for such measurements presents a worth-while problem for future study.

ALFRED WATSON.[12] In the application of the electrical-conductivity method to the determination of the purity of steam, the most perplexing problem has been the separation of the effect of dissolved solids from that of the ionized dissolved gases, such as ammonia and carbon dioxide. Various investigators have alternated between the two main lines of attack: (1) Measurement of the concentrations of ammonia and carbon dioxide, calculation of the increment of conductivity due to these concentrations, subtraction of this value from the observed conductivity, and calculation of the residual conductivity into terms of dissolved salts; and (2) physical elimination, in so far as possible, of dissolved gases before measurement of the conductivity, followed by direct calculation of the latter into terms of dissolved salts.

Application of the first method has been hampered by uncertainty as to the corrections to be applied when both ammonia and carbon dioxide were present in the sample of condensate; application of the second by the difficulty of removing all the ammonia by any practical means. The authors have offered the compromise of removing substantially all of the carbon dioxide and part of the ammonia, so that correction need be made only for low residual concentrations of ammonia.

While equipment for degasification of condensed-steam samples may well form part of the permanent testing equipment in a large central station or industrial steam plant, it is inconvenient to transport from plant to plant. The engineer engaged in field tests is predisposed, therefore, to rely upon the first method of leaving the ammonia and carbon dioxide in the sample, and to develop as accurate a means as he can for correcting his observed values for conductivity in the light of his analyses for these gases.

Offhand, it might seem suitable in making correction for carbon dioxide and ammonia to read off from the specific-conductivity curves of each, respectively, that conductivity value corresponding to the determined concentration, to add these two values, and to subtract the total from the observed conductivity of the sample regarding the difference as the conductivity due to dissolved solids.

In a great many instances quite anomalous values have been obtained through the use of this method of correction. The most common anomaly is that of a negative value when the total correction is subtracted from the observed conductivity. Such a value is, of course, an impossibility. Wherein does the error lie?

It is the writer's opinion that the method often followed of making separate corrections for ammonia and for carbon dioxide and then totaling these two values is incorrect, because it neglects the fact that the sample of water can have one and only one pH value and one equilibrium between the various ions for the conditions which existed when the conductivity was measured. Actually, since ammonia is a base and carbon dioxide an acid in solution, with different relative amounts of these two, the relative concentrations of H^+, NH_4^+, OH^-, HCO_3^-, and CO_3^{--} ions in the sample will vary. The specific conductivity of OH^- ion is, however, nearly 3 times, and that of H^+ ion 5 times that of NH_4^+, HCO_3^-, or CO_3^{--} ions. Correction values obtained from the separate specific-conductivity curves of carbon dioxide and ammonia, determined respectively at low and at high pH values, cannot be consistently correlated, since these curves have no community of pH value, either with each other or with the sample to which the correction is to be applied. Therefore, it is not permissible to add such separate corrections and subtract the total from the specific conductivity of the sample.

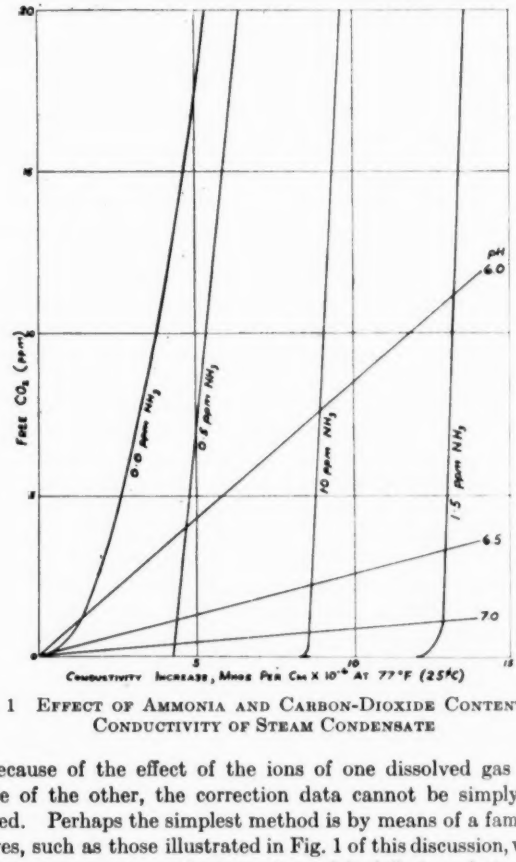

FIG. 1 EFFECT OF AMMONIA AND CARBON-DIOXIDE CONTENTS ON CONDUCTIVITY OF STEAM CONDENSATE

Because of the effect of the ions of one dissolved gas upon those of the other, the correction data cannot be simply presented. Perhaps the simplest method is by means of a family of curves, such as those illustrated in Fig. 1 of this discussion, which give the increase in conductivity for widely differing relationships of carbon dioxide and ammonia in the sample at its resultant pH value. These curves, based on the dissociation constants of carbonic acid and ammonium hydroxide, represent equilibrium conditions.

[12] Hall Laboratories, Inc., Pittsburgh, Pa.

The curves of Fig. 1 are expressed in terms of ammonia and of "free" rather than total carbon dioxide, as determined by standard methods. The most significant feature is the extremely slight effect of carbon dioxide upon the conductivity when ammonia is also present and the pH value is below 7.

The suggested procedure for testing a sample of steam condensate is as follows:

1 (*a*) The concentrations of "free" carbon dioxide and ammonia in the sample are determined by recognized standard methods.[13]

(*b*) The pH value of the sample may be determined by the glass electrode, as with Coleman electrometer Model 3D, or Leeds and Northrup No. 7661-A1, or equal.

2 In case the content of "free" carbon dioxide is zero or negative, or the pH value exceeds 7, for the most accurate work it will be advisable to adjust the "free" carbon dioxide to an adequate excess or the pH to below 7 by means of pure carbon dioxide, and recheck the ammonia content.

3 The specific conductivity of the sample under these conditions is obtained by means of a conductivity-resistivity indicator, such as Leeds and Northrup No. 4866, or equal.

4 The correction for dissolved gases is read from a chart of the type of Fig. 1 of this discussion, and subtracted from the observed conductivity.

5 The corrected conductivity is converted into ppm of dissolved salts by the use of a suitable factor.

Table 1 with this discussion, presents data on conductivity, ammonia, and carbon dioxide, obtained in a plant test on steam quality. In this case columns 5 and 6 give the correction values and the dissolved solids, respectively, when separate correction factors for carbon dioxide and ammonia were used, neglecting the fact that the sample could only have one pH value. Columns 7 and 8 give the values obtained when the correction value was read off from the curves of Fig. 1. It is notable that in the former case the value for dissolved solids is negative in every case but one—an obvious impossibility. In the latter all values are on the positive side.

The suggestion of adding carbon dioxide to a sample of steam condensate instead of removing it may seem unorthodox, but is as fundamentally sound as the data for the dissociation of carbonic acid and ammonium hydroxide. It should be kept in mind that the curves of Fig. 1 are calculated from these values in the literature, and the job of verifying them completely in practical determinations has only begun. We plan much further work along this line, and, finally, to present this entire subject in more complete form at a later date.

[13] "Standard Methods for the Examination of Water and Sewage," Eighth edition, American Public Health Association, New York, N. Y., 1936.

Authors' Closure

As Messrs. E. B. and S. T. Powell point out in their discussions, it has been demonstrated to be possible to determine, continuously, solids carry-over in steam in proportions as low as 0.1 ppm. The authors feel that they have contributed to this important power-plant problem. The variety of conditions found in different plants and the requirements of different individuals, as pointed out by Mr. Watson, seems to indicate that considerable flexibility will be required in test methods. Under such circumstances, the problem of carry-over measurement must be attacked from all angles.

The drying temperature for gravimetric determination of total solids residue, requested by Messrs. McKinney and Hecht was 110 C. The weight of the residue upon successive weighings, involving the incidental transferring from desiccator to balance, did not change, indicating that hydration and carbonation were not taking place. It is possible to weigh the residue to 0.01 mg but the authors do not believe this accuracy is warranted at present. It is worth-while to point out the fact that the temperature between successive weighings should be practically constant. The question of steam sampling has been considered by the authors and suitable flow maintained to secure proper velocities. This phase of the problem has also been emphasized by S. T. Powell.[11] Messrs. McKinney and Hecht correctly indicate that dissolved solids rather than total solids should be made the basis of calibration for electrolytic conductivity versus dissolved solids. In the case of the Louisiana Station, the dissolved and total solids are substantially the same. The correspondence between gravimetrically determined dissolved solids, after subtracting the weight of nonconducting residue, and independently determined dissolved solids by conductivity measurement bears this out.

Mr. Watson's procedure for computing the correction to be applied to electrolytic-conductivity measurements by determining the ammonia and carbon-dioxide concentration in the condensed steam, adjusted to a pH equal or less than 7 with carbon dioxide, is quite interesting.

In conclusion the authors would again like to repeat: The problem of producing pure steam is of great importance and justifies the attention of all power-plant operators.

A Theoretical Investigation of Plastic Torsion in an I-Beam

By D. G. CHRISTOPHERSON,[1] OXFORD, ENGLAND

The distribution of stress in an I-beam in torsion is investigated by a method of successive approximation, and the regions of initial yielding are determined for several values of the angle of twist. Formulas are given for elaborating the methods of Southwell(1)[2] and of Shortley and Weller (2) in order to facilitate this determination.

The value of the stress-concentration factor in the fillets is found to agree well with results obtained by soap-film tests, and regions of plastic flow approximate closely those observed by MacGregor and Hrones (3) by the use of the etching method.

ACCORDING to the standard theory, the problem of the torsion of a prismatic bar reduces to the determination of a function such that

$$\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\right) \phi = -2G\alpha \ldots\ldots\ldots\ldots [1]$$

where G is the rigidity modulus, α the angle of twist per unit length, and ϕ has boundary values everywhere zero.

Many writers have pointed out that an approximate solution to this equation may be obtained by transforming it into an equation of finite differences, in which the value of the stress function at any point is obtained in terms of its value at a number of surrounding points. The most usual procedure has been to cover the area under consideration with a rectangular grid,[3] to compute the value of ϕ at the nodes, and to argue that a surface passing through these points will have nearly the same properties as the actual stress surface, i.e., its contours and gradients will give the directions and magnitudes of the shear stresses, its volume being equal to one half the applied torque. In this procedure the value of ϕ is given in terms of four equidistant values by the equation

$$4\phi_0 = \phi_1 + \phi_2 + \phi_3 + \phi_4 + 2G\alpha h^2 \ldots\ldots\ldots\ldots [2]$$

where h is the length of the side of any square in the mesh.

Means of obtaining a rapid solution of such equations in bulk have recently been given by Southwell (1) and by Shortley and Weller (2), although the latter confine themselves to the solution of Laplace's equation $(\partial^2/\partial x^2 + \partial^2/\partial y^2)\ \phi = 0$

They also give an interpolation function in polynomial form

$$\phi = a_0 + a_1 r \cos\theta + b_1 r \sin\theta + a_2 r^2 \cos 2\theta + b_2 r^2 \sin 2\theta \ldots [3]$$

where r, θ are polar coordinates and ar, br, constant coefficients for use over any single square of the mesh, which affords an excellent basis for the deduction of formulas given later in this paper.

Southwell's solution, on the other hand, was applicable to Poisson's equation

$$\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\right) \phi = f(x, y)$$

where $f(x, y)$ was any continuous function whatsoever. In making this generalization some rapidity in the convergence of the solution was lost, but in the paper (1) referred to previously a number of problems were solved, including one which referred to plastic torsion.

This present paper was planned with a view to comparing this theoretical approach to the problem of plasticity with the experimental approach recently presented by MacGregor and Hrones (3). However, it has been found desirable to make use of certain formulas not contained in the earlier paper (1), which, it is believed, increase the accuracy obtainable by the use of a mesh of given size, and thus accelerate the convergence.

It is evident that Equation [2] can only be used exclusively when the section under consideration is such that it can be covered by exact squares. For all other sections it is necessary to develop an analogous relation between the ϕ's when the surrounding points are all at different distances h_1, h_2, h_3, and h_4, from the center, as shown in Fig. 1. This relation is

$$\left[\frac{1}{h_1 h_3} + \frac{1}{h_2 h_4}\right]\phi_0 = \frac{1}{h_1 + h_3}\left[\frac{\phi_1}{h_1} + \frac{\phi_3}{h_3}\right] + \frac{1}{h_2 + h_4}\left[\frac{\phi_2}{\phi_4} + \frac{\phi_4}{h_4}\right] + G\alpha \ldots [2a]$$

[3] An exception is Southwell's (1) triangular mesh.

Presented at the Annual Meeting, Philadelphia, Pa., December 4–8, 1939, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until April 10, 1940, for publication at a later date. Discussion received after the closing date will be returned.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

These are the only equations necessary to determine the required values of the stress function in the elastic problem. From these, with the assistance of the interpolation function given previously in Equation [3], the values of the gradients, hence of stresses, may easily be obtained. The volume, hence the torque, comes from the relation

$$\text{Volume of single square} = \left[\frac{\phi_1 + \phi_2 + \phi_3 + \phi_4}{4} + \frac{1}{6}G\alpha h^2\right] h^2$$

When we pass beyond the yield point, however, a different state of affairs obtains. It is first necessary to make a simplifying assumption with regard to the stress-strain curve of the material, and the idealized diagram shown in Fig. 3 is chosen. On this

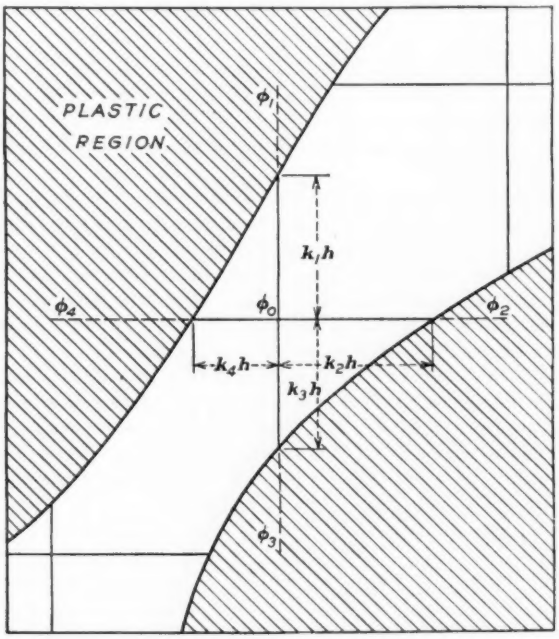

FIG. 2

assumption we may make use of the concept of a roof, or limiting value of the stress function, described by Nádai (4). The contours of this roof run everywhere parallel to the boundary of the section and the gradient is uniform and equal to the limiting shear stress.

On this understanding it is easy to compute the values of the ordinates of the Nádai roof over any section, and to make use of the overriding conditions that ϕ must not exceed these values. All that will then be required will be formulas, which provide relations between the ϕ's when some parts of the square under consideration fall in the plastic zone and some (including the central point) in the elastic.

Let us suppose that the limits of the plastic region lie at distances k_1h, k_2h, k_3h, and k_4h, as shown in Fig. 2 so that when the plastic region does not invade the square under consideration at all

$$k_1 = k_2 = k_3 = k_4 = 1$$

Then the relation which we require is

$$2\left(\frac{1}{K_1 + K_3} + \frac{1}{K_2 + K_4}\right)\phi_0 = \frac{\phi_1 + \phi_3}{K_1 + K_3} + \frac{\phi_2 + \phi_4}{K_3 + K_4} + G\alpha h^2 \quad [4]$$

where $K_1 = 2k_1 - k_1^2$, $K_2 = 2k_2 - k_2^2$, etc.

But for every link crossing the plastic boundary one new variable k will be introduced, so one more equation will be required. This equation is afforded by the fact that at the point of contact the stress surface ϕ is tangent to the roof, which has a known gradient. From this condition we deduce the equation

$$\phi_0[K_1 + K_3 + 2k_1^2] = k_1\phi_3 + (2k_1 + K_3)\phi_1 + (K_1 + K_3)\tau_0 h \sin\psi \quad [5]$$

In this equation ψ is the angle made by the link with the contour line of the roof at the point of contact; τ_0 is the maximum

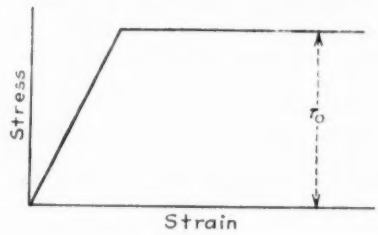

FIG. 3

shear stress as indicated in Fig. 3. There will be one such equation for every link crossing the boundary between the elastic and plastic zones, i.e., for every value of k required.

It is not proposed in this paper to enter into detail with regard to the means of obtaining a rapid solution of these equations. The processes used have been described fully in other papers (1, 2). It is therefore only necessary to consider means of dealing with the additional variables k, and the equations giving them.

Fortunately this presents little difficulty, for, if we bear in mind the condition that the stress function cannot have ordinates in excess of those of the roof, and that, when the elastic equations indicate that it does so, the point considered must fall in the plastic region, we may rapidly obtain an estimate of the boundaries of this region. Applying then equations of the type of Equation [4] only, we shall be able to determine values of ϕ everywhere, using the assumed values for k. Substituting these ϕ's in equations of the type of Equation [5] we can redetermine more exactly the limits of the plastic zone. It will be found that changes in these limits will produce only small or negligible changes in the vertical ordinates of the neighboring points. That this must be so may readily be seen from geometrical considerations. A small and nearly normal displacement of a surface tangent to a given plane produces a large change in the position of the line of contact.

The whole question of the accuracy and convergence of finite difference equations applied in this manner will not be gone into here. It is hoped that the degree of correlation with experimental evidence which has been obtained will be regarded as providing sufficient justification for the procedures used.

We are now at liberty to proceed to the consideration of the specific problem presented in this paper. Evidently, what in fact we need to determine is the extent to which orthodox (simple) theory is erroneous. For this purpose it is desirable to use as standard of comparison the simplest possible theory of the I-beam—that which assumes the beam to be built up of a number of independent rectangles, each of which is long enough in comparison with its breadth for end effects to be negligible.

On this understanding the relation between torque and twist is

$$T = \sum \frac{1}{3} b^3 l G\alpha \quad [6]$$

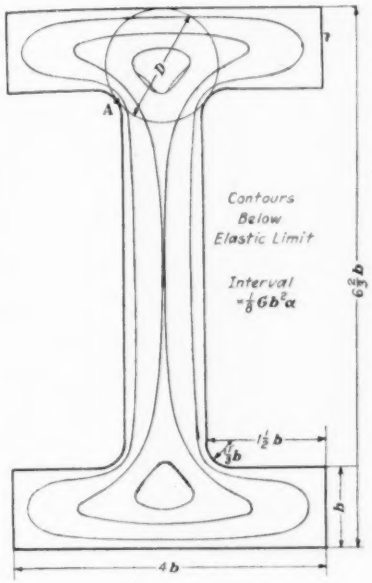

Fig. 4

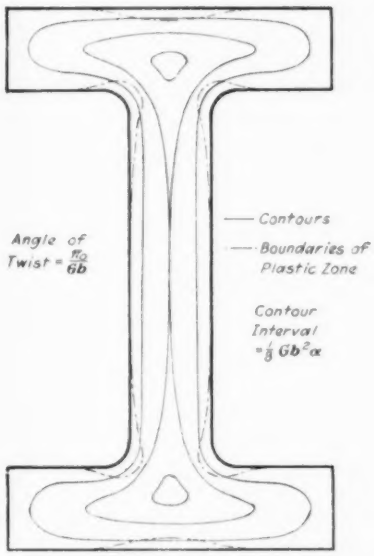

Fig. 5

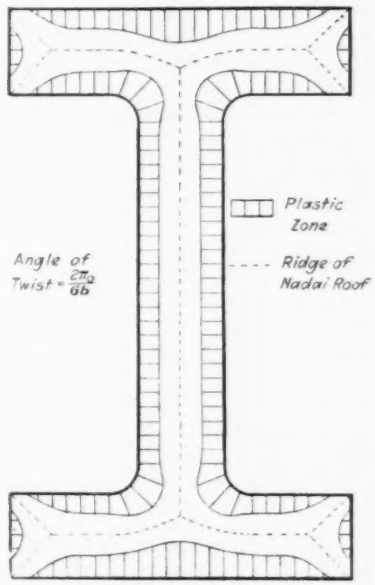

Fig. 6

where l is the length of a given rectangle and b is its breadth. Also the maximum stress in the section is

$$\tau = bG\alpha \quad \text{.....[7]}$$

Using these relations for comparison, we shall determine first, in the elastic region of the stress-strain curve, (*a*) the actual maximum stress in the fillets for a given angle of twist, and (*b*) the actual torsion modulus of the section; then, second, in the region beyond the elastic limit, (*a*) the extent and shape of the plastically deformed areas, for several values of the angle of twist, and (*b*) the torque-twist relationship beyond the elastic limit. The results are presented in this order.

Stress Concentration in Fillets

The maximum stress in the fillets was found to be

$$\tau_{max} = 1.85\, bG\alpha$$

giving a stress-concentration factor of 1.85 when referred to Equation [7]. The greatest stress occurred very near the point of contact of the inscribed circle, that is, at point A in Fig. 4. It is of interest to compare this result with that obtained by experiment on this section. Using the soap-film analogue, Ehasz (5) obtained a curve showing the value 1.90 for the dimensions here analyzed, and claimed an accuracy of 2 per cent. The earlier work of Griffiths and Taylor (6), although it is by no means so complete, appears to indicate a slightly lower value. On the whole, bearing in mind the fact that any errors which exist, either in experimental or in computational technique, are at their maximum in the determination of this quantity, the present author is satisfied with the results obtained.

Torsion Modulus for the Section

With regard to the torsion constant K in the equation

$$\text{Torque} = \alpha GK$$

the elementary theory as expressed in Equation [6] applied to this section gives the results

$$K = 4.222b^4$$

The more complex formula utilized by Lyse and Johnston (7)

$$K = \sum \frac{1}{3} b^3 l + 2\beta D^4 - 0.42016b^4$$

in which the constant β is determined from soap-film experiments gives the value

$$K = 4.748b^4$$

and the present investigation leads to the conclusion

$$K = 4.726b^4$$

While it is difficult to estimate the accuracy which can be guaranteed for the first of these two results it is believed that the difference between them (0.5 per cent approximately) is well within the limits of expected error.

Fig. 4 shows typical stress lines in the elastic region. This figure may be compared to Fig. 9 of a paper by Trayer and March (8) which is a similar contour diagram obtained by soap-film experiment; the similarity between the results of the two processes is very clearly demonstrated.

Regions of Plastic Flow

The boundaries of the plastic region where determined for an angle of twist

$$\alpha = \tau_0/Gb$$

which, according to the elementary theory expressed in Equation [7] would be the twist at the elastic limit, and for angles two thirds as great and twice as great as this. The results for the first and last of these determinations are given in Figs. 5 and 6.

In the second case the plastic area was found to be restricted almost entirely to the fillets, and an additional diagram was not considered necessary. Fig. 5 shows contours identical with those in Fig. 4 and is intended to indicate the effect of the onset of plasticity on the direction of stress in the fillets. It is noticeable in this figure that, while the angle of twist has been almost doubled since the elastic limit was reached, the plastic zone has not yet covered more than 10 per cent of the total area of the section.

Redoubling this angle, however, has the effect of producing a very much larger area of plasticity, as is shown in Fig. 6. This is intended to be compared with Fig. 8, for permission to repro-

duce which I am much indebted to C. W. MacGregor. The dark wedge-shaped marks on Fig. 8 indicate very clearly the regions of plastic flow obtaining in the experiment, as they may be observed by the etching method. It will be seen that the result of such a test agrees well in general shape with the result we have obtained by computation. In order to estimate the quantitative significance of the comparison, we must first consider the torque-twist relation for the section, which is given in Fig. 7.

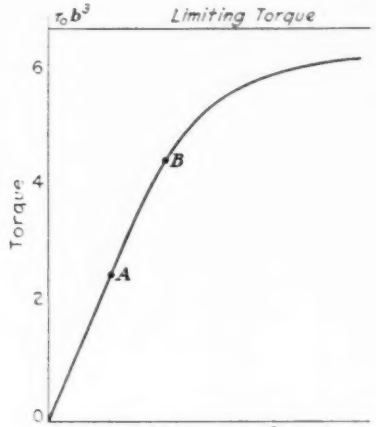

FIG. 7

We have assumed a stress-strain diagram, shown in Fig. 3, which has no true yield point, in the sense that there is no point on the curve at which increasing strain produces a decrease of stress. It is evident that, on this theory, the torque will increase indefinitely to a finite limit, given by the volume of the Nádai roof. The torque-twist curves given by MacGregor and Hrones (3), on the other hand, do not conform to this condition, indicating that for the material of the specimen (S.A.E. 1112 steel) the assumption of Fig. 3 is seriously in error. It is a matter of considerable interest, therefore, if we can demonstrate that in spite of this the position and size of the plastic region is adequately determined. We may best do this by comparing the value of τ_0 the maximum shear stress, observed in the experiment, with the value which must be assumed in the computation in order to obtain, for the same angle of twist, a diagram identical, as far as one can judge, with the experimental picture.

The actual maximum shear strength observed varied between 48,500 and 53,000 lb per sq in. To obtain a diagram identical for identical conditions of twist the assumed value had to be 54,000 lb per sq in., but difficulty in measuring from Fig. 8 may introduce an error of at least 5 per cent in this value. The agreement may therefore be regarded as satisfactory.

In spite of failure to agree with results of experiment, Fig. 7 has some additional interest as describing the properties of a hypothetical material. It is noticeable that while the plastic flow actually begins at the point A, very little falling off from the straight-line relation is visible before the point B, which is the elastic limit under the rudimentary theory of Equation [7], is reached. At this point also the torque-twist ratio differs by only about 4 per cent from the value predicted by this theory. It may therefore be argued that for a material of this type under a state

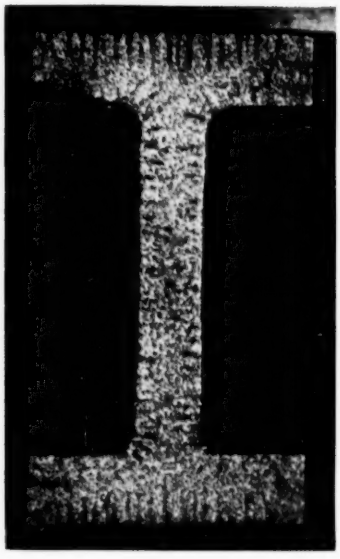

FIG. 8

of stress such that considerations of fatigue could be neglected this very simple theory may be applied with much greater success than could be expected. Evidently the errors resulting from neglecting both end effects and fillets tend to neutralize one another to a great extent.

The author hopes that this paper will have some interest as providing additional corroboration for the results obtained by the soap-film analogue, and as helping to demonstrate that the assumption inherent in the Nádai roof analogy does not lead to erroneous conclusions being reached as to the limits of plastic overstrain.

In conclusion he wishes to express his most grateful thanks to C. W. MacGregor and to R. W. Vose for advice and assistance throughout the preparation of this paper.

Stress-Concentration Factors Around a Central Circular Hole in a Plate Loaded Through Pin in the Hole

By M. M. FROCHT[1] and H. N. HILL[2]

This paper deals with factors of stress concentrations in plates of finite width with central circular holes loaded through pins or rivets. Two sets of results are presented, one from oversize aluminum specimens in which the stresses were determined from strain-gage measurements, the other, from photoelastic tests with small bakelite models. The two investigations were conceived and executed independently. The tests involving the use of strain gages were made at Aluminum Research Laboratories and the photoelastic tests were made at the Photoelastic Laboratory of the Carnegie Institute of Technology.

While most of the tests involved plates loaded through a single pin in a hole on the longitudinal center line of the plate, several tests were made on plates loaded through two pins symmetrically situated about the center line of the plate. Numerical values for the stress-concentration factor k are given for ratios of hole diameter to width of plate ($2r/D$) ranging from 0.086 to 0.76.

KNOWLEDGE of stress-concentration factors is frequently essential to a proper design, particularly of machine parts and structural members or joints subjected to fatigue stresses. The strength of such elements is greatly affected by concentrations of stress. Riveted and bolted joints or connections are typical examples of such elements. In recent years numerous tests have been made to study the fatigue strength of joints (1, 2).[3] The problem of the determination of the fatigue strength of a joint is of such complexity that it can probably best be solved by a direct experimental approach. A knowledge of the distribution of stresses in such a joint, however, would obviously be of considerable value in the analysis and in the extension of test results.

This paper deals with the problem of determining stress concentrations in a riveted or bolted joint, reduced to its simplest form. While a knowledge of the stress-concentration factors for this simple case is not in itself sufficient for the determination of the maximum stresses in a complicated joint, test results indicate that these stress-concentration factors probably represent upper limits. Although a knowledge of stress-concentration factors might be of rather limited value in a study of the fatigue strength of riveted or bolted joints of mild steel (a material for which the endurance limit is just slightly less than the yield strength), the value might not be so limited when dealing with joints of high-strength alloy steels or lightweight alloys (materials for which the endurance limits are well within the elastic range).

The problem of the determination of the stress distribution in a plate loaded through a pin in a hole in the plate has been treated mathematically, notably by Bickley and Knight (3, 4). Bickley confined his treatment to a plate of infinite width, assuming various expressions for the nature of the distribution of forces between pin and plate. Knight considered only one set of boundary forces on the hole but extended his solution to cover plates of finite width giving specific results for the case of a plate having a width twice as great as the diameter of the hole. Published results of experimental studies of this problem seem to be very meager. Coker (5) reports the results of a photoelastic investigation on one specimen $18 \times 6 \times 0.157$ in. in which the load was applied through a neat-fitting pin of 0.766 in. diameter. The results of an investigation of a specimen of different proportions are credited to Stoltenburg (6).

Tests Involving Strain-Gage Measurements

The tests made using the strain-gage method employed a 1-in-thick plate of high-strength aluminum alloy of the duralumin type and an 8-in-diameter pin. To obtain different ratios of pin diameter to plate width, the plate was decreased in width in successive steps from its original value of 55 in. to a final width of 12 in. Fig. 1 shows the test setup when the plate was 55 in. wide. The original head distance H of 20 in., shown in Fig. 2, was maintained until the final test with the plate 12 in. wide. For this test the head distance was reduced to 12 in.

Strains in the immediate vicinity of the hole were measured with Huggenberger tensometers of $^1/_2$ in. gage length. Strains at other locations in the plate were measured with tensometers of 1 in. gage length. In the vicinity of free boundaries, strains were measured in directions parallel to and normal to the boundary. Elsewhere strains were measured on three or more intersecting gage lines. Because of the finite gage length and width of knife-edges of the instruments, it was impossible to obtain a direct measure of the maximum unit strains occurring at the edge of the hole. These values were obtained by extrapolation of curves constructed from measured values.

In the tests involving the strain-gage method, some tests were made using a steel pin, while in other tests the pin was of the same material as the plate. In most of these tests the pin was a neat fit in the hole, the diameter of the pin and hole being the same within 0.0005 in. In other tests a pin was used which had a clearance of 0.015 in. on the diameter. Several tests were made with neat-fitting pins to study the effect of lubrication of the pin on the factor of stress concentration. A colloidal-graphite grease was used as the lubricant.

Stress-concentration factors have been determined for each test as the ratio of the maximum tensile stress at the edge of the hole to the average stress on the minimum net section of the plate. These factors have been plotted in Fig. 2.

Photoelastic Results

In the photoelastic investigations the models, both plate and pin, were of bakelite BT-61-893. The pins or bushings were reinforced with a steel core and the load was applied through a clevis which made it possible to obtain a clear stress pattern of the highly stressed regions around the hole. Fig. 3 shows the test setup in which the clevis used for tests involves two pins. A typical stress pattern is shown in Fig. 4.

The specimens used in the photoelastic investigation had a nominal thickness of $^1/_4$ in. Dimensions of the specimens were chosen so that the influence of the following four factors on the stress-concentration factor could be studied:

1 The ratio of the diameter of the hole to the width of the plate ($2r/D$).

2 The clearance between the pin and the hole.

3 The ratio of the head distance to the width of the plate (H/D).

4 Applying the axial load through two symmetrically placed pins of equal diameters.

Factors of stress concentration have been calculated directly from the data furnished by the stress pattern in the usual manner, using

$$k = \frac{n_{\max} F}{P/A}$$

where k is the factor of stress concentration, $n_{\max}$ is the maximum

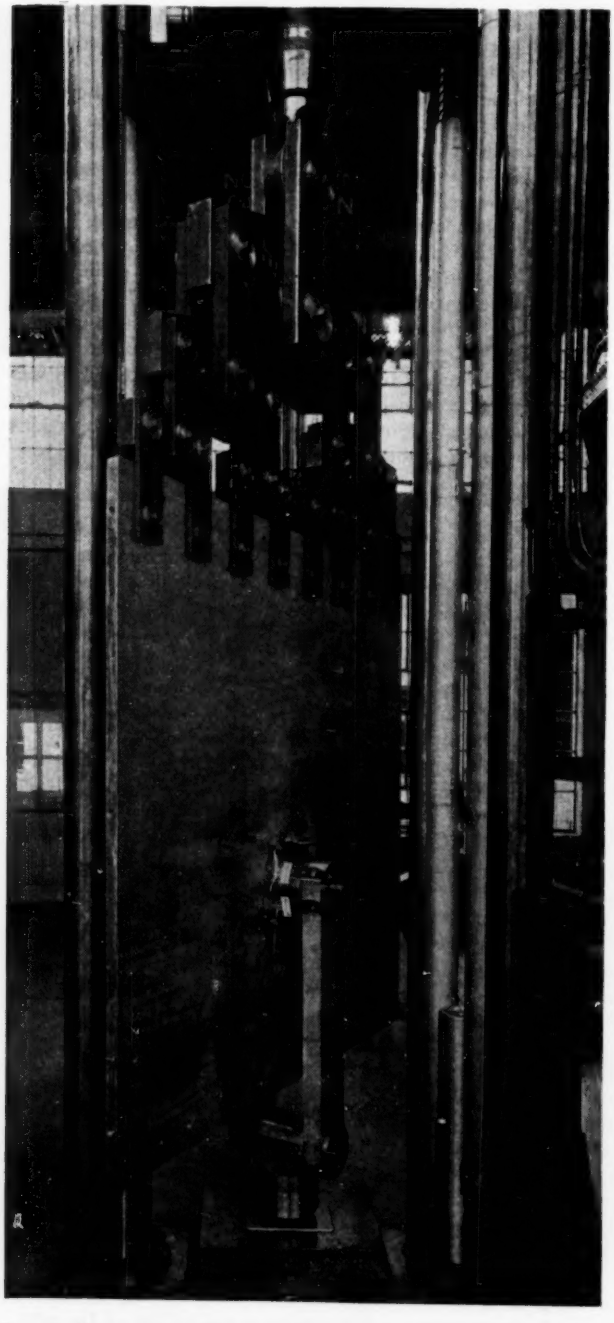

Fig. 1 Setup for Testing Oversize Aluminum Specimens

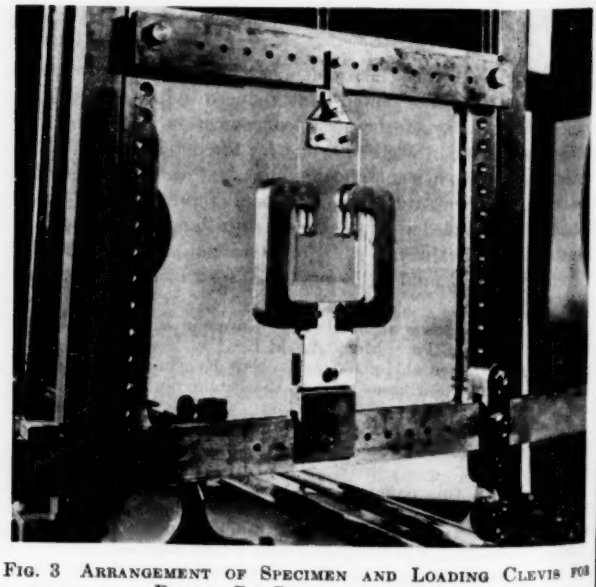

Fig. 3 Arrangement of Specimen and Loading Clevis for Double-Pin Photoelastic Tests

fringe order, F is the model fringe value, P is the applied load, and A is the minimum net area through the hole or holes. Stress-concentration factors thus determined for each of the cases photoelastically investigated are plotted in Fig. 5.

In the test in which the plate was loaded through two pins, the head distances H were great enough so that they did not influence the stress-concentration factors. The diameters of the pins in the double-pin tests were taken equal to the radius of the single pin used for a plate of the same dimensions. The results thus obtained and shown in Fig. 5 provide a comparison between the factors of stress concentration for the single-pin and the double-pin tests under conditions of constant ratio of bearing to mean tensile stresses. The factors shown in Fig. 5 for the double-pin tests have been plotted against ratios of $2r/D$, in which r is the radius of the equivalent single pin for the same ratio of bearing to mean tensile stress. Several tests were made in which the distance between the centers of the pins was varied and this distance was found to have no effect on the factor of stress concentration. Further tests would be necessary, however, in order to determine fully the influence of the distance between the pins on the value of k.

Summary and Discussion of Results

1 *Effect of $2r/D$ Ratio.* As can be seen in Figs. 2 and 5, there is a definite relationship between the stress-concentration factor and the ratio of hole diameter to width of plate. For a $2r/D$ ratio of 0.7, the stress-concentration factors are in the neighborhood of 2. The factors increase as the ratios $2r/D$ decrease, being in the region of 6 to 8 when that ratio is 0.15. The spread in the stress-concentration factors shown for a given ratio of $2r/D$ is largely caused by the effects of the clearance between the pin and the hole, and the head distance.

2 *Effect of Clearance Between Pin and Hole.* Both investigations show that the factors of stress concentration are increased by the presence of clearance between the pin and the hole. This effect was evidenced throughout the whole range of $2r/D$ ratios from 0.086 to 0.76, as can be seen in Figs. 2 and 5. The effect

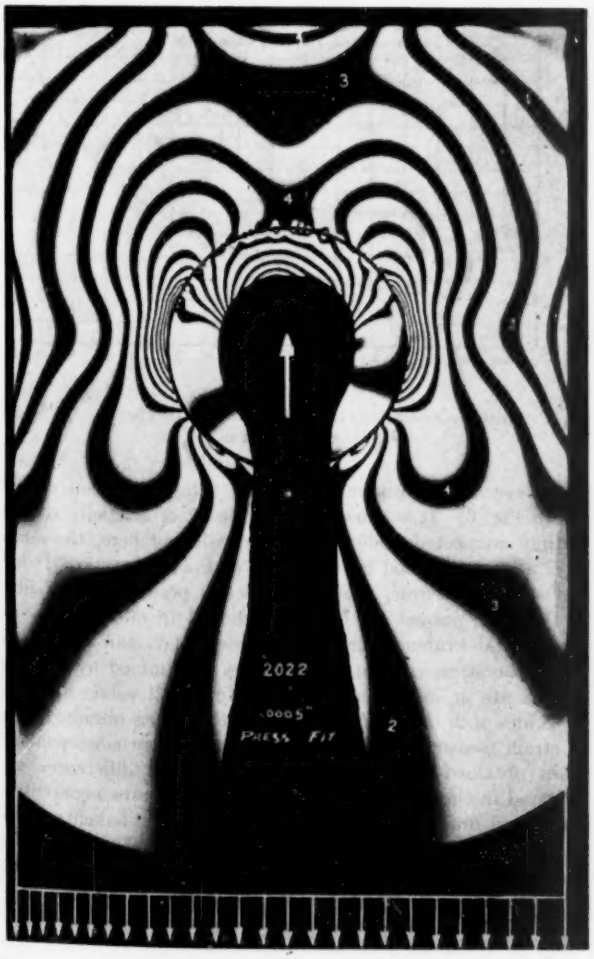

Fig. 4 Typical Stress Pattern From Photoelastic Test

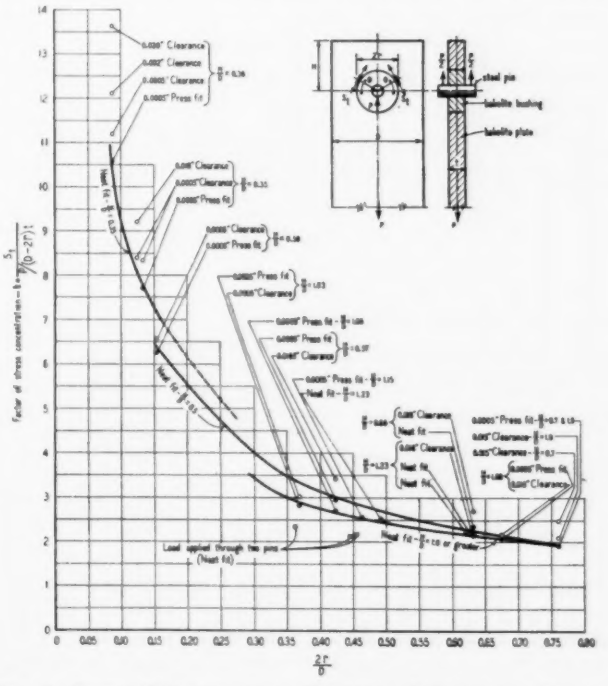

Fig. 5 Stress-Concentration Factors Determined Photoelastically

of the clearance is associated with head distance, being greater for the smaller ratios of H/D. For instance, for a $2r/D$ ratio of 0.76, a stress-concentration factor of 1.9 was determined photoelastically for a neat-fitting pin, both when the head distance ratio (H/D) was 0.7 and 1.9, as shown in Fig. 5. Similarly, in the investigation involving the oversize aluminum specimens at a $2r/D$ ratio of 0.067 in Fig. 2, the introduction of clearance increased the stress-concentration factor about 35 per cent when the H/D ratio was 1.67, while for an H/D ratio of 1.00 the increase was about 50 per cent. The effect of clearance on the maximum stresses has also been observed on previous occasions (7, 8, 9). This effect can be explained on the theory that it permits sharp local changes in the curvature of the circular boundary of the hole.

From the noted description of the points plotted in Fig. 2, it can be seen that for the tests in the investigation involving strain measurements, in which there was clearance between pin and hole, the maximum stresses did not always occur at the ends of the horizontal diameter. However, in every case involving neat-fitting pins, the maximum stresses did occur at the ends of the horizontal diameter. This same effect of the clearance of the pin on the location of the maximum tensile stress at the edge of the hole was noticed in the photoelastic investigation.

As might be expected, while the relation between maximum stress and load was practically linear for the cases involving neat-

fitting pins, for the tests in which the pin was smaller than the hole, the stress-concentration factor was somewhat higher for the smaller loads. This effect is demonstrated by the two values shown in Fig. 2 for a $2r/D$ ratio of 0.145 and the steel pin with 0.015 in. clearance. The same relation between load and maximum stress was encountered in the photoelastic tests. The variations in stress-concentration factors with the load for the cases involving clearance on the pin were small compared to the differences between the factors for the loose pin and the neat-fitting pin.

3 *Effect of Head Distance (Ratio of H/D).* Fig. 6 shows a

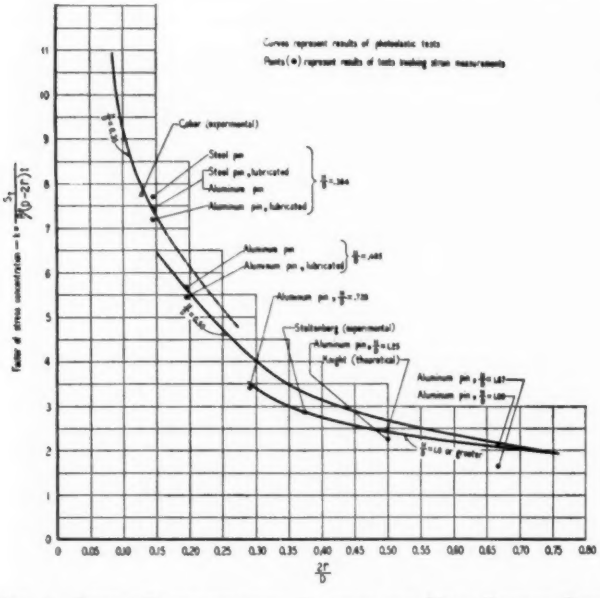

FIG. 6 STRESS-CONCENTRATION FACTORS FOR NEAT-FITTING PINS

composite of the values of k for neat-fitting pins obtained from both investigations, as well as the results of other investigators, both theoretical and experimental. In this figure the effects of clearance have been eliminated but the effect of the head distance on the factors of stress concentration has been emphasized. As the ratio of H/D decreases, the maximum stress and consequently the stress-concentration factor increases. Thus at $2r/D = 0.15$, k equals 6.5 when $H/D = 0.5$ and k equals 7.3 when $H/D = 0.35$. The results of the photoelastic investigation indicate that the effect of the head distance decreases with increasing ratios of $2r/D$. Beyond a certain value of H/D, an increase in head distance has little effect. For a $2r/D$ ratio of 0.76, two specimens were found to have the same factor of stress concentration (for the case of a neat-fitting pin) for an H/D ratio of 1.9, as for an H/D ratio of 0.7. This behavior is not entirely substantiated by the results of the strain-gage measurements on the oversize aluminum specimens. In this investigation, for a neat-fitting pin and a $2r/D$ ratio of 0.667, a stress-concentration factor of 1.65 was determined for an H/D ratio of 1.67, while the corresponding value for an H/D ratio of 1.00 was 2.1, as shown in Fig. 6.

4 *Effect of Number of Pins.* The results of the photoelastic investigation in Fig. 5 show that the stress-concentration factors are smaller when the load is equally distributed between two symmetrically situated pins than when the plate is loaded through a single central pin of a diameter equal to the sum of the diameters of the two pins. The few tests of this type made indicated decreases in the factor of stress concentration of about 20 per cent as compared with corresponding values for plates loaded through a single pin.

5 *Effects of Material of Pin and Lubrication.* The tests made on the aluminum specimens, the results of which are shown in Fig. 2, indicated a very slight increase in the maximum stress when the neat-fitting aluminum pin was replaced by a steel pin having the same fit. Lubrication of the pin produced a small but measurable decrease in the values of k.

6 *Factors of Stress Concentration Based on Average Bearing Stresses.* In Fig. 7 are shown values for a stress-concentration factor k_b defined as the ratio of the maximum tensile stress at the edge of the hole to the average bearing stress on the pin. The same data given in Fig. 6 have been replotted in this manner in Fig. 7. In addition, two points are shown representing the values determined by Bickley (3) and Knight (4) for the case of a hole in an infinite plate. The curve shown in Fig. 7 falls below the plotted points in the region of small $2r/D$ values, because these points represent the results of tests in which the maximum stresses were influenced by the head distance, as shown in Fig. 2. The curve of Fig. 7 indicates that for all cases of a plate loaded through a neat-fitting or loose pin in a hole in the plate, the maximum tensile stresses at the edge of the hole will be greater than the average bearing stress on the pin.

7 *Agreement Between Results of Strain-Gage and Photoelastic Investigation.* Perhaps one of the most important aspects of this paper lies in the agreement between the results of the photoelastic tests, and those obtained from the strain measurements

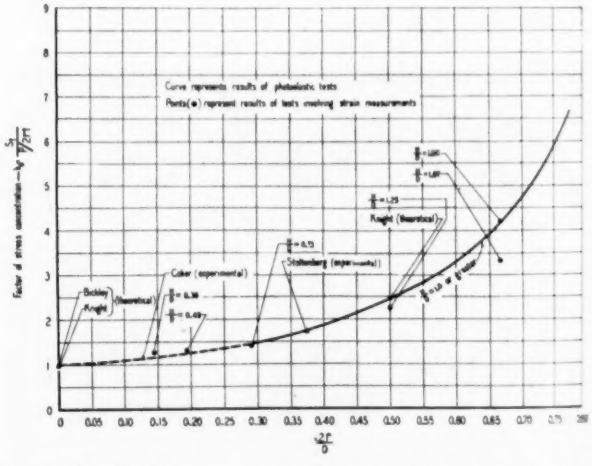

FIG. 7 STRESS-CONCENTRATION FACTORS BASED ON AVERAGE BEARING STRESS

on the oversize aluminum specimens. This agreement can be seen in Fig. 6. It is shown by the theory of elasticity that in multiply connected bodies such as considered here, the stress distribution is affected by the value of Poisson's ratio. It has been stated, however, that this effect is practically negligible (3, 4). The present results are believed to offer convincing experimental evidence for this statement. As can be seen in Fig. 6, the stress-concentration factors determined by the two methods are in very good agreement for small values of $2r/D$. For values of $2r/D$ of 0.5 and greater, the values obtained from the strain measurements are slightly lower than corresponding values obtained photoelastically. The slight differences encountered in these investigations, between the stress-concentration factors obtained for the aluminum and the bakelite specimens, are in the opposite direction to that which theory indicates as the effect of a difference in Poisson's ratio values of the two materials.

The problem of the stress distribution in riveted joints and similar allied problems are becoming increasingly important and merit further study.

Acknowledgment

The tests on the oversize aluminum specimens were conducted under the supervision of R. L. Templin of the Aluminum Research Laboratories by C. Dumont of the same organization. Mr. M. M. Leven, mechanician in the photoelastic laboratory at the Carnegie Institute of Technology assisted in the performance of the photoelastic tests.

The Distribution of Load on the Threads of Screws[1]

By J. N. GOODIER,[2] ITHACA, N. Y.

The distribution of load on the threads of screws and the types of deformation affecting it have been investigated by means of extensometer measurements made on the outside of the nut. The types of deformation characteristic of concentrations of load on different parts of the thread were found by using a bolt carrying only a single turn of thread. At low loads the deformations of nuts with complete bolts closely resemble the effects of the artificial concentration of load on the base part of the thread, whereas there are marked contrasts with the effects of loads concentrated at the middle or at the free end. At higher loads a more uniform distribution is indicated. Similar conclusions follow from the application of an approximate method for deducing the distribution from the deformation measurements.

It is shown that the distribution is governed by (*a*) stretch and compression in bolt and nut, respectively, which are primarily responsible for concentration at the base; and (*b*) by bending of the thread, circumferential stretch (at the base), and contraction (near the free end) of the nut wall, which have comparable effects in reducing the concentration.

IT IS well known that the thread of a screw connection does not bear its load evenly. The supposition that it does so leads at once to a contradiction. For, in the case of a nut and bolt, the bolt would be everywhere in tension, and would stretch, whereas the nut would be in compression, and would contract. If the threads fitted before loading, they could no longer be in complete contact afterward.

The opinion generally held is that the load is concentrated toward the base of the nut. Evidence has been drawn from modes of failure (1, 6),[3] from the deformation of plane rubber models (1), and from photoelastic observations, also on plane models (2, 3). Of the latter, however, one (2) showed concentration at the free end.

The thread may be regarded as a cantilever "gallery" built into the wall of the nut or the core of the bolt. It will bend under load, and the relative displacements so caused can be roughly estimated by means of beam formulas. They are found to be of the same order of magnitude as those due to simple stretching of the bolt and compression of the nut. It might then be supposed that this bending could take up the gaps due to the stretching and contraction. Den Hartog (3) and Jaquet (1) have given solutions of the problem of elasticity so defined, and both have found severe concentration of load at the base, one case showing a maximum load intensity nine times the average. All but a short base part of the thread is then of course practically free from load. The thread of an actual nut under such conditions would evidently yield at low loads and so modify the distribution.

In view of the rather radical differences between a nut and bolt, and a plane model, and on the other hand of the neglect in the theoretical work of types of deformation other than elastic thread bending, and simple stretch or contraction in bolt core or nut wall, it appeared desirable to make an investigation based on observation of actual nuts and bolts. Since any direct measurement of load intensity along the threads seemed impracticable, external deformations of the nuts were examined, and the character of the load distribution inferred from them. To simplify the relation, the nuts used had their hexagonal corners turned off to render the system approximately symmetrical about its axis.

The Radial Displacement

The curves shown in Figs. 1 to 4, inclusive, represent the measured radial displacements v of points on a generator of the external cylindrical surface, for various $1^1/_4$-in. specimens and loads of 8000, 15,000 (25,000 in Fig. 3), and 50,000 lb. They indicate, therefore, in exaggeration, the actual deformed profile.

The full-line curves shown in Fig. 5 are similar, except that the bolt used carried only a single turn of thread, the rest being turned off. It thus produced an artificial concentration of load wherever it was placed. It was set successively at the free end, middle, and base of the nut. It will be observed that the resulting curves are markedly different. Only that for the base position resembles those of Figs. 1, 2, 3, and 4. It appears then that in actual nuts and bolts there is little load at the free end or middle, but a concentration at the base, the concentration being less marked at the higher loads.

If there were a uniform distribution of load we should expect the curve to resemble the average of the three full-line curves of Fig. 5, which is drawn with a broken line. The influence of the free-end (top) load appears in the curvature, concave to the left, toward the top of the nut. None of the curves obtained with complete bolts show such curvature.

The loads on the middle and top together have the effect of raising the point at which the average curve crosses the axis ($v = 0$). Not all the curves of Figs. 1, 2, 3, and 4 cross the axis, but in those which do, increase of load raises the point of intersection, indicating a more uniform distribution.

The radial displacement at any given point is not proportional to the load. At the base it is less than the proportional value at the higher loads, and this is to be expected if the higher loads are less concentrated at the base. However, the same kind of departure from proportionality occurs for the single-thread bolt, where the cause cannot be redistribution. It seems probable that it is varying friction at the base.

The Axial Displacements

A typical set of curves for three loads is shown in Fig. 6, while the set obtained with the single-thread bolt in three positions is
